When discussing the process of polygon splitting in the last section it became apparent that much of the process involves the classification of each vertex in the source polygon against the split plane. This is so we can determine whether a given vertex belongs to the front split or the back split fragment. Although we have discussed several times in past lessons how the classification of a point against a plane is a simple dot product and an addition in order to compute the plane equation, we have wrapped this operation in a method called PointClassifyPlane in our CCollision object. Instead of just returning the result of the dot product, the function returns one of four possible members of the CLASSIFYTYPE enumerator shown below (defined in the CCollision namespace):

Excerpt from CCollision.h

```
// Enumerators
enum CLASSIFYTYPE { CLASSIFY_ONPLANE = 0,
                    CLASSIFY_BEHIND = 1,
                    CLASSIFY_INFRONT = 2,
                    CLASSIFY_SPANNING = 3 };
```

As you can see, it is much nicer during our building routines to get back a result that clearly is behind, in front, on plane, or spanning the plane rather than us having to determine this ourselves using the sign of the dot product result. The PointClassifyPlane function will only ever return either CLASSIFY_ONPLANE, CLASSIFY_BEHIND or CLASSIFY_INFRONT as it is impossible for a single point in space to be spanning a plane. However, the CLASSIFY_SPANNING member will be returned by other classification functions that we will discuss shortly. Let us now look at this new function (which is really just a dot product wrapper).

14.10.1 PointClassifyPlane – CCollision (static)

The PointClassifyPlane method accepts three parameters. The first is the vector describing the point we would like to classify with respect to the plane, the second is the normal of the plane, and the third is the distance to the plane from the coordinate system origin. The function then evaluates the plane equation by performing the dot product between the point and the plane normal (two 3D vectors) and then adding the resulting distance. This is obviously equivalent to performing AX+BY+CZ+D where ABC is the plane normal, D is the plane distance, and XYZ is the point being classified. The result of the plane equation is stored in the local variable fDistance.

```
CCollision::CLASSIFYTYPE CCollision::PointClassifyPlane
                         ( const D3DXVECTOR3& Point,
                           const D3DXVECTOR3 &PlaneNormal,
```

```
                            float PlaneDistance )
{
    // Calculate distance from plane
    float fDistance = D3DXVec3Dot( &Point, &PlaneNormal ) + PlaneDistance;

    // Retrieve classification
    CLASSIFYTYPE Location = CLASSIFY_ONPLANE;
    if ( fDistance < -1e-3f ) Location = CLASSIFY_BEHIND;
    if ( fDistance >  1e-3f ) Location = CLASSIFY_INFRONT;

    // Return the classification
    return Location;
}
```

Be default we assume that the point is on the plane by setting the local Location variable to CLASSIFY_ONPLANE and then go on to test the sign of the result of the plane equation. If fDistance is less than zero (with tolerance) then the point is behind the plane. If fDistance is greater than zero then the point is in the plane's front halfspace. At the bottom of the function the local Location variable will contain either CLASSIFY_ONPLANE, CLASSIFY_BEHIND or CLASSIFY_INFRONT which is then returned to the caller.

The above function will be used by our polygon splitting routine, but the following routine will be used by the core tree building functions to determine if a given polygon needs to be split. It is this next routine that can be used to determine whether a given polygon is in front or behind a plane, lying on the plane, or spanning the plane. In the spanning case we know we have a polygon that has vertices on both sides of the plane, which tells us the polygon needs to be split.

14.10.2 PolyClassifyPlane – CCollision (static)

This is another very useful function that you will likely find yourself using many times as you progress in your 3D programming career. For this reason, we have not built it into the tree code, but have added it to our collision library where we can continue to use it in the future without any dependency on anything else. Remember, these static members always exist even when an instance of the CCollision object does not. Thus CCollision represents a handy collection of intersection routines that can be used by the application even if the application is not using the actual collision system.

This function has a fairly simple task in that it is really just performing the test described in the above function for each vertex in the passed polygon. That is, we classify each point in the polygon against the plane and keep a record of how many points were found behind the plane, in front of the plane, and on the plane. After testing each vertex we can then examine these results to get our final outcome. For example, if the number of vertices found in front of the plane is equal to the vertex count of the polygon, then it must mean the entire polygon is in front of the plane. Likewise, if the number of vertices found behind the plane is equal to the vertex count of the passed polygon then the entire polygon must lay behind the plane. If all points lay on the plane then the polygon is obviously on the plane and we return that result. Finally, we know that if none of the above conditions are true then it must mean some vertices were behind the plane and some were in front of it and therefore, we return CLASSIFY_SPANNING.

Although our spatial trees will all store their static polygon data at the leaves of the tree in CPolygon structures (something we will look at in a moment) we really do not want any generic and potentially reusable routine that we add to our collision namespace to be so reliant on external structures. For example, in a future lab project we might not store our polygon data in a CPolygon object, or we may change the format of its internal vertices, which would mean in either case that we would not be able to use this function. Therefore, we have kept this function as generic as possible by allowing the application to pass the vertex data of the polygon being classified as three parameters.

The first parameter is a void pointer which should point to an array of vertices which define the polygon. This is a void pointer so that it can be used to point to any arbitrary array of vertex components. For example, this could be a pointer into a locked system memory vertex buffer or the vertex array of a CPolygon structure. As this function is only interested in the positional data of each vertex and has no interest in other vertex components, we could also just pass an array of 3D position vectors. The second parameter is the number of vertices in this array so that the function knows how many vertices it has to test. The third parameter is a stride value describing the size of each vertex in the array (in bytes). Remember, this function has no idea how many vertex components you have in your structure, so it has no idea how large each one is and how many bytes a pointer must be advanced to point to the next vertex in the array. Passing a stride value solves this problem and allows the function to step from vertex to vertex in the array without caring about what other data follows the positional data. As the fourth and fifth parameters we pass the normal and the distance of the plane which we wish to classify the polygon against. Below we present the complete code listing to the function, which you should be able to understand with very little explanation.

```
CCollision::CLASSIFYTYPE CCollision::PolyClassifyPlane(
                                                void *pVertices,
                                                ULONG VertexCount,
                                                ULONG Stride,
                                                const D3DXVECTOR3& PlaneNormal,
                                                float PlaneDistance )
{
    ULONG   Infront  = 0, Behind = 0, OnPlane=0, i;
    UCHAR   Location = 0;
    float   Result   = 0;
    UCHAR  *pBuffer  = (UCHAR*)pVertices;

    // Loop round each vector
    for ( i = 0; i < VertexCount; ++i )
    {
        // Calculate distance from plane
        float fDistance = D3DXVec3Dot((D3DXVECTOR3*)pBuffer,
                                      &PlaneNormal ) + PlaneDistance;
        pBuffer += Stride;

        // Retrieve classification
        Location = CLASSIFY_ONPLANE;
        if ( fDistance < -1e-3f ) Location = CLASSIFY_BEHIND;
        if ( fDistance >  1e-3f ) Location = CLASSIFY_INFRONT;

        // Check the position
        if (Location == CLASSIFY_INFRONT )
            Infront++;
        else if (Location == CLASSIFY_BEHIND )
```

```
            Behind++;
        else
        {
            OnPlane++;
            Infront++;
            Behind++;

        } // End if on plane

    } // Next Vertex

    // Return Result
    if ( OnPlane == VertexCount ) return CLASSIFY_ONPLANE;     // On Plane
    if ( Behind  == VertexCount ) return CLASSIFY_BEHIND;      // Behind
    if ( Infront == VertexCount ) return CLASSIFY_INFRONT;     // In Front
    return CLASSIFY_SPANNING; // Spanning
}
```

In the above code we first cast the void pointer to a byte pointer so that the stride value will describe exactly how much we need to increment this pointer to step to the next vertex. We then set up a loop to loop through each vertex of the polygon. For each vertex we compute the plane equation for that vertex and the plane and store the result in fDistance. We then increment the vertex pointer by the stride value so that it is pointing at the next vertex in the array. Next we test the value of fDistance and set the value of Location to either CLASSIFY_ONPLANE, CLASSIFY_INFRONT or CLASSIFY_BEHIND depending on the result. Then we test the value of the Location variable and increment the relative counter. For example, if the vertex is behind the plane, then we increment the Behind counter. If it is in front of the plane we increment the InFront counter. Otherwise it means the vertex is on the plane and we increment the OnPlane, InFront, and Behind counters. It is very important that in the on plane case we also increment the InFront and Behind counters because these counters are trying to record how many vertices would exist in a front split and back split polygon were we actually creating one. Obviously, if a point is on the plane, it could belong to either a front split or a back split polygon. Using this strategy allows us to perform simple tests at the bottom of the function to determine if the polygon is considered in front or behind the plane. Remember, a polygon may still be considered to be behind a plane even if some of its vertices are touching the plane.

At the bottom of the main for loop we can see that we have stored the values of how many vertices to be found in each condition in the OnPlane, Behind and InFront local variables. If the OnPlane value is equal to the vertex count for example, then we know the polygon is completely on the plane. If the vertex count is equal to the number vertices found to be in front or behind the plane then it must mean the polygon lay in front or behind the plane, respectively. Finally, if none of these cases are true we return CLASSIFY_SPANNING since there were obviously vertices found in both plane halfspaces.

14.10.3 CPolygon – Our Static Geometry Container

Earlier we noted that our spatial tree objects will store static polygon data in the leaves of the tree. Therefore, we need a data structure that we can use to pass this data into our tree (prior to the build process being called). This same structure will also be used once the tree is compiled to store the polygon data at the leaf nodes. The object we use for this is defined in CObject.h and CObject.cpp and is called CPolygon.

CPolygon is a simple class that essentially just contains a list of CVertex structures and has two methods that allow us to add vertices to its list or insert vertices in the middle of its list. We will not be showing the code to these functions as they are simple array resize and manipulation functions the likes of which we have seen many times before. However, this object also has a method called Split which allows us to pass in a plane and it will clip/split the polygon to that plane. The CPolygon object's vertex array is not altered by this process as this function allocates and returns two new CPolygon objects containing the front and back split fragments. After calling this function and retrieving the two split polygon fragments the caller will usually delete the original polygon as it is probably no longer needed. Below we show the class declaration in CObject.h.

```
class CPolygon
{
public:

    // Constructors & Destructors for This Class.
             CPolygon();
    virtual ~CPolygon();

    // Public Functions for This Class
    long            AddVertex           ( USHORT Count = 1 );
    long            InsertVertex        ( USHORT nVertexPos );
    bool            Split               ( const D3DXPLANE& Plane,
                                          CPolygon ** FrontSplit = NULL,
                                          CPolygon ** BackSplit = NULL,
                                          bool bReturnNoSplit = false ) const;

    // Public Variables for This Class
    ULONG       m_nAttribID;            // Attribute ID of face
    D3DXVECTOR3 m_vecNormal;            // The face normal.
    USHORT      m_nVertexCount;         // Number of vertices stored.
    CVertex    *m_pVertex;              // Simple vertex array
    D3DXVECTOR3 m_vecBoundsMin;    // Minimum bounding box extents of this polygon
    D3DXVECTOR3 m_vecBoundsMax;    // Maximum bounding box extents of this polygon
    ULONG       m_nAppCounter;     // Automatic 'Already Processed' functionality
    BOOL        m_bVisible;        // Should it be rendered
};
```

When our application loads static geometry from an IWF file (inside CScene::ProcessMeshes) we will store each face we load in a new CPolygon object and pass it to the spatial tree for storage. After the spatial tree's Build function has been called, the tree will contain a number of leaf structures, each containing an array of the CPolygon pointers that exist in that leaf. A CPolygon structure will contain a convex clockwise winding N-gon which means a single polygon may represent multiple triangles.

The member variables are fairly self-explanatory but we will briefly explain them here since some new ones have been added since the introduction of this class in some of our Module I lab projects.

ULONG m_nAttribID
Each polygon will store an attribute ID that has some meaning to our application (e.g., which textures and materials will need to be set when this polygon is rendered). Therefore, when we create a CPolygon object during the loading of an IWF file, we will store the global subset ID of the polygon in this member. As with our previous lab projects, this will actually be an index into the scene's attribute array where each element in that array describes the texture and material that should be bound to the device prior to rendering this polygon. Although we will not discuss our rendering strategy until the next lesson, this member is used by the tree so that it can render all polygons from all visible leaves together so that efficient batch rendering is maintained.

D3DXVECTOR3 m_vecNormal
This member will contain the normal of the polygon.

USHORT m_nVertexCount
This member contains the number of vertices currently stored in this polygon and contained in the m_pVertex array described next.

CVertex *m_pVertex
This is a pointer to the polygon's vertex array. Each element in this array is the now familiar CVertex object, which contains the positional data of the vertex, its normal, and its texture coordinates.

D3DXVECTOR3 m_vecBoundsMin
D3DXVECTOR3 m_vecBoundsMax
In these two members we will store the world space axis aligned bounding box of the polygon. That is, each polygon in our spatial tree will contain an AABB that will be used to speed up collision testing against the spatial tree's geometry database.

Our collision system will now store its static geometry in a spatial tree instead of just in a polygon array. When collision queries are performed, the collision system will ask the spatial tree for a list of all the leaves that the swept sphere's AABB intersects (broad phase). Once the collision system is returned a list of leaves that contain the potential colliders, we could just collect the polygons from each returned leaf and send them to the narrow phase process. However, the actual intersection tests performed between the swept sphere and the polygon are very expensive, and even though we have rejected a large number of polygons by only fetching polygon data from the leaves that intersect the swept sphere AABB, many of the polygons contained in these leaves may be positioned well outside this AABB. Therefore, once we have the list of leaves which the swept sphere's AABB intersects, we will loop through each polygon in those leaves and test its bounding box against the bounding box of the swept sphere. This way we avoid transforming polygons into eSpace and performing the full spectrum of intersection tests on it when we can quickly tell beforehand that the polygon and the sphere could not possibly intersect because their AABBs do not intersect. Although this might sound like a small optimization to the broad phase which would hardly seem worth the memory taken up by storing an AABB in each polygon, the speed improvements to the broad phase on our test machines were very

dramatic. Using the spatial tree and this additional broad phase step in our collision system, queries on large scenes increased in performance by a significant amount.

> **Note:** We tested our collision system using a fairly large level Quake III™ level (on a relatively low end machine) prior to adding the broad phase. Due to the fact that the collision system had to query the entire scene each frame at the polygon level, a collision query was taking somewhere in the region of 10 to 12 seconds. With the spatial tree added, the time was reduced to a few milliseconds, allowing us to achieve interactive frame rates well above 60 frames per second. What a difference, 60 frames per second versus 1 frame every 12 seconds. Even on a simple level such as colony5.iwf, frame rate jumped from 30 frames per second to over 300 frames per second with the introduction of the broad phase. Proof for sure that the broad phase component of any collision system is vitally important. Also proof that hierarchical spatial partitioning is an efficient way to get access to only the areas of the scene you are interested in for a given query.

ULONG m_nAppCounter

This member is used to avoid testing a polygon for collision multiple times if a non-clipped spatial tree is being used. As we know, if a non-clipped tree is constructed, a single polygon may span multiple leaves. This means its CPolygon pointer will be stored in the polygon array of multiple leaf structures. When the collision system fetches the list of intersecting leaves from the spatial tree it has to make sure that if a polygon exists in multiple leaves it is not tested twice.

To get around this problem we decide to add an application counter member variable to our CGameApp class. This is a simple DWORD value that can be incremented via the CGameApp::IncrementAppCounter method and retrieved via the CGameApp::GetAppCounter. In other words, this is a simple value that can be increment by external components.

Our collision system uses the app timer in the following way: Prior to a collision test, the app counter is incremented and then fetched so that we now have a new unique counter value for this update. When we fetch the intersecting leaves from the spatial tree and find a polygon that needs to be tested at the narrow phase level, we will store the app counter value in this member of the CPolygon. If a little later, when testing the polygons from another leaf, we find that we are about to test a polygon that has an m_nAppCounter value which is equal to the current value of the CGameApp's application counter, it must mean that this polygon has already been processed in this update because it belonged in a leaf that we have previously tested. Therefore, we do not need to test it again.

This is a much nicer and more efficient solution than simply storing a 'HasBeenTested' boolean in the polygon structure because this would involve us having to reset them all back to false prior to performing another collision test. We would certainly not want to have to do that for every polygon in the scene. By storing the application counter in the polygon, as soon as we wish to perform another query, we can just increment the application timer which will immediately invalidate all the polygons because their m_nAppCounter variables will no longer match the current value of the application counter.

bool m_bVisible
We will see this member of the polygon structure being used in the following lesson when we implement the rendering system. Essentially, it allows us to flag a polygon as being invisible when added to the tree. This is useful if we wish to add a polygon to the collision system but would not like to have it rendered The collision system will ignore this member and will test the swept sphere against any polygons in its vicinity. The rendering system however (which will use the same tree) will only render a polygon if it has this boolean set to true. This boolean is set to true by default in the CPolygon constructor.

Split - CPolygon

The only method of CPolygon that we have to discuss is an important one since it is the key to creating a clipped tree. The CPolygon::Split method implements the splitting strategy discussed in the last section. Unfortunately, the code may at first seem a little confusing due to two reasons. First, we want the function to also double as a clipper, so there are several conditional blocks in the code that only get executed if the caller has requested that it is interested in getting back the relevant split fragment. For example, if the caller passes NULL as the FrontSplit parameter the function will discard any portion of the polygon that lies in front of the plane and will only return the back split fragment. Second, the function is ordered in a way that means we only allocate the memory for the new polygon data when we know we actually need it.

We have also added a fourth parameter to this function, which is a boolean that allows us to specify what should happen when the passed plane does not intersect the polygon. When this boolean is set to false, the polygon data will always be created and returned in either the front or back split. That is, if the polygon is completely in front of the passed plane, a new front split polygon will be returned which contains a copy of all the data from the original polygon. This way we will always get back either a front split polygon or a back split polygon even if the polygon is not spanning the plane. Although this might sound like a strange way for the function to behave, it can be useful during a recursive clipping process to always assume that the original polygon is no longer needed after its Split method has been called. However, it is also often the case that if the polygon does not span the passed plane, then you do not want any front split or back split polygon created and would rather just continue to work with the original polygon. This is what the final parameter to this function is for. If set to true, it will only return front split and back split polygons if the original polygon is spanning the plane. If not, it will just return immediately and essentially will have done nothing. If set to false, it will always return a polygon in either the front or back split polygons even if the polygon was completely in front or completely behind the plane. In other words, the function will always create a new polygon in this instance allowing you to discard the original one.

Let us have a look at the code to this function a section at a time. There are four parameters. The first is the clip/split plane and it is expected in the form of a D3DXPLANE structure which describes the plane in AX+BY+CZ+D format. The second and third parameters are the addresses of CPolygon pointers which on function return will point to the new front and/or back polygon fragments. The caller does not have to allocate the CPolygon objects to contain the front and back splits, it simply has to pass the address of two CPolygon pointers. The Split function will allocate the CPolygon objects and assign the pointers you pass to point at them, so the caller can access them on function return. The fourth parameter

is the boolean parameter describing whether the function should only create new polygons if the polygon is spanning the plane or whether it should do nothing.

```
bool CPolygon::Split( const D3DXPLANE& Plane,
                      CPolygon ** FrontSplit,
                      CPolygon ** BackSplit,
                      bool bReturnNoSplit ) const
{
    CVertex    *FrontList     = NULL, *BackList = NULL;
    USHORT      CurrentVertex = 0, CurrentIndex = 0, i = 0;
    USHORT      InFront       = 0, Behind       = 0, OnPlane = 0;
    USHORT      FrontCounter  = 0, BackCounter  = 0;
    UCHAR      *PointLocation = NULL, Location;
    float       fDelta;

    // Bail if no fragments passed (No-Op).
    if (!FrontSplit && !BackSplit) return true;

    // Separate out plane components
    D3DXVECTOR3 vecPlaneNormal = (D3DXVECTOR3&)Plane;
    D3DXVECTOR3 vecPlanePoint  = vecPlaneNormal * -Plane.d;
```

The first section of the function is fairly simple. First, if the caller has not passed a front split or a back split pointer then we have no way of returning any clipped/split polygon data back anyway so we may as well just immediately return. It is ok to pass only one pointer (either a front split pointer or a back split pointer) which will turn the function into a clipper instead of a splitter. However, if no pointers are passed, there is no point continuing.

We can also see how we use the passed D3DXPlane structure to separate the plane into two components, a plane normal and a point on that plane. Getting the plane normal is easy as the first three members of the plane structure (a, b, and c) are the plane normal. So we can do a straight cast of these three members into a 3D vector. Calculating a point on the plane is also easy as we know that the **d** member contains the distance to the plane from the origin. That means that if we moved a point from the origin of the coordinate system in the direction of the plane normal for this distance we would have a point on that plane. As we are using the AX+BY+CZ+D version of the plane equation, D is a negative value for points behind the plane. Therefore, we just have to negate its sign and use it to scale the normal and we will have created that point on the plane.

In the next section of code we prepare the memory that will be needed for performing the split operation and the various tests. First we will need to know the location of each vertex in the polygon with respect to the plane, so we will allocate an array of unsigned chars (one for each vertex in the original polygon). In a moment, we will loop through each vertex and use the CCollision::PointClassifyPlane method we implemented earlier. This will return either CLASSIFY_FRONT, CLASSIFY_BACK or CLASSIFY_ONPLANE. We will store the results in the array.

```
    try
    {
        // Allocate temp buffers for split operation
        PointLocation = new UCHAR[m_nVertexCount];
        if (!PointLocation) throw std::bad_alloc(); // VC++ Compat
```

As you can see, this array is called PointLocation and it must be large enough to hold the classification result of each vertex in the original polygon. In a moment we will fill this array with the classification results of each vertex with respect to the plane.

What we will do now is also allocate two arrays of vertices. These two arrays will be used to collect the vertices that get added to the front split and back split polygons respectively. Of course, if the caller did not pass in either a front split or a back split pointer, then it means we do not have to allocate a vertex array to deal with vertices in that halfspace of the plane. That is, if only the address of a CPolygon pointer has been passed for the FrontSplit parameter, there is no need to allocate a vertex array to collect vertices that are in the back split. Also, if the user as passed true as the bReturnNoSplit parameter, then it means this function should only create a front split and back split polygon if the polygon is spanning the plane. Therefore, if true has been passed, we will not allocate those vertex arrays here; we will allocate them later when we know we definitely have a split case. It would be wasteful to allocate the memory for either a front split or a back split polygon only to find that we do not need it because the caller has requested that no polygons be created in the no split case.

```
        // Allocate these only if we need them
        if (FrontSplit && !bReturnNoSplit)
        {
            FrontList = new CVertex[m_nVertexCount + 1];
            if (!FrontList) throw std::bad_alloc(); // VC++ Compat
        } // End If

        if ( BackSplit && !bReturnNoSplit )
        {
            BackList = new CVertex[m_nVertexCount + 1];
            if (!BackList) throw std::bad_alloc(); // VC++ Compat
        } // End If

    } // End Try

    catch (...)
    {
        // Catch any bad allocation exceptions
        if (FrontList)      delete []FrontList;
        if (BackList)       delete []BackList;
        if (PointLocation)  delete []PointLocation;
        return false;
    } // End Catch
```

Notice that when we allocate the front and back split vertex arrays we make them large enough to hold one more than the number of vertices in the original polygon that is being clipped.

We do this because when we clip or split a polygon to a plane, although new vertices are introduced along the edges that intersect the plane (for both fragments), none of the fragments can ever have its vertex count increased beyond the original number of vertices plus one. This is shown in Figure 14.45 where a triangle in split to an arbitrary plane creating two polygons. One has four vertices and the other has three. It should be noted that this rule is only applicable to convex polygons. Since we are always dealing with convex polygons this is just fine.

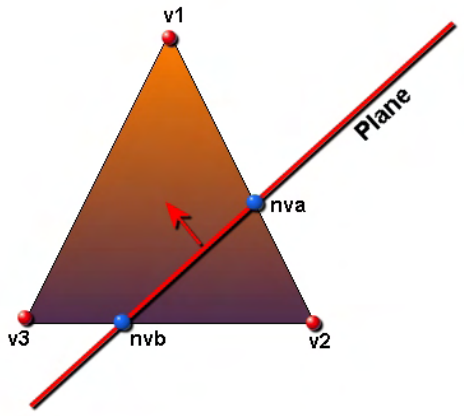

Figure 14.45

In this image we can see that the triangle to be clipped originally consisted of vertices v1, v2, and v3. However, during the testing of the edges, two were found to be spanning the plane and the vertices nva and nvb are generated and added to both the front and back vertex lists. This generates a front split vertex list of v1, nva, nvb and v3 and a back split vertex list of nva, v2 and nvb. No matter how we rotate the plane and regardless of the shape of the original polygon being clipped, we will never generate a new split polygon that has more than one additional vertex beyond the original polygon from which it was clipped/split from. So we can see in Figure 14.45 that if we allocate both the front and the back vertex lists to hold four vertices (number of vertices in the original triangle plus one) we definitely have enough room to store the vertices for each fragment.

At this point we have front and back vertex lists allocated (only if bReturnNoSplit equals false) and we also have a PointLocation array large enough to child a classification result for each vertex in the original polygon. Let us now fill out the point location array by looping through each vertex in the polygon and classifying it against the plane (using our new PointClassifyPlane function). We store the result for each vertex in the corresponding element in the PointLocation array as shown below.

```
    // Determine each points location relative to the plane.
    for ( i = 0; i < m_nVertexCount; ++i )
    {
        // Retrieve classification
        Location = CCollision::PointClassifyPlane( (D3DXVECTOR3&)m_pVertex[i],
                                                   (D3DXVECTOR3&)Plane,
                                                    Plane.d );

        // Classify the location of the point
        if (Location == CCollision::CLASSIFY_INFRONT ) InFront++;
        else
        if (Location == CCollision::CLASSIFY_BEHIND ) Behind++;
        else
        OnPlane++;

        // Store location
        PointLocation[i] = Location;

    } // Next Vertex
```

Now we have an array that stores whether each vertex is in front, behind, or on the plane. Note that we maintain three counters (InFront, Behind, or OnPlane) so that at the end of the above loop we know exactly how many vertices (if any) are in each classification pool.

In the following code section we test the value of the InFront counter and if it is not greater than zero then it means no vertices were located in the front halfspace. If the caller passed true for bReturnNoSplit, then there is nothing to do other than release the PointLocation array and return. This is because if the InFront counter is set to zero, the polygon cannot possibly span the plane. Thus in the bReturnNoSplit=true case, this means we just wish the function to return.

```
    // If there are no vertices in front of the plane
    if (!InFront )
    {
        if ( bReturnNoSplit ) { delete []PointLocation; return true; }
        if ( BackList )
        {
            memcpy(BackList, m_pVertex, m_nVertexCount * sizeof(CVertex));
            BackCounter = m_nVertexCount;
        } // End if

    } // End if none in front
```

Notice that if the InFront counter is zero but the caller did not pass true as the bReturnNoSplit parameter, all the vertices in the polygon belong to the back split fragment. When this is the case we copy all the vertex data from the source polygon into the vertex list being compiled for the back split. We also set the BackCounter variable equal to the number of vertices in the source polygon so we know how many vertices we have collected in the BackList vertex array.

In the next snippet of code we do exactly the same thing again only this time we are handling the case where no vertices were found to lie behind the plane. When this is the case we simply return if bReturnNoSplit was set to true, or we consider all the vertices of the source polygon to belong to the back split polygon and copy over its vertices into the front split vertex list.

```
    // If there are no vertices behind the plane
    if (!Behind )
    {
        if ( bReturnNoSplit ) { delete []PointLocation; return true; }
        if ( FrontList )
        {
            memcpy(FrontList, m_pVertex, m_nVertexCount * sizeof(CVertex));
            FrontCounter = m_nVertexCount;
        } // End if

    } // End if none behind
```

If both the InFront and Behind counters are set to zero then it must mean that every vertex in the source polygon lies on the split plane. This means no splitting is going to occur and the polygon does not belong in any halfspace. When this is the case we return.

```
    // All were onplane
    if (!InFront && !Behind && bReturnNoSplit )
       { delete []PointLocation; return true; }
```

Earlier in the function we allocated arrays to hold the front and back vertex lists but only if the bReturnNoSplit parameter was set to false. This is because one way or another we knew we would definitely need them even if the polygon was not spanning the plane because the function will always return a copy of the source polygon in either the front or back split polygons. However, we did not allocate these arrays if the bReturnNoSplit boolean was set to true since we would only need the front and back split vertex lists compiled if the source polygon is spanning the plane. Otherwise the function would have simply returned by now and done nothing.

In the next section of code we perform the front and back vertex list allocations for the bReturnNoSplit is true case. The memory will have already been allocated for these arrays earlier in the function if bReturnNoSplit was false.

```
    // We can allocate memory here if we wanted to return when no split occurred
    if ( bReturnNoSplit )
    {
        try
        {
            // Allocate these only if we need them
            if (FrontSplit)
            {
                FrontList = new CVertex[m_nVertexCount + 1];
                if (!FrontList) throw std::bad_alloc(); // VC++ Compat
            } // End If

            if ( BackSplit )
            {
                BackList = new CVertex[m_nVertexCount + 1];
                if (!BackList) throw std::bad_alloc(); // VC++ Compat
            } // End If

        } // End Try

        catch (...)
        {
            // Catch any bad allocation exceptions
            if (FrontList)      delete []FrontList;
            if (BackList)       delete []BackList;
            if (PointLocation)  delete []PointLocation;
            return false;
        } // End Catch

    } // End ReturnNoSplit case
```

This is all pretty familiar stuff. We know at this point that if bReturnNoSplit is true that the polygon must be spanning, otherwise we would have returned by now. So, provided the caller passed valid front and back CPolygon pointers, we allocate the vertex arrays for the front and back lists just as we did earlier for the case when bReturnNoSplit did not equal true.

At this point, regardless of the mode of the function being used, we have two empty vertex arrays that will be used to hold the vertex lists for the front and back split polygons. It is now time to look at the core piece of the function that populates the vertex lists for the front and back splits and creates new vertices when an edge is found to be spanning a plane. The code is only executed if the InFront and Behind counters are both non zero since this will only be the case when the polygon is spanning the plane. Remember, earlier in the function, if the polygon was found to be totally on one side of the plane then the source polygon's vertices were copied over into the vertex array for either the front or back split.

The following code loops through each vertex in the polygon and compares the classification result we stored for it earlier with the classification result of the next vertex in the list (the other vertex sharing the edge). If the entire edge is on one side of the plane then the vertex being tested is added to the front or back list. If however, the vertex being tested and the next vertex in the list are on opposing sides of the plane, the edge formed by those two vertices spans the plane and a new vertex is generated on the plane. This new vertex is added to both the front and the back lists.

```
    // Compute the split if there are verts both in front and behind
    if (InFront && Behind)
    {
        for ( i = 0; i < m_nVertexCount; i++)
        {
            // Store Current vertex remembering to MOD with number of vertices.
            CurrentVertex = (i+1) % m_nVertexCount;

            if (PointLocation[i] == CCollision::CLASSIFY_ONPLANE )
            {
                if (FrontList) FrontList[FrontCounter++] = m_pVertex[i];
                if (BackList)  BackList [BackCounter ++] = m_pVertex[i];
                continue; // Skip to next vertex
            } // End if On Plane

            if (PointLocation[i] == CCollision::CLASSIFY_INFRONT )
            {
                if (FrontList) FrontList[FrontCounter++] = m_pVertex[i];
            }
            else
            {
                if (BackList) BackList[BackCounter++] = m_pVertex[i];

            } // End if In front or otherwise
```

In the first section of the loop shown above we set up a loop to iterate through the PointLocation results for each vertex. Loop variable *i* contains the index of the current vertex being processed and local variable CurrentVertex contains the index of the next vertex in the list. Notice we do the modulus operation to make sure that this wraps back around to vertex zero which forms the end vertex for the final edge.

First, we test to see if the classification result for the vertex we are currently testing is CLASSIFY_ONPLANE. If it is, then the vertex itself should be added to both of the vertex lists. On plane vertices will belong to both of the split polygons as shown in Figure 14.46. You can see in the above code that when this is the case, we copy the vertex into both the front and back vertex lists. Notice

that as we do we increment the FrontCounter and BackCounter local variables that are initialized to zero at the head of the function and are incremented in this loop every time we add a vertex to a list. This is so we can keep a count of the number of vertices in each list which we will need at the bottom of the function when we allocate the back split and front split polygons.

If the current vertex is not on the plane then we test to see if it is in front of the plane and if so add the vertex to the front list. Otherwise, the vertex is behind the plane so we add it to the back list.

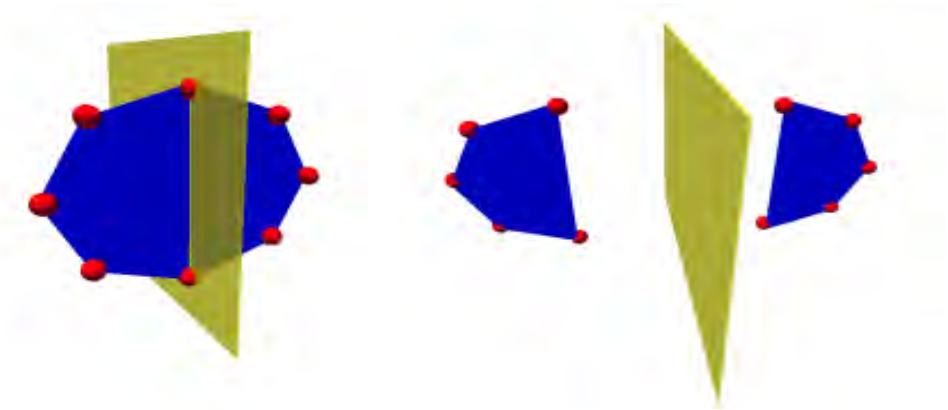

Figure 14.46 : On Plane vertices are added to both splits

We now correctly added the vertex to the front or back split but we cannot just progress to the next item in the list. If the vertex we just added and the next vertex in the list are on opposite sides of the plane we will need to treat these two vertices (the spanning edge) as a ray and intersect it with the plane.

The next section code does just that. If the next vertex in the list (CurrentVertex = i +1) is on the plane or is on the same side of the plane as the vertex we just added, then we can just continue to the next loop iteration where it will be added to its respective list.

```
        // If the next vertex is not causing us to span the plane then continue
        if (PointLocation[CurrentVertex]== CCollision::CLASSIFY_ONPLANE||
                                           PointLocation[CurrentVertex] ==
                                           PointLocation[i] )
            continue;
```

However, if we make it this far through the loop then the vertex we just added and the next vertex in the source polygon are on opposite sides of the plane and a new vertex will have to be added to both lists. This will be the vertex at the point of intersection between the edge and the plane.

We do this by making the vertex we just processed (*i*) the ray origin and then subtract the ray origin from the position of the next vertex in the list (CurrentVertex) which gives us our ray delta vector. We then use our CCollision::RayIntersectPlane function to calculate the *t* value of intersection.

```
            // Calculate the intersection point
            D3DXVECTOR3 vecOrigin  =(D3DXVECTOR3&)m_pVertex[i];
            D3DXVECTOR3 vecVelocity=(D3DXVECTOR3&)m_pVertex[CurrentVertex]
                                    - vecOrigin;
```

```
            CCollision::RayIntersectPlane( vecOrigin,
                                           vecVelocity,
                                           vecPlaneNormal,
                                           vecPlanePoint,
                                           fDelta,
                                           true );

            // create new vertex position
            CVertex NewVert;
            (D3DXVECTOR3&)NewVert = vecOrigin + (vecVelocity * fDelta);
```

When this function returns, local variable fDelta will contain the intersection point parametrically. This will be a value between 0.0 and 1.0 describing the position of intersection between the first and second vertex. You can see at the bottom of the above code that by scaling the ray delta vector (vecVelocity) by the *t* value of intersection (fDelta) and adding the result to the ray origin we have the position of the new vertex that we need to add.

Of course, we do not just need to calculate the new position of the vertex; we also have to interpolate the values of any other components that might be stored in the vertices, such as color and/or UV coordinates.

Figure 14.47 shows how a triangle polygon might be mapped to a given texture. Note the texture coordinates for v1 and v2. The red line shows where an intersection with the plane has occurred with this polygon and this is the point where a new texture coordinate needs to be created (percent = 0.5).

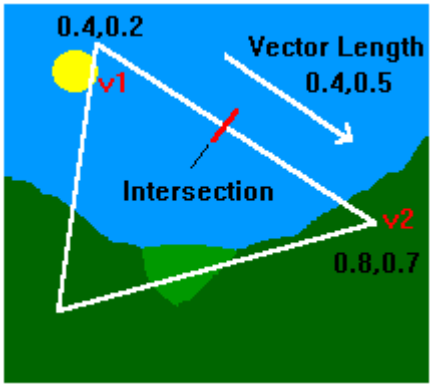

Figure 14.47

First we will subtract the first vertex texture coordinates from the second and end up with the vector length of the line between v1 and v2 in texture space. You can see that <0.8,0.7> - <0.4,0.2> = <0.4,0.5>. This is the direction and the length between texture coordinates v1 and v2. The great thing is that our RayIntersectPlane function returned a *t* value from the start of the line to the point where the intersection occurred. We can now use this value for texture coordinate interpolation, color interpolation, and even normal interpolation to generate all the other data we need for the newly created vertex. For example, imagine that the fDelta values returned from RayIntersectPlane was 0.5. This tells us that the edge intersects the plane exactly halfway between vertex v1 and vertex v2. If we multiply the texture coordinate delta vector by the *t* value (0.5 in this example) we get a vector of

<0.4*0.5, 0.5*0.5> = <0.2, 0.25>

Now we just have to add this scaled texture coordinate delta vector to the texture coordinates of the first vertex in the edge (v1) and we have the new texture coordinate of the vertex inserted at the intersection point.

New Texture Coordinates = <0.4, 0.2> + <0.2, 0.25> = <0.6, 0.45>

Incidentally, we use this same linear interpolation to generate a normal for the newly created vertex. Below we see the next section of the code that generates the normal and texture coordinate information for the new vertex.

```
            // Interpolate Texture Coordinates
            D3DXVECTOR3 Delta;
            Delta.x    = m_pVertex[CurrentVertex].tu - m_pVertex[i].tu;
            Delta.y    = m_pVertex[CurrentVertex].tv - m_pVertex[i].tv;
            NewVert.tu = m_pVertex[i].tu + ( Delta.x * fDelta );
            NewVert.tv = m_pVertex[i].tv + ( Delta.y * fDelta );

            // Interpolate normal
            Delta          = m_pVertex[CurrentVertex].Normal - m_pVertex[i].Normal;
            NewVert.Normal = m_pVertex[i].Normal + (Delta * fDelta);
            D3DXVec3Normalize( &NewVert.Normal, &NewVert.Normal );

            // Store in both lists.
            if (BackList)  BackList[BackCounter++]   = NewVert;
            if (FrontList) FrontList[FrontCounter++] = NewVert;

        } // Next Vertex

    } // End if spanning
```

Notice how the newly created vertex is added to both vertex lists. And that is the end of the loop.

At this point we have built the vertex lists for both of the polygons if applicable. Now it is time to actually allocate the new CPolygon objects (again, where applicable). In this first section we allocate the new polygon that will contain the front split vertex list. Obviously we only do this if the caller passed a valid FrontSplit pointer as a function parameter and if we have more than 2 vertices in the front list. Once the new polygon is allocated, we call its AddVertex method so that the CPolygon can reserve enough space in its vertex array for the correct number of vertices that we have compiled in the front vertex list. We then copy over the vertices that we have compiled in the temporary front list into the vertex array of CPolygon.

```
    // Allocate front face
    if (FrontCounter >= 3 && FrontSplit)
    {
        // Allocate a new polygon
        CPolygon * pPoly = new CPolygon;

        // Copy over the vertices into the new poly
        pPoly->AddVertex( FrontCounter );
        memcpy(pPoly->m_pVertex, FrontList, FrontCounter * sizeof(CVertex));

        // Copy over other details
        pPoly->m_nAttribID   = m_nAttribID;
        pPoly->m_vecNormal   = m_vecNormal;

        // Store the poly
        *FrontSplit = pPoly;

    } // End If
```

Notice in the above code that after we have copied the vertex data into the polygon, we also copy over the attribute ID and the normal of the source polygon. However much we split the polygon, every fragment will always exist on the same plane as the parent, so the normal can be safely inherited. The attribute id is also inherited into the child splits. This makes good sense because if we have a polygon with a wood texture applied and we split it, we get two polygons with that same wood texture applied. Finally, we assign the FrontSplit pointer passed by the caller to point to this newly created polygon so that when the function returns the caller will have access to it.

In the next section of code we do the same thing all over again for the back split polygon.

```
    // Allocate back face
    if (BackCounter >= 3 && BackSplit)
    {
        // Allocate a new polygon
        CPolygon * pPoly = new CPolygon;

        // Copy over the vertices into the new poly
        pPoly->AddVertex( BackCounter );
        memcpy(pPoly->m_pVertex, BackList, BackCounter * sizeof(CVertex));

        // Copy over other details
        pPoly->m_nAttribID   = m_nAttribID;
        pPoly->m_vecNormal   = m_vecNormal;

        // Store the poly
        *BackSplit = pPoly;

    } // End If
```

At this point our job is done so we release the temporary memory we used for the clipping/splitting process before returning true.

```
    // Clean up
    if (FrontList)      delete []FrontList;
    if (BackList)       delete []BackList;
    if (PointLocation)  delete []PointLocation;

    // Success!!
    return true;
}
```

Although that was a somewhat tricky function, the core process it performs is delightfully easy. It has been made much less reader friendly because it has many early out conditionals so that memory is not allocated unnecessarily, but nevertheless, it is still a pretty straightforward algorithm. You will see the Split method being used quite a lot during the construction of the clipped spatial tree.

We have now covered every thing we need to know about CPolygon; the structure used by our spatial trees to store static polygon data. We are now ready to look at ISpatialTree, the abstract base class for all of our new tree types and the interface our application will use to communicate with our trees.

14.11 The Abstract Base Classes

In the file ISpatialTree.h you will find the declaration of the ISpatialTree class. This is an abstract interface which exists to provide a consistent means of communication between our application and our various trees. As long as our quad-tree, oct-tree and kD-tree classes are derived from this interface and implement its methods, our application can use the same code to interface with any of these tree types. All the trees we have discussed share a lot of common functionality. For example, regardless of how they are built, they all contain an array of leaf nodes and an array of CPolygons assigned to each leaf node.

The ISpatialTree interface exposes all the methods an application will need to communicate with a spatial tree. We can think of it as defining a minimum set of functionality that must be implemented in our derived classes. It enforces for example that each of the trees we implement has an AddPolygon method so that an application can add CPolygons to its static geometry data. It enforces that our derived classes must implement an AddDetailArea method so that the application can register areas of interest for use during the build process. Another example of a method that must be implemented is the Build method which an application can use to instruct the spatial tree to compile its spatial information using the polygon data and detail areas that have been assigned to it. Further, in the ISpatialTree.h file, you will also see several structures and typedefs defined that will be used by all of our derived classes. Let us start to have a look at what is inside this file now.

The first structure defined in this file is the one that is used to pass detail information to and from the tree. This structure is very simple and has three members. The first two should contain the minimum and maximum extents of its world space AABB and the second is a context pointer that can be used by the application to point at any data it so chooses. Beyond the examples discussed earlier, this context pointer might point to some structure that contains settings to configure fog on the device. The detail area in this instance would be used to represent an area within the scene where fog should be enabled during rendering. The TreeDetailArea structure is shown below and is something we will see being used in a moment.

Excerpt From ISpatialTree.h

```
typedef struct _TreeDetailArea
{
    D3DXVECTOR3     BoundsMin;      // Minimum AABB extents of the area
    D3DXVECTOR3     BoundsMax;      // Maximum AABB extents of the area
    void          * pContext;       // A context pointer that can be assigned.

} TreeDetailArea;
```

Because all our various tree types will have support for the registration of detail areas, we have defined this structure in the main header file and have made the AddDetailArea and GetDetailAreaList methods members of the base class.

14.11.1 ILeaf – The Base Class for all Leaf Objects

Another thing that all of our trees will have in common is that they will all need the ability to store leaf information at terminal nodes in the tree. There are certain methods that we will want a leaf object to expose so that the tree (or application) can interface with a leaf more easily. For example, we will usually want a leaf to have an IsVisible method so that the application can query whether a given leaf is visible and should have its contents rendered. We will also want the ability to get back a list of all the detail areas and polygons that are assigned to a leaf. Furthermore, we know that each leaf will also need to store an AABB describing the region of space it occupies. Obviously, the leaf is only visible if this bounding box is contained either fully or partially inside the camera frustum.

Although we may want a leaf to contain much more information than this, the abstract ILeaf class is shown below and defines the base interface that our application will use to access and query a leaf. As with the ISpatialTree class, it is abstract, so it can never be instantiated directly. It must be derived from so that the function bodies can be implemented. These base interfaces force us to support and implement all the function in the base class when writing any tree type now or in the future. If we do not, we will get a compiler error. As long as we implement the functions specified in the base classes our application will happily work with the tree as its spatial manager with no changes to the code. This is because our application will only ever work with the ISpatialTree and ILeaf. As long as we derive our classes from these interfaces and implement the specified methods, we are in good shape to plug in whatever tree types we like down the road.

Below we see the class declaration for ILeaf.

```
class ILeaf
{
public:
    // Constructors & Destructors for This Class.
    virtual ~ILeaf() {};  // No implementation, but forces all derived classes
                             to have virtual destructors

    // Public Pure Virtual Functions for This Class.
    virtual bool            IsVisible           ( ) const = 0;
    virtual unsigned long   GetPolygonCount     ( ) const = 0;
    virtual CPolygon *      GetPolygon          ( unsigned long nIndex ) = 0;
    virtual unsigned long   GetDetailAreaCount  ( ) const = 0;
    virtual TreeDetailArea *GetDetailArea       ( unsigned long nIndex ) = 0;
    virtual void            GetBoundingBox      ( D3DXVECTOR3 & Min,
                                                  D3DXVECTOR3 & Max ) const = 0;
};
```

All of the methods shown above must be implemented in any derived leaf objects we create since they will be used by the spatial tree. Let us first discuss what these methods are supposed to be used for and what information they should return.

virtual bool IsVisible ( ) const = 0;
It is very important that a leaf expose this method as it is the application's means of testing whether a given leaf was found to be inside the frustum during the last update. This is very useful for example when performing queries on the tree such as testing to see if a dynamic object should be rendered.

virtual unsigned long GetPolygonCount ( ) const = 0;
This method returns the number of polygons contained in the leaf. This is very important and will be used often by our collision system. For example, whenever the player's position is updated, an AABB will be constructed and fed into the spatial tree's CollectLeavesAABB method. This method will traverse the tree and compile a list of all the leaves the passed AABB was found to intersect. In the case our broad phase collision pass, this will allow us to get back a list of leaf pointers after having passed the swept sphere's bounding box down the tree. We know that only the polygons in those leaves need to tested in the narrow phase. Of course, in order to test each polygon in the leaf we must set up a loop to count through and retrieve these polygons from the leaf. This method would be used to retrieve the number of polygons in the leaf that will need to be extracted and passed to the narrow phase.

virtual CPolygon * GetPolygon (unsigned long nIndex) = 0;
This method is used by the collision system (for example) to retrieve the CPolygon object in the leaf's polygon array at the index specified by the parameter. For example, if the GetPolygonCount function returns 15, this means that you will have to call GetPolygon 15 times (once for each index between 0 and 14) to extract each polygon pointer.

virtual unsigned long GetDetailAreaCount ( ) const = 0;
Each leaf may also contain an array of detail areas. That is, when the tree is built, any detail areas that had been registered with the tree prior to the build process commencing will have their pointers copied into a leaf's DetailArea array for any leaf whose bounding box intersects the bounding box of the detail area. A detail area will typically span many leaves, so it is quite typical during the build process for the same detail area to have its pointer stored in the DetailArea array of multiple leaf nodes.

virtual TreeDetailArea *GetDetailArea (unsigned long nIndex) = 0;
This method allows the application to fetch a detail area from the leaf. The input index must be between 0 and one less than the count returned from GetDetailAreaCount method.

virtual void GetBoundingBox(D3DXVECTOR3 & Min, D3DXVECTOR3 & Max) const = 0;
It can prove handy to be able to retrieve the AABB of a leaf, so this function provides that service. When passed two vectors, it will fill them with the minimum and maximum extents of the leaf's AABB.

14.11.2 ISpatialTree – The Base Tree Class

The ISpatialTree class is the abstract base class from which our spatial trees will be derived. It specifies the core functions that our derived classes must implement in order to facilitate communication with the application. Provided our derived classes (quad-tree, kD-tree, oct-tree, etc.) are all derived from this class and implement all the pure virtual functions specified, our application can work with all our tree objects using this common interface. This means that our application code will never change even if we decide to switch from a quad-tree to an oct-tree. The class also defines some types that the derived classes can use to declare polygon lists, leaf lists, and detail area lists. ISpatialTree contains no member variables and no default functionality, so we can never instantiate an object of this type. However, it does provide a consistent API that our derived tree classes must support in order for our application to effortlessly switch between tree types and build and query the given tree. How these functions are actually implemented in the derived classes is of no concern to the application, just so long as they perform the desired task.

ISpatialTree is contained in the file ISpatialTree.h, along with ILeaf, and its declaration is shown below.

```
class ISpatialTree
{
public:

    // Typedefs, Structures and Enumerators.
    typedef std::list<ILeaf*>           LeafList;
    typedef std::list<CPolygon*>        PolygonList;
    typedef std::list<TreeDetailArea*>  DetailAreaList;

    // Constructors & Destructors for This Class.
    virtual ~ISpatialTree() {};     // No implementation, but forces all derived
                                       classes to have virtual destructors

    // Public Pure Virtual Functions for This Class.
    virtual bool            AddPolygon       ( CPolygon * pPolygon ) = 0;
    virtual bool            AddDetailArea    (const TreeDetailArea & DetailArea)=0;
    virtual bool            Build               ( bool bAllowSplits = true ) = 0;
    virtual void            ProcessVisibility   ( CCamera & Camera ) = 0;
    virtual PolygonList    &GetPolygonList      ( ) = 0;
    virtual DetailAreaList &GetDetailAreaList   ( ) = 0;
    virtual LeafList       &GetLeafList         ( ) = 0;
    virtual bool            GetSceneBounds      ( D3DXVECTOR3 & Min,
                                                  D3DXVECTOR3 & Max ) = 0;
    virtual bool            CollectLeavesAABB   ( LeafList & List,
                                                  const D3DXVECTOR3 & Min,
                                                  const D3DXVECTOR3 & Max ) = 0;
    virtual bool            CollectLeavesRay    ( LeafList & List,
                                                  const D3DXVECTOR3 &RayOrigin,
                                                  const D3DXVECTOR3 &Velocity)= 0;

    // Public Optional Virtual Functions for This Class.
    virtual bool            Repair              ( ) { return true; }
    virtual void            DebugDraw           ( CCamera & Camera ) {};
    virtual void            DrawSubset          ( unsigned long nAttribID ) {};
};
```

The class contains a lot of function declarations and some typedefs which define how the system should work. Before moving on and examining how these methods are implemented in the derived class, let us first discuss what each method is expected to do so that we understand what is required of us in our derived class implementations.

typedef std::list<ILeaf*> LeafList
typedef std::list<CPolygon*> PolygonList
typedef std::list<TreeDetailArea*> DetailAreaList

These three type definitions are conveniences that the derived class can use to allocate variables of a certain type. For example, all of our trees will maintain a list of CPolygon pointers. Although you can feel free to store these polygon pointers in any format you choose in your derived class, the base class defines some handy type definitions allowing us to easily declare an STL list of polygons using the variable type 'PolygonList'. You can also see that there are type definitions that describe variables of type LeafList and DetailAreaList to be STL lists of those respective structures. Remember, these are just type definitions, so this class has no members and you can feel free not to use these types to store your polygon, leaf, and detail area data. However, we use variables of the types shown above in our derived classes to store the three key data elements managed by the tree (polygons, leaves, and detail areas).

virtual bool AddPolygon (CPolygon * pPolygon)
virtual bool AddDetailArea (const TreeDetailArea & DetailArea)

It makes sense that all of our derived tree classes will need to implement a function that will allow the application to add polygon and detail area data to its internal lists prior to its Build function being called. The two functions shown above must be implemented in the derived class so that the application has a means to do that. For example, when the application loads a static polygon from an IWF file, it will store it in a CPolygon structure and call the tree's AddPolygon method to register that polygon with the tree. This method will be implemented such that it stores the passed polygon pointer in its internal polygon pointer list (a variable of type PolygonList). The AddDetailArea is expected to be implemented in the same way so that the application can register areas of interest with the tree class. They will be used later in the build process to include areas that contain no polygon data (for example) within the volume of space partitioned by the tree.

virtual bool Build (bool bAllowSplits = true)

Every tree class that we develop will certainly need to expose a build function that allows the application to instruct the object to build its spatial hierarchy once it has registered all the polygon data and detail area data with the object. The build function of the derived class will be implemented differently depending on the type of tree being built. When the build function returns control back to the application, the spatial hierarchy will have been constructed and it will be ready for collision querying and visibility testing.

All of our trees will also have the option during creation to build a clipped on non-clipped tree. Thus, conditional logic will need to be put in place to determine what action should be taken if a polygon spans the bounds of a leaf in which it is partially contained. The bAllowSplits parameter to this function is the application's means of letting the tree know which type of build strategy should be employed. If the parameter is set to true, a clipped tree will be built. Any polygons that span multiple leaf nodes will be clipped to the bounds of each leaf in which it is contained and every leaf will ultimately contain a list

of polygons that are contained totally within its bounds. If this parameter is set to false, then any polygon that spans multiple leaf nodes will have its pointer stored in each of those leaf nodes.

> **Note:** Remember that clipping the polygons to the leaf nodes increases the polygon count of the level, potentially by a considerable amount. This means more polygons need to be rendered and more draw primitive calls have to be made. In our test level, this was a major problem with the oct-tree, where the polygon count increased between 60% and 90% when clipping was being used (depending on leaf size).

virtual void ProcessVisibility (CCamera & Camera)

Our application will also expect every tree class to implement the ProcessVisibility method, which exists to perform a hierarchy traversal with the passed camera and set any leaves that exist inside or partially inside the frustum as visible. This function, along with much of the rendering system of our tree classes, will be discussed in detail in the next chapter since this chapter is going to focus on the core building code. For now, just know that this function will be called by the scene prior to the tree being rendered. When this function returns, each leaf in the tree will know whether it is visible or not. When the application then issues a call to the ISpatialTree::DrawSubset method, the tree will know that it only has to render polygons that are contained in leaves that currently have their visible status set to true. Obviously, this will allow us to reject a lot of the geometry from being rendered most of the time.

virtual PolygonList &GetPolygonList ( )
virtual DetailAreaList &GetDetailAreaList ( )
virtual LeafList &GetLeafList ( )

These three methods must be implemented to allow the application to retrieve the polygon list, the detail area list and the list of leaves being used by the tree. This might be useful is the application would like to save the compiled tree data to file or would like to perform some custom optimization on the data. The GetPolygonList method is essential, since after the build process has completed, the internal list of polygons used by the tree might be quite different from the list the application originally registered with the tree. If clipping is being used, many of the polygons from the original list added by the application will have been deleted and replaced by the fragments they were divided into. Therefore, these functions are usually called after the build process so that the application has some way to access the data stored in the tree. Of course, the leaf list is not even compiled until the tree is built, so it would serve no purpose to call this function prior to calling the Build function.

virtual bool GetSceneBounds (D3DXVECTOR3 & Min, D3DXVECTOR3 & Max)

This method allows the application to retrieve an axis aligned bounding box that bounds the entire area of space partitioned by the tree. This is essentially the bounding box of the root node of the tree. Of course, this is not necessarily an AABB bounding only the static polygon data, it will also account for detail areas. Our derived classes will implement this method by simply returning the bounding volume of the root node.

virtual bool CollectLeavesAABB (LeafList & List, const D3DXVECTOR3 & Min, const D3DXVECTOR3 & Max)

This key method is one that the collision system uses to run queries on the tree. When this function is called, the application will pass an axis aligned bounding box and an empty leaf list (an STL list of ILeaf structures). This function should be implemented such that it will traverse the tree from the root node

and collect the leaves whose volumes are intersected by the passed AABB, attaching them to the input list. We can think of two situations where this function will be useful immediately.

When implementing the broad phase of our collision system we will wish to pass only polygons in the immediate area of the swept sphere's AABB to the narrow phase. In order to do this we will want to pass the swept sphere's AABB into the tree and get back a list of leaves that intersect it. It is only the polygons in those leaves that will have to be further checked at a lower level. Any polygons not contained in those leaves will never be considered by the collision system. This function will speed up our collision system by an order of magnitude.

Another time when our application will need to use this method is when determining in which leaves a dynamic object is located. Whenever a dynamic object has its position updated, we can pass its AABB into the tree and get back a list of intersected leaves. These are the leaves the dynamic object is currently contained within. This leaf list will be maintained internally for the object, but we can retrieve it via an ID prior to executing any draw calls. Before the scene renders any geometry, it will call the ISpatialTree::ProcessVisibility method which will determine which leaves are visible and which leaves are not. Since we know what leaves a dynamic object resides in, we can quickly test whether any of them were visible and take appropriate measures.

This function will be implemented as a simple recursive procedure that traverses the tree from the root node and performs and AABB/AABB intersection test between the passed AABB and the bounding volume of the node currently being visited. Once again, this is very fast because as soon as we find a node whose volume does not intersect the query volume, we never have to bother stepping into its child nodes, thus rejecting huge portions of the tree from having to be tested.

This function will need to be implemented differently in each derived class because the layout of the node structure and the way the tree is traversed will differ between tree types. For example, in a quad-tree we will need to step into four children at each node, while the oct-tree would recur into eight children. Of course, the underlying algorithm will be the same: perform AABB/AABB tests at each node and determining whether traversing into the children is necessary. Whenever we traverse into a leaf, it means that leaf is contained inside the query volume and it is added to the passed leaf list so that the caller will have access to it. We will discuss how to perform AABB/AABB intersections tests in a moment when we add that functionality to our CCollision class.

virtual bool CollectLeavesRay (LeafList & List, const D3DXVECTOR3 &RayOrigin, const D3DXVECTOR3 &Velocity)

This function has an almost identical purpose to the previously described function, only this time the query object is a ray instead of an AABB. There will be several times when we may wish to determine which polygons in the scene a ray intersects, and this function will allow us to do this efficiently.

The function is passed the ray origin and delta vectors along with an empty leaf list. The function should be implemented such that it will traverse the tree and return a list of leaves whose bounding volumes were intersected by the ray. Once again, this will have to be implemented slightly differently in each derived class as the way in which the tree is traversed is dependant on the node type (i.e., different numbers of children).

The function will step through each node in the tree and perform a ray/AABB intersection test with the node's bounding volume. If the ray does not intersect a volume then its child nodes do not have to be tested. For any node whose bounding box intersects the ray, we step into its children and perform the same process. Whenever we reach a leaf node, it means the ray must be partially contained within that leaf and the leaf structure is added to the leaf list so it can be returned to the caller.

virtual bool Repair ( ) { return true; }

The repair function is not an abstract function as it does have an implementation in ISpatialTree that essentially does nothing. This means that we do not have to bother implementing this function in the derived classes. However, it does give us an opportunity to perform some optimizations on the tree polygon data after the tree has been built. We will implement this function in our derived classes to perform a weld operation on the polygon vertices allowing to get rid of any redundant vertices (i.e., vertices that share the same position in 3D space and have the same attributes). This allows us to cut down on the number of vertices used by our scene quite dramatically in certain cases. In the case of GILES™, every face will have its unique vertices, so a cube constructed from 6 faces will actually contain 6*4=24 vertices. If the attributes of each face are identical, then at each corner of the cube there will be three vertices sharing the same space that have the same attributes (1 for each face that forms that corner). By performing a weld operation, we can collapse these three vertices at each corner into a single vertex that each of the three faces will index.

Another task that we will perform inside our Repair function will be the repair of T-junctions. T-junctions will be explained later, but as mentioned earlier, they frequently occur when lots of clipping has been performed. Since they cause very unsightly visual artefacts, we will definitely wish to repair them if we have built a clipped tree and intend to use the tree for rendering. Even if a non-clipped tree is being used, it is not uncommon for the source geometry to contain T-junctions that the artist may have inadvertently created, so we can repair those too.

If you do decide to derive your own tree types from ISpatialTree, you do not have to implement this step. Everything will still work fine because the default implementation will do nothing and just return. This method will be called by the scene after the Build function has returned and the tree has been completely built.

virtual void DebugDraw (CCamera & Camera) {}

This function is another function that has a default implementation that does nothing, so you do not have to implement it in your derived classes. However, it is often very useful for the application to be able to get some debug information about how the tree was constructed. As you have no doubt become aware, finding potential problems in recursive code can be very difficult, so if your spatial tree is not behaving in quite the way it should, it is useful to have this function available so that some rendering can be done to help you visualize how space has been partitioned. It is also useful when you are trying to configure the settings for your scene, such as the minimum leaf size (i.e., the size at which we make a node a leaf regardless of how much data it contains). As the leaf size will be directly related to the scale of your scene, you will likely want a way to see how the space has been partitioned.

In each of our derived tree classes we implement this method so that we can render the bounding boxes around each leaf node. Figure 14.51 shows a screen shots from Lab Project 14.1 with debug drawing enabled for a kD-tree (available via a menu option). On the code side, all the CScene::Render method

does after rendering the tree polygons and any dynamic objects, is call the tree's DebugDraw method. This method traverses the tree searching for visible leaf nodes. Once a leaf node is found it fetches the bounding box of the leaf and draws it using a line list primitive type.

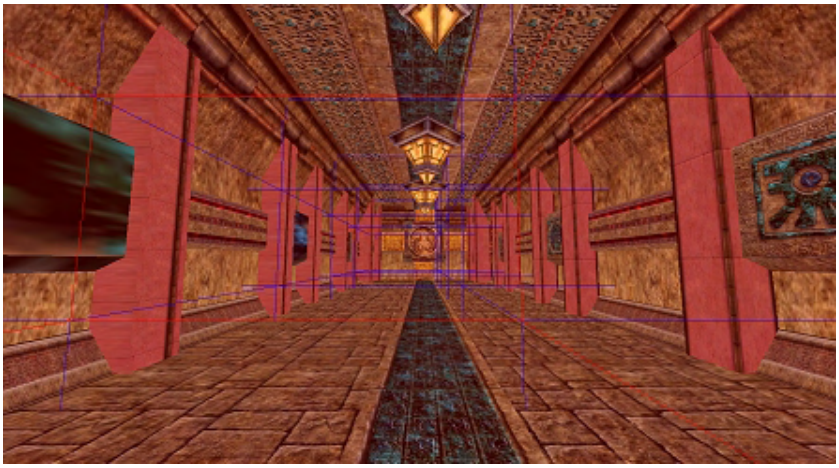

Figure 14.51

With debug draw enabled we can easily see the size of each leaf node and how the space is partitioned which, as mentioned, is very useful indeed when diagnosing various issues. In Figure 14.51 you can see that the bounding box of the leaf in which the camera is currently located is rendered in red instead of blue like all other leaf nodes. When the debug draw renders a red box it means that you are currently located in a leaf that contains something; either geometry or a detail area. However, if the leaf in which the camera is currently located is an empty leaf node the box is rendered in green as shown in Figure 14.52.

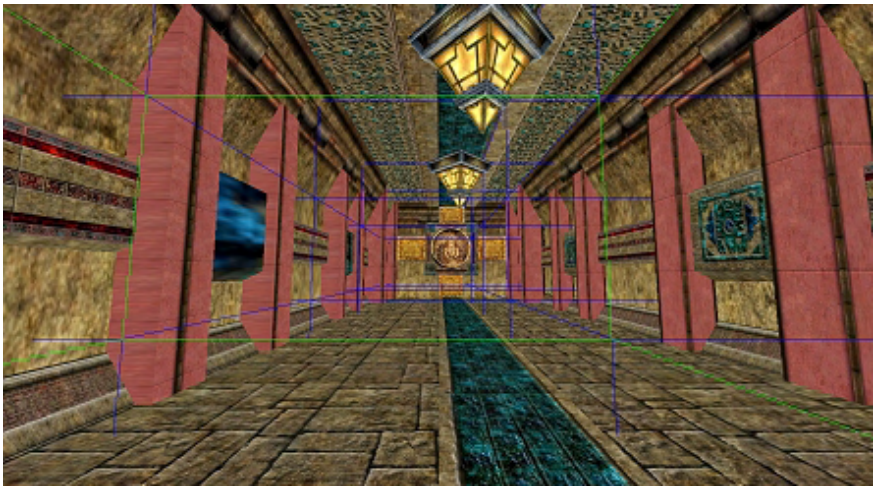

Figure 14.52

The DebugDraw method is a method that will have to be implemented slightly differently in each derived tree class. Although the output will be the same in all versions of this function (for the quad-tree, oct-tree and kD-tree) it is a function that needs to traverse the tree hierarchy and therefore, is dependant on the node structure of the tree being used and the number of children spawned from each node. However, each version of this function (for each tree type) will be almost identical. They will all traverse the tree looking for leaf nodes and then render bounding boxes using the bounding volume information. We will look at the code to these functions later in the lesson.

virtual void DrawSubset (unsigned long nAttribID) {}

In theory, rendering a spatial tree is very easy. For example, we could just traverse the hierarchy and collect the polygons from the visible leaf nodes and copy them into dynamic index and vertex buffers. Unfortunately, with such a scheme, memory copying really hampers performance when we are building those render buffers. Using a dynamic index buffer only approach is certainly much better, but still not optimal. Rendering a tree efficiently in a way that does not hamper the performance of powerful 3D

graphics cards is not so easy and in the next chapter we will discuss the rendering system that we have put in place that all of our spatial trees will use to collect and render their geometry.

> **Note:** Since the spatial tree rendering system will be rather involved, we will dedicate a good portion of the next chapter entirely to this one topic. Although this rendering system is used in Lab Project 14.1, note that this same lab project will be discussed over these two chapters. In this chapter we will discuss building the spatial tree and the upgrade of the collision system to use the spatial tree during its broad phase pass. In the next lesson we will discuss exactly how the tree data is converted into hardware friendly render batches so that we can minimize draw primitive calls and maximize batch rendering. When examining the code to Lab Project 14.1, it may be best for you to ignore how the tree is rendered for now.

The DrawSubset function will need to be implemented by each tree class so that the application can instruct the tree that it needs to render all visible polygons belonging to the passed subset. As we know, our scene is responsible for setting textures and materials and it does not want to set the same one more than once if it can be avoided. That is, we wish to setup a given attribute and then render all the polygons in the scene that use it. This minimizes render state changes and DrawPrimtive calls, which can really help performance. The CScene::Render method will first call the ISpatialTree::ProcessVisibility method prior to any rendering taking place. This instructs the tree to traverse its hierarchy and mark any leaves that are inside the view frustum as being visible. Our scene will then loop through each attribute used by the scene and call this method, each time passing in the current attribute/subset being processed. This will instruct the tree to render any polygon in any of the currently visible leaves that belong to this subset. As you will see in the next lesson, doing this efficiently means putting quite a complex system in place.

Although we have not yet discussed the implementation details of any of the functions declared in the base class, discussing ISpatialTree and the methods it exposes has given us an understanding of how our tree will work, the functions that we are expected to implement in our derived classes, and the way in which our application will communicate with our trees both when querying it and rendering it. With that said, let us start coding.

14.11.3 CBaseTree & CBaseLeaf – Base Functionality Classes

For the most part, in this course we have not really had to implement chains of derived classes. At most we have sometimes implemented a base class and a derived class as this makes the code clearer to read, easier to learn, and it makes program flow easier to follow (and of course, it is often good OOP). However, sometimes it makes sense to have an additional layer of inheritance when all your derived classes will share many properties and would need to have identical code duplicated for each. For example, regardless of the tree types we implement, they will all share a lot of common ideas. Each tree type will store a list of polygons, leaves, and detail areas, and will need to implement methods that allow the application to add and retrieve elements to/from these lists.

Likewise, the leaf structure used by each tree will essentially be the same and will have the same tasks to perform. Each will store a bounding box and will need to implement methods to add polygons and detail areas to its internal lists and expose functions which allow the tree to set its visible status during a

visibility update. Furthermore, although we will not discuss the rendering subsystem in this chapter, the same system will be used by each of the derived tree classes. If we were simply going to derive our quad-tree, kD-tree, and oct-tree classes directly from ISpatialTree, we would have to implement this code in each of our derived classes. This is wasteful since we would be duplicating identical code in each derived class. For example, the AddPolygon method will be implemented identically in each tree type; it will be a simple function that accepts a CPolygon pointer and stores that pointer in the tree's polygon list.

To minimize redundancy across these common tasks, we will include a middle layer called CBaseTree. CBaseTree will be derived from ISpatialTree and will implement many of the functions that are common to all tree types. It will also implement all the code to the rendering system which will be used by each derived tree class. Although we will never be able to instantiate an object of type CBaseTree (as it does not implement all the method from ISpatialTree) it will provide all of the housekeeping code. We will derive our quad-tree, oct-tree, and kD-tree classes from CBaseTree.

Due to the fact that CBaseTree contains a lot of code that is common to all tree types, implementing our actual tree classes will involve just the implementation of a few functions. For example, when implementing a quad-tree class, we essentially just have to implement the methods from ISpatialTree that are not implemented in CBaseTree. One such method is the Build method which will obviously be different for each tree type. The only other method we will have to implement in the lower level tree classes are the query routines such as CollectLeavesAABB, CollectLeavesRay, and ProcessVisibility. As these methods are tree traversal methods, they must be implemented by the actual types. Thus, if you open up the CQuadTree.cpp file for example, you will see that very little code is contained in there, as most of the common functionality is contained inside CBaseTree.

In this next section we will discuss the implementation of the CBaseTree methods that are used during the building phase. The rendering system contained in CBaseTree will be discussed in the following lesson, so its methods will be removed from the class declaration at this time. In this lesson, we are just concentrating on the CBaseTree methods used by the tree building process and the methods associated with querying the tree (such as the method used by our collision system). The code to CBaseTree and CBaseLeaf are stored in the files CBaseTree.h and CBaseTree.cpp.

14.11.4 CBaseLeaf – The Source Code

CBaseLeaf is derived from ILeaf and implements all the functionality of the base class. That is, all of our trees will store leaves of type CBaseLeaf. The class declaration is shown below and we will discuss it afterwards. Notice how the first pool of function declarations are those from ILeaf that will be implemented in this class. This is followed by some functions which CBaseTree will need to communicate with a leaf.

```
class CBaseLeaf : public ILeaf
{
public:

    // Constructors & Destructors for This Class.
    virtual ~CBaseLeaf( );
```

```
            CBaseLeaf( CBaseTree *pTree );

    // Public Virtual Functions for This Class (from ISpatialTree).
    virtual bool            IsVisible           ( ) const;
    virtual unsigned long   GetPolygonCount     ( ) const;
    virtual CPolygon *      GetPolygon          ( unsigned long nIndex );
    virtual unsigned long   GetDetailAreaCount  ( ) const;
    virtual TreeDetailArea* GetDetailArea       ( unsigned long nIndex );
    virtual void            GetBoundingBox      ( D3DXVECTOR3 & Min,
                                                  D3DXVECTOR3 & Max ) const;

    // Public Functions for This Class.
    void                    SetVisible          ( bool bVisible );
    void                    SetBoundingBox      ( const D3DXVECTOR3 & Min,
                                                  const D3DXVECTOR3 & Max );
    bool                    AddPolygon          ( CPolygon * pPolygon );
    bool                    AddDetailArea       ( TreeDetailArea * pDetailArea );

protected:

    // Protected Structures, Enumerators and typedefs for This Class.
    typedef std::vector<CPolygon*>          PolygonVector;
    typedef std::vector<TreeDetailArea*>    DetailAreaVector;

    // Protected Variables for This Class
    PolygonVector       m_Polygons;     // Array of polygon pointers in this leaf.
    DetailAreaVector    m_DetailAreas;  // Array of detail area pointers in leaf.
    bool                m_bVisible;     // Is this leaf visible or not?
    D3DXVECTOR3         m_vecBoundsMin; // Minimum bounding box extents
    D3DXVECTOR3         m_vecBoundsMax; // Maximum bounding box extents.
    CBaseTree          *m_pTree;        // The tree that owns this leaf
};
```

Looking at the above class declaration we can see that it implements those methods from the base class that allows the application to perform queries on the leaf such as retrieving the leaf's visible status or retrieving its bounding volume. Following these declarations are the functions that are new to this class which CBaseTree and any class derived from it can use to add detail areas or polygons to the leaf's arrays. It also exposes methods which CBaseTree (or any class derived from it) can use to set the visibility status of a leaf (inside the ProcessVisibility function) and methods allowing the tree building functions to set the leaf's AABB.

Following that are two type definitions called PolygonVector and DetailAreaVector. These are STL vectors which the leaf will use to store the polygon pointers and detail area pointers assigned to it. Unlike the CBaseTree which stores its polygon and detail area data in STL lists (linked lists) for efficient manipulation during the tree building process, the data that ends up being assigned to a leaf remains static once the leaf has been built. Therefore, we use vectors for faster access.

Finally, at the bottom of the declaration we can see the member variables that each leaf structure contains. They are discussed below, although their meaning will most likely be self-explanatory given their names.

PolygonVector m_Polygons
This member is an STL vector that will be used to store the polygons assigned to this leaf. During the build process, once a node has been reached which suits the criteria for being a terminal node (such as its bounding volume is sufficiently small or the number of polygons is below a certain threshold) a new CBaseLeaf object will be created and added to the tree's leaf list. The leaf structure will also be attached to the node in the tree and the polygon data that made it into that node will be added to the leaf via the CBaseLeaf::AddPolygon method. This method will store the passed CPolygon pointer in this vector.

DetailAreaVector m_DetailAreas
In an almost identical manner to the method described above, this vector will be used to store pointers to any detail objects that exist inside or partially inside the leaf.

bool m_bVisible
This member is used internally by the leaf to record its current visibility status. If, during the last ProcessVisibility test, its bounding box was found to be inside or partially inside the frustum, the tree would have set this boolean to true through the use of the CBaseLeaf::SetVisible method. The application (or the tree itself) can query the visibility status of a leaf using the CBaseLeaf::IsVisible method, which simply returns the value of this boolean.

D3DXVECTOR3 m_vecBoundsMin
D3DXVECTOR3 m_vecBoundsMax
Each leaf will store a bounding volume (an AABB) which will be set by the tree during the build process. When a leaf is created, the bounding box of the polygon data and the detail area data that made it into that node is computed. The tree will then use the CBaseLeaf::SetBoundingBox method to set the bounding box for the leaf.

CBaseTree * m_pTree
Each leaf will store a copy of the pointer to the tree which owns it. We will see how this pointer is used in the next chapter when we discuss rendering.

Let us now take a look at the method implementations shown above. Remember, if you are following along with the lab project source code files open, you will see many other method in CBaseTree that we have not discussed here. These are methods related to the rendering system which will be fully explained in the next lesson.

Constructor - CBaseLeaf

The CBaseLeaf constructor could not be simpler. We just initialize its visibility status to true. We will assume that the default state of any node/leaf in the tree is visible so that if for some reason we do not wish to perform the ProcessVisibility pass, all leaves will be rendered.

```
CBaseLeaf::CBaseLeaf( CBaseTree *pTree )
{
    // Reset required variables
    m_bVisible          = true;
```

```
     .. render data ..

    // Store the tree
    m_pTree = pTree
}
```

When the leaf is first created its polygon and detail area vectors will be empty and its bounding box will be uninitialized. Note that the leaf also accepts and stores a pointer to the base tree to which it belongs.

Setting/Getting the Leaf's Visibility Status - CBaseLeaf

The method that allows the application to query the visibility status of a leaf with a simple one line function that returns the value of the leaf's visibility flag.

```
bool CBaseLeaf::IsVisible( ) const
{
    return m_bVisible;
}
```

Likewise, the method that allows our tree classes to set the visibility status of a leaf (during the ProcessVisibility pass) is a one line function that sets the boolean member equal to the boolean parameter passed.

```
void CBaseLeaf::SetVisible( bool bVisible )
{
    // Flag this as visible
    m_bVisible = bVisible;
}
```

AddPolygon – CBaseLeaf

The AddPolygon method is called by the tree building process whenever a terminal node is encountered. A new CBaseLeaf object is allocated and its pointer is stored in the terminal node. The AddPolygon method will then be called for each polygon that made it into the terminal node. The method adds the passed CPolygon polygon pointer to the leaf's polygon vector (with exception handling to return false should an error occur in the process).

```
bool CBaseLeaf::AddPolygon( CPolygon * pPolygon )
{
    try
    {
        // Add to the polygon list
        m_Polygons.push_back( pPolygon );

    }
```

```
    catch ( ... )
    {
        return false;

    }

    // Success!
    return true;
}
```

AddDetailArea – CBaseLeaf

When a leaf is created and added to a terminal node during the building process, any detail area that made it into that node will also be added to the leaf. The AddDetailArea adds the passed TreeDetailArea pointer to the leaf's internal detail area vector. The function code is shown below.

```
bool CBaseLeaf::AddDetailArea( TreeDetailArea * pDetailArea )
{
    try
    {
        // Add to the detail area list
        m_DetailAreas.push_back( pDetailArea );

    } // End Try Block

    catch ( ... )
    {
        return false;

    } // End Catch Block

    // Success!
    return true;
}
```

Retrieving the Polygon Data from a Leaf – CBaseLeaf

It will often be necessary for the application to retrieve the polygon data stored in a leaf. This is certainly true in our broad phase collision step when we will send the swept sphere's AABB down the tree and get back a list of intersecting leaves using the tree's CollectLeavesAABB method. Once this list of leaves is returned, the broad phase can fetch each polygon from each returned leaf and test it more thoroughly (first with an AABB/AABB test between the AABB of the swept sphere and the AABB of the polygon and then with the more expensive narrow phase if the prior test returns true for an intersection).

For the collision system to get this information, it must know how many polygons are stored in a leaf and have a way to access each polygon in that leaf. Below we see the implementations of the

CBaseLeaf::GetPolygonCount and CBaseLeaf::GetPolygon methods which are part of the ISpatialTree interface. The GetPolygonCount method simply returns the size of the leaf's internal CPolygon vector.

```
unsigned long CBaseLeaf::GetPolygonCount( ) const
{
    // Return number of polygons stored in our internal vector
    return m_Polygons.size();
}
```

The GetPolygon method accepts an index (in the range of zero to the value returned from GetPolygonCount - 1) and returns the CPolygon pointer stored at that location in the vector.

```
CPolygon * CBaseLeaf::GetPolygon( unsigned long nIndex )
{
    // Validate the index
    if ( nIndex >= m_Polygons.size() ) return NULL;

    // Return the actual pointer
    return m_Polygons[nIndex];
}
```

Retrieving the Detail Area Data from a Leaf – CBaseLeaf

An application may also wish to retrieve the information about which detail areas are stored in a leaf. For example, perhaps you have inserted a specific detail area that has a context pointer that points to a structure filled with fog settings. Whenever the camera is in a leaf which contains such a detail area, the pipeline's fog parameters could be set and enabled as described by the detail area's context pointer. Such a task could be performed by finding the leaf the camera is currently in and then fetching the number of detail area areas assigned to this leaf. You could then set up a loop to extract and test each detail area. If a detail area is found which has a context pointer that points to a fog structure, fog could be enabled.

In order to do this we would need to be able to fetch the number of detail areas in a leaf and expose a means for those detail areas to be retrieved and examined. The CBaseLeaf::GetDetailAreaCount is a simple function that returns the size of the leaf's detail area vector:

```
unsigned long CBaseLeaf::GetDetailAreaCount( ) const
{
    // Return number of polygons stored in our internal vector
    return m_DetailAreas.size();
}
```

The CBaseLeaf::GetDetailArea method is passed an index between 0 and the value returned by the GetDetailAreaCount function minus 1. It returns the TreeDetailArea pointer stored at that position in the vector.

```
TreeDetailArea * CBaseLeaf::GetDetailArea( unsigned long nIndex )
{
    // Validate the index
```

```
    if ( nIndex >= m_DetailAreas.size() ) return NULL;

    // Return the actual pointer
    return m_DetailAreas[nIndex];
}
```

Setting and Retrieving a Leaf's Bounding Box - CBaseLeaf

The application may want to retrieve the leaf bounding box for custom intersection routines. The CBaseLeaf::GetBoundingBox method accepts two 3D vector references and populates them with the minimum and maximum extents of the leaf's AABB.

```
void CBaseLeaf::GetBoundingBox( D3DXVECTOR3 & Min, D3DXVECTOR3 & Max ) const
{
    // Retrieve the bounding boxes
    Min = m_vecBoundsMin;
    Max = m_vecBoundsMax;
}
```

The application will never need to set the bounding box of a leaf since that is the responsibility of the tree building process. Therefore, the SetBoundingBox method is not a member of ILeaf (the API used by the application); it is added to CBaseLeaf instead. The derived tree classes will call this method when the leaf is created at a terminal node and pass it the minimum and maximum extents of an AABB which represents the area of the terminal node (the leaf). Below we see the code to the function that will be called by the tree building process after a leaf has been allocated at a terminal node.

```
void CBaseLeaf::SetBoundingBox( const D3DXVECTOR3 & Min, const D3DXVECTOR3 & Max )
{
    // Store the bounding boxes
    m_vecBoundsMin = Min;
    m_vecBoundsMax = Max;
}
```

We have now covered all of the housekeeping methods in our CBaseLeaf class (the class that will be used to represent polygon and detail area data at terminal nodes in the tree). This object will be used by all of our derived tree classes to represent leaf data.

There are some additional members and methods that are not shown here as they relate to the rendering subsystem of CBaseTree. These will be discussed in the following lesson. For now, we have covered all the important code that will be needed to understand the construction and configuration of leaf data both during the build process and during collision queries.

14.11.5 CBaseTree – The Source Code

CBaseTree is the class that our other tree classes will be derived from. It implements many of the methods required by the ISpatialTree interface and as such, by deriving our tree classes from this class,

we avoid having to duplicate such housekeeping functionality. As discussed earlier, with CBaseTree in place, we can easily create almost any tree type we want simply by deriving a new class from it and implementing its build and query traversal functions. CBaseTree will be responsible for managing the polygon, leaf, and detail area lists and implementing the methods from ISpatialTree that allow the application to register data with the tree prior to the build process.

CBaseTree will also implement other methods that our derived classes will not want to worry about, such as the repair method from ISpatialTree. The CBaseTree::Repair method will repair T-junctions in the geometry and can be called after the tree has been built. Although we will not discuss the rendering logic in this chapter, this class also implements the DrawSubset method responsible for rendering the various subsets of static polygons stored within the tree. It also has an implementation of a ProcessVisibility method, although this method must be overridden in your derived class. The derived version must call the CBaseTree version prior to performing its visibility traversal. Although the meaning of the CBaseTree version of this method will not be fully understood until the next lesson, this method essentially gives CBaseTree a chance to flush its render buffers before they get refilled by the derived class. This will be explained later, so do not worry too much about it for now.

Finally, CBaseTree implements some utility methods that can be called by the derived class to make life easier. An example of this happens when implementing the DebugDraw method in your derived classes. As discussed earlier, the DebugDraw method traverses the hierarchy and renders a bounding box for any visible leaf node. This allows us to see each leaf's volume when running our application. However, although this function essentially has the same task to perform for each tree type, the method must be implemented for each tree type due to the fact that we traverse an oct-tree differently from how we traverse a quad-tree. But the traversal code is very small; it is really the rendering of the bounding box which takes a bit more code and will be identical for each tree type.

Because of this fact, CBaseTree will expose a method called DrawBoundingBox which can be called from a derived class and passed an AABB. This method will take case of the actual construction and rendering of the bounding box to the frame buffer. Therefore, all we have to do when we implement the DebugDraw method in our derived tree classes is write code in there that traverses the tree looking for visible leaf nodes. As we find each one, we just call the CBaseTree::DrawBoundingBox method and pass it the AABB of the leaf in question. This function will then render the bounding box and we minimize redundant code. This class also implements another DebugDraw helper function called CBaseTree::ScreenTint that can be passed a color and will alpha blend a quad over the entire frame buffer. We use this in our derived class's DebugDraw method to tint the screen red when the camera enters a leaf that has data contained in it (a non-empty leaf).

Below we see the class declaration of CBaseTree. We have removed any functions, structures, and member variables related to its rendering subsystem since we will introduce these in the following lesson.

```
class CBaseTree : public ISpatialTree
{
public:

    // Friend list for CBaseTree
    friend void CBaseLeaf::SetVisible( bool bVisible );
```

```
    // Constructors & Destructors for This Class.
    virtual ~CBaseTree( );it easily
    CBaseTree( LPDIRECT3DDEVICE9 pDevice, bool bHardwareTnL );

    // Public Virtual Functions for This Class (from base).
    virtual bool            AddPolygon       ( CPolygon * pPolygon );
    virtual bool            AddDetailArea    ( const TreeDetailArea& DetailArea );
    virtual bool            Repair             ( );
    virtual PolygonList    &GetPolygonList     ( );
    virtual DetailAreaList &GetDetailAreaList  ( );
    virtual LeafList       &GetLeafList        ( );
    virtual void            DrawSubset         ( unsigned long nAttribID );
    virtual void            ProcessVisibility  ( CCamera & Camera );

protected:
    bool          PostBuild         ( );
     void         DrawBoundingBox   ( const D3DXVECTOR3 & Min,
                                      const D3DXVECTOR3 & Max,
                                      ULONG Color, bool bZEnable = false );

    void          DrawScreenTint    ( ULONG Color );
    void          CalculatePolyBounds ( );
    void          RepairTJunctions  ( CPolygon * pPoly1,
                                      CPolygon * pPoly2 );

    // Protected Variables for This Class.
    LPDIRECT3DDEVICE9          m_pD3DDevice;
    bool                       m_bHardwareTnL;
    LeafList                   m_Leaves;
    PolygonList                m_Polygons;
    DetailAreaList             m_DetailAreas;
};
```

A few things in the above declaration are worthy of node. First, notice how the CBaseLeaf::SetVisible method is made a friend, so that we can access it from within this class. The tree will need to be able to set the visible status of a leaf when it is performing its visibility pass. Also notice that it has a method called PostBuild. This method will be called by the derived class after the tree has been constructed. For example, our CQuadTree class will call this method at the very end of its Build function after the tree has been constructed. The PostBuild method does two things. The first thing it does is call the CBaseTree::CalculatePolyBounds method which will loop through each CPolygon stored in the tree, calculate its bounding box, and store that bounding box in the polygon structure. The polygon bounding boxes will be used by our broad phase collision step so that only polygons whose bounding boxes intersect the AABB of the swept sphere get passed onto the narrow phase. This is another example of a function that would otherwise need to be implemented in each of the derived classes if it were not for CBaseTree managing such functionality. The second thing the CBaseTree::PostBuild method does is call CBaseTree::BuildRenderData. This method is not shown above because we will discuss it in the next chapter (basically, it configures the rendering subsystem for CBaseTree).

We can see in the above declaration that the CBaseTree also has a method called RepairTJunctions. It is called from the CBaseTree::Repair method to mend any T-junctions which were introduced during the building phase. If the tree is not being used for rendering and you wish to repair T-junctions introduced in the build phase, then the application should call the Repair method after the tree has been built. If the tree is being used for rendering then there is no need, because the BuildRenderData method will

automatically call this method before preparing the render data. Keep in mind that if a tree is being used for rendering, we definitely want to always repair T-junctions to remove unsightly artifacts. We will examine what T-junctions are and how they can be repaired later in this lesson.

Let us now discuss the member variables declared in CBaseTree which will be used for storage by the derived classes.

LPDIRECT3DDEVICE9 m_pD3DDevice
If the application wishes to use the tree for rendering, it should pass a valid pointer to a Direct3D device into the constructor of the derived class, which will pass it along to the base class for storage in this member. If NULL is passed to the derived class constructor then NULL will be passed to the constructor of CBaseTree as well and this parameter will be set to NULL. If this parameter is NULL, no render data will be built when PostBuild is called at the end of the derived class's Build method.

bool m_bHardwareTnL
This boolean will also be set via the application passing its value to the derived class constructor, which in turn will be passed to the CBaseTree constructor and stored in this member. We have used a boolean value like this many times before to communicate to a component whether the device being used is a hardware or software vertex processing device. We will see in the following chapter how the base tree class will need to know this information when building the vertex and index buffers for its render data.

LeafList m_Leaves
PolygonList m_Polygons
DetailAreaList m_DetailAreas
Earlier we saw that the types LeafList, PolygonList, and DetailAreaList were defined in ISpatialTree as STL lists (linked lists) of ILeaf, CPolygon, and TreeDetailArea objects, respectively. These linked lists store the leaves, polygons, and detail areas when they are added to the tree. At any point (even pre-build) the m_Polygons and m_DetailAreas lists will contain all the polygons and details areas registered and in use by the tree at that time. m_Leaves will only contain valid data after the tree has been built and the leaves have been created.

Before the tree is built, the application will need a way to register detail areas and polygons with the tree so that they can be used in the building process. For example, every time we load a polygon from an IWF file we will call the AddPolygon method that will add it to the above list. After all the data has been added to the tree, but prior to the Build function being called, this list will contain all the polygon data that will be partitioned by the build process. After the build process has completed however, the polygons stored in the m_Polygons array (and in the leaf polygon arrays) may be different from the original list that existed prior to tree compilation. This is certainly true if a clipped tree is being constructed since many of the polygons in the original list will be deleted and replaced by two split fragments. Likewise, even if the lists are the same post-build, if you call the Repair function to mend T-junctions, additional triangles will be inserted to repair those T-junctions. The important point is that whether post-build or pre-build, the m_Polygons and m_DetailAreas lists will always contain all the polygons and detail areas being used by the tree. In the post-build case, we will also have pointers to all the polygons and detail areas in these lists stored in the polygon and detail area vectors of the leaves as well.

Constructor – CBaseTree

The CBaseTree constructor is called from the constructor of the derived class and is passed two parameters supplied by the application. If pDevice is not NULL then it means that the application wishes to use this tree for rendering and the rendering subsystem will be invoked (described in the next chapter). The device pointer and the boolean describing the hardware/software status of the device are stored in the base class variables and the reference count of the device is incremented.

```
CBaseTree::CBaseTree( LPDIRECT3DDEVICE9 pDevice, bool bHardwareTnL )
{
    // Store the D3D Device and other details
    m_pD3DDevice    = pDevice;
    m_bHardwareTnL  = bHardwareTnL;

    // Add ref the device (if available)
    if ( pDevice ) pDevice->AddRef();
}
```

There are a few additional lines to this constructor not shown here since they concern the rendering system which we will introduce later.

AddPolygon - CBaseTree

All of our derived classes will have a few things in common. One is the need for the application to add polygon data to its internal arrays in preparation for the build process. The AddPolygon method will be called by the application every time it loads a static polygon which it would like to be part of the data set that is to be spatially partitioned. If you look in the CScene::ProcessVertices function of Lab Project 14.1, you will see that a new line has been inserted that adds the vertices of the polygon currently being processed to the spatial tree being used by the scene. This is the function it calls, and as you can see, it simply adds the passed polygon pointer to its internal polygon list.

```
bool CBaseTree::AddPolygon( CPolygon * pPolygon )
{
    try
    {
        // Add to the polygon list
        m_Polygons.push_back( pPolygon );

    } // End Try Block
    catch ( ... )
    {
        return false;

    } // End Catch Block

    // Success!
    return true;
}
```

Only after the application has called the AddPolygon method for every static polygon it wishes to be stored in the tree should it call the tree's Build method. We will see later how the derived class's Build function will use the polygon list to build its spatial hierarchy.

AddDetailArea - CBaseTree

The application will also need the ability to register detail areas with the tree prior to the Build method being executed. This method is passed a TreeDetailArea structure which will be added to the tree's detail area list.

```
bool CBaseTree::AddDetailArea( const TreeDetailArea & DetailArea )
{
    try
    {
        // Allocate a new detail area structure
        TreeDetailArea * pDetailArea = new TreeDetailArea;
        if ( !pDetailArea ) throw std::bad_alloc();

        // Copy over the data from that specified
        *pDetailArea = DetailArea;

        // Add to the area list
        m_DetailAreas.push_back( pDetailArea );

    } // End Try Block

    catch ( ... )
    {
        return false;

    } // End Catch Block

    // Success!
    return true;
}
```

This method should be called by the application for each detail area (AABB) it would like to register with the tree prior to tree compilation. These detail areas can be used to force the tree to partition space that contains no static polygon data or not partition space that contains much polygon data. We will understand exactly how this is achieved later when we look at the Build methods for the various derived classes.

Retrieving Data from the Tree - CBaseTree

There may be times after the build process has been completed (or pre-build with respect to the polygon and detail area lists) when an application would like to retrieve a list of all the polygons, leaves, and

detail areas being used by the entire tree. The following three methods are simple access functions which return the leaf list, polygon list, and the detail area list back to the caller.

```
CBaseTree::LeafList & CBaseTree::GetLeafList()
{
    return m_Leaves;
}
```

```
CBaseTree::PolygonList & CBaseTree::GetPolygonList()
{
    return m_Polygons;
}
```

```
CBaseTree::DetailAreaList & CBaseTree::GetDetailAreaList()
{
    return m_DetailAreas;
}
```

AddLeaf - CBaseTree

Our derived classes will need a way to add leaves to their arrays during the build process. When a terminal node is encountered and a new CBaseLeaf is allocated and attached to the terminal node, we will also want to store that leaf's pointer in the tree's leaf list. Since this functionality will be the same for each tree type we will implement, this method in CBaseTree will save us the trouble of reinventing the wheel in each of our derived classes. The code simply adds the passed leaf pointer to the tree's internal leaf list.

```
bool CBaseTree::AddLeaf( CBaseLeaf * pLeaf )
{
    try
    {
        // Add to the leaf list
        m_Leaves.push_back( pLeaf );

    } // End Try Block

    catch ( ... )
    {
        return false;

    } // End Catch Block

    // Success!
    return true;
}
```

PostBuild - CBaseTree

The PostBuild method of CBaseTree should be called by the derived class after the tree has been constructed. In our derived classes, we will call this function at the very bottom of their Build method. PostBuild first calls the CBaseTree::CalculatePolyBounds method (which we will discuss next) which loops through each polygon in the tree's polygon list and calculates and stores its AABB. It then calls the CBaseTree::BuildRenderData method which allows the CBaseTree to initialize the render system with the tree data that has just been constructed. Many of you used to working with MFC might recognize this type of relationship, as it is much like creating a window. In MFC, methods can be overridden that allow your application to perform some default processing either just before or just after the window has been created. In this case, we are letting the base tree know that the tree building process is complete so that it can be prepared for rendering. The code to the function is shown below.

```
bool CBaseTree::PostBuild( )
{
    // Calculate the polygon bounding boxes
    CalculatePolyBounds( );

    // Build the render data
    return BuildRenderData( );
}
```

The CalculatePolyBounds method will be discussed next but we will defer our discussion of the BuildRenderData method until the next lesson where we discuss the rendering system. If the application did not pass a 3D device pointer into the derived tree's class constructor, this function will simply return without doing anything. In this case, the tree's rendering functionality will not be available but it can still be queried by the collision system.

CalculatePolyBounds - CBaseTree

The CalculatePolyBounds function will be used by all of our derived tree types. It will particularly important for an efficient broad phase collision step. Rather than ask the tree to return a list of leaves that intersect the swept sphere's AABB and the send the polygons in those leaves immediately on to the narrow phase, we will introduce an intermediate broad phase step which will be cheap but very effective. After we have retrieved the leaves that the swept sphere intersects, we will test each polygon in those leaves against the swept sphere AABB using their respective bounding boxes. Only polygons whose bounding boxes intersect the bounding box of the swept sphere will need to be passed to the more expensive narrow phase. This is an inexpensive test that gives us a very impressive performance enhancement.

> **Note:** Performing the polygon bounding box test in our lab testing really did increase speed by an impressive amount. For example, on one of the levels we were testing with the collision system, even when using the tree to collect only the relevant leaves, but without performing the polygon bounding box tests, our frame rates fell to ~30fps when querying a particularly dense leaf (i.e., a leaf with many polygons in it). After adding the polygon bounding box test, many polygons were rejected and did not get sent to the narrow phase and our frame rate in that same leaf increased to a solid 560fps. That is

obviously quite a savings and well worth the small amount of additional memory the bounding boxes add to each polygon.

This method is called from the CBaseTree::PostBuild method, which itself is called from the Build function of the derived class after the tree has been fully constructed. The job of the function is straightforward enough; loop through each static polygon stored in the tree (the m_Polygons STL linked list) and compile a bounding box for each one.

The firsts section of the function (shown below) creates an STL list iterator (a PolygonList iterator) which it uses to step through the elements in the polygon list. For each polygon, it aliases its bounding box minimum and maximum extents vectors with local variables Min and Max (for ease of use) and then sets the bounding box of the polygon to initially bogus values.

```
void CBaseTree::CalculatePolyBounds( )
{
    ULONG                   i;
    CPolygon               *pCurrentPoly;
    PolygonList::iterator   Iterator;

    // Calculate polygon bounds
    for ( Iterator = m_Polygons.begin(); Iterator != m_Polygons.end(); ++Iterator )
    {
        // Get poly pointer and bounds references for easy access
        pCurrentPoly = *Iterator;
        if ( !pCurrentPoly ) continue;
        D3DXVECTOR3 & Min = pCurrentPoly->m_vecBoundsMin;
        D3DXVECTOR3 & Max = pCurrentPoly->m_vecBoundsMax;

        // Reset bounding box
        Min = D3DXVECTOR3( FLT_MAX, FLT_MAX, FLT_MAX );
        Max = D3DXVECTOR3( -FLT_MAX, -FLT_MAX, -FLT_MAX );
```

Since FLT_MAX contains the maximum number that we can store in a float, and we set the maximum extents vector initially to the minimum possible value and the minimum extents vector to the maximum possible values, we create an initial huge “inside-out” box.

In the next section of the loop we test the position of each vertex in the polygon to see if it is contained within the box we have currently compiled. If not, the box will be adjusted to contain the vertex (this will always be the case for the first vertex due to the initial starting values of the box).

```
        // Build polygon bounds
        for ( i = 0; i < pCurrentPoly->m_nVertexCount; ++i )
        {
            CVertex & vtx = pCurrentPoly->m_pVertex[i];
            if ( vtx.x < Min.x ) Min.x = vtx.x;
            if ( vtx.y < Min.y ) Min.y = vtx.y;
            if ( vtx.z < Min.z ) Min.z = vtx.z;
            if ( vtx.x > Max.x ) Max.x = vtx.x;
            if ( vtx.y > Max.y ) Max.y = vtx.y;
            if ( vtx.z > Max.z ) Max.z = vtx.z;

        } // Next Vertex
```

Finally, before moving on to process the next polygon in the list, we will grow the box by 0.1 units in each direction to create a small buffer around the polygon. The reason we do this is to provide us a safety buffer when performing floating point tests. If two boxes (the polygon box and swept sphere box) were next to each other such that they were exactly touching, we risk the polygon being rejected for the narrow phase due to floating point accumulation/rounding errors. We certainly want to make sure that we do not reject a polygon from the narrow phase that we may be colliding with or we might be allowed to pass straight through it. By growing the box just slightly, we make this a fuzzy test where their boxes would overlap and the polygon would definitely be included in the case just mentioned.

```
        // Increase bounds slightly to relieve this operation during
        // intersection testing
        Min.x -= 0.1f; Min.y -= 0.1f; Min.z -= 0.1f;
        Max.x += 0.1f; Max.y += 0.1f; Max.z += 0.1f;

    } // Next Bounds
}
```

When this function, returns every polygon in the tree will contain a world space bounding box that the collision system (or any external component) can use to further refine the number of polygons in a leaf that get passed to the narrow phase.

14.11.6 Utility Methods - CBaseTree

These last two methods are not used by the application or by any other function in CBaseTree. They exist to make your life easier should you choose to implement the DebugDraw method in your derived classes. It is purely optional that you implement this method since ISpatialTree provides a default implementation that does nothing. Therefore, the application can always call this method even if you have not implemented it and no harm will be done.

The DebugDraw method will be implemented in all our derived classes in a very similar way. As discussed earlier, it will traverse the tree searching for visible leaf nodes. When a leaf node is found, we will draw a bounding box around the area represented by the leaf. We will also tint the screen red if the camera is currently contained in a leaf that contains polygon data. Since most of the code is geared towards generating and rendering the bounding box and handling the screen tinting, we decided to add the two functions that perform these tasks to CBaseTree (DrawBoundingBox and DrawScreenTint) and avoid duplicating code unnecessarily.

DrawBoundingBox – CBaseTree

The CBaseTree::DrawBoundingBox method will be called by the DebugDraw method in each of our derived classes (assuming the scene is calling ISpatialTree::DebugDraw). It will be passed the world space bounding box (the minimum and maximum extent vectors) of the leaf and (as its third parameter) the color we would like to render the wireframe box. The fourth parameter is a boolean that will indicate whether we would like the box to be rendered using the depth buffer.

When our DebugDraw routines call this method for a visible leaf which the camera is not currently in, the box will be rendered normally with depth testing enabled. For the current camera leaf we will pass false as this parameter and render it to the screen without depth testing. This ensures that it will always be rendered on top of anything already in the frame buffer, making it easier to see the box for the leaf we are currently standing in without it being obscured by nearby geometry.

The function has two static members. The first is an array of 24 vertices that will define the four vertices of each face of the cube (6 faces * 4 vertices = 24). We will also use a static boolean called BoxBuilt to indicate whether we have already built the box in the previous call. Since these are static methods they will retain their values each time the function is called. We do this so that the box mesh is only ever built the first time the method is ever called. If this method has never been called before, then the static BoxBuilt will be set to false and code will be executed to generate the box vertices and add them to the static vertex array. The BoxBuilt boolean will then be set to true so that the next time the method is called it will know that the box mesh has already been constructed and we will not have to do it again. Since the box we wish to draw will be a wireframe box, the vertices in this array will describe a list of line primitives which will be rendered using the D3DPT_LINELIST primitive type. The line list mesh will be stored in the vertices array as a 1x1x1 cube and it will be transformed and scaled to the size and position of the current leaf node. Let us look at this function in a few sections.

In the first section of the function we can see that a local structure is defined to describe what a box vertex looks like. Basically, it contains a position and a color. We can also see that if the tree does not currently store a pointer to a 3D device, then this is not a tree that is intended to be rendered and we return.

```
void CBaseTree::DrawBoundingBox( const D3DXVECTOR3 & Min,
                                 const D3DXVECTOR3 & Max,
                                 ULONG Color,
                                 bool bZEnable /* = false */ )
{
    struct BoxVert
    {
        D3DXVECTOR3 Pos;
        ULONG       Color;
    };

    ULONG          i;
    static BoxVert Vertices[24];
    static bool    BoxBuilt = false;
    D3DXMATRIX     mtxBounds, mtxIdentity;
    D3DXVECTOR3    BoundsCenter, BoundsExtents;
    ULONG          OldStates[6];

    // If there is no device, we can't draw
    if ( !m_pD3DDevice ) return;
```

Next we create an identity matrix (which will be used in a moment) and if the BoxBuilt boolean is false, we fill in the elements of the static vertex array. Notice that we position the 24 vertices such that they describe the vertices of each face in a unit sized cube; a cube of 1 unit in size in each direction which is centered at (0, 0, 0). This means the cube vertices are in the -0.5 to +0.5 range along each axis. We can think of this cube at this point as being in model space.

```
    // We need an identity matrix later
    D3DXMatrixIdentity( &mtxIdentity );

    // Build the box vertices if we have not done so already
    if ( !BoxBuilt )
    {
        // Bottom 4 edges
        Vertices[0].Pos  = D3DXVECTOR3( -0.5f, -0.5f, -0.5f );
        Vertices[1].Pos  = D3DXVECTOR3(  0.5f, -0.5f, -0.5f );

        Vertices[2].Pos  = D3DXVECTOR3(  0.5f, -0.5f, -0.5f );
        Vertices[3].Pos  = D3DXVECTOR3(  0.5f, -0.5f,  0.5f );

        Vertices[4].Pos  = D3DXVECTOR3(  0.5f, -0.5f,  0.5f );
        Vertices[5].Pos  = D3DXVECTOR3( -0.5f, -0.5f,  0.5f );

        Vertices[6].Pos  = D3DXVECTOR3( -0.5f, -0.5f,  0.5f );
        Vertices[7].Pos  = D3DXVECTOR3( -0.5f, -0.5f, -0.5f );

        // Top 4 edges
        Vertices[8].Pos  = D3DXVECTOR3( -0.5f,  0.5f, -0.5f );
        Vertices[9].Pos  = D3DXVECTOR3(  0.5f,  0.5f, -0.5f );

        Vertices[10].Pos = D3DXVECTOR3(  0.5f,  0.5f, -0.5f );
        Vertices[11].Pos = D3DXVECTOR3(  0.5f,  0.5f,  0.5f );

        Vertices[12].Pos = D3DXVECTOR3(  0.5f,  0.5f,  0.5f );
        Vertices[13].Pos = D3DXVECTOR3( -0.5f,  0.5f,  0.5f );

        Vertices[14].Pos = D3DXVECTOR3( -0.5f,  0.5f,  0.5f );
        Vertices[15].Pos = D3DXVECTOR3( -0.5f,  0.5f, -0.5f );

        // 4 Side 'Struts'
        Vertices[16].Pos = D3DXVECTOR3( -0.5f, -0.5f, -0.5f );
        Vertices[17].Pos = D3DXVECTOR3( -0.5f,  0.5f, -0.5f );

        Vertices[18].Pos = D3DXVECTOR3(  0.5f, -0.5f, -0.5f );
        Vertices[19].Pos = D3DXVECTOR3(  0.5f,  0.5f, -0.5f );

        Vertices[20].Pos = D3DXVECTOR3(  0.5f, -0.5f,  0.5f );
        Vertices[21].Pos = D3DXVECTOR3(  0.5f,  0.5f,  0.5f );

        Vertices[22].Pos = D3DXVECTOR3( -0.5f, -0.5f,  0.5f );
        Vertices[23].Pos = D3DXVECTOR3( -0.5f,  0.5f,  0.5f );

        // We're done
        BoxBuilt = true;

    } // End if box has not yet been built
```

At this point all 24 model space box vertices have been placed in the vertex array and the BoxBuilt boolean will be set to true. Thus, the above code will not be performed the next time this function is called to render another leaf box.

In the next section we loop through each of the 24 vertices and set their color value to the color parameter passed by the caller (the DebugDraw method of the derived class).

```
    // Set the color to that specified.
    for ( i = 0; i < 24; ++i ) Vertices[i].Color = Color;
```

In the next section we need to create a matrix that, when set on the device as a world matrix, will transform and scale the model space vertices such that the box is transformed into a box that is equal in size to the passed box vectors (the leaf's bounding box) and positioned in the world such that its center point is at the center point of the leaf.

First we need to find the world space center point of the leaf bounding box, which we can calculate by adding the leaf's world space minimum and maximum box vector and dividing the result by 2. We then calculate the size of the box (the diagonal size of the leaf's bounding box) by subtracting the minimum extent vector from the maximum vector.

```
    // Compute the bound's centre point and extents
    BoundsCenter  = (Min + Max) / 2.0f;
    BoundsExtents = Max - Min;
```

At this point BoundsExtents contains the diagonal length of the leaf bounding box. Since our box mesh is defined to be a 1x1x1 unit square (0.5 units in each dimension), if we store the BoundsExtents in the diagonal of a matrix, we will have a scaling matrix that will transform the vertices of the box mesh so that it becomes the same size as the leaf box in world space.

For example, let us imagine that the world space leaf bounding box extents are the two vectors (50, 50, 50) and (60, 60, 60). In this case, BoundsExtents will be:

$$(60, 60, 60) - (50, 50, 50) = (10, 10, 10)$$

If we store the x, y, and z components of the resulting vector in the diagonal of a matrix, we will get a matrix which will scale any x, y, and z vertex components by 10. Since the box is defined in the -0.5 to 0.5 range along each axis, we can see that when the box vertices are multiplied by this scaling matrix, it will result in vertices in the -0.5*10=-5 to 0.5*10=5 range (i.e., a box in the range of [-5, 5] along each axis). This is exactly as it should be as it matches the size of the leaf bounding box. All we have to do now is place the world space position vector of the center of the leaf (BoundsCenter) in the translation row of the matrix and we will have a world matrix that will properly scale and position the model space box mesh to match the leaf.

```
    // Build the scaling matrix
    D3DXMatrixScaling( &mtxBounds,
                       BoundsExtents.x,
                       BoundsExtents.y,
                       BoundsExtents.z );

    // Translate the bounding box matrix
    mtxBounds._41 = BoundsCenter.x;
    mtxBounds._42 = BoundsCenter.y;
    mtxBounds._43 = BoundsCenter.z;
```

```
    // Set the bounding box matrix
    m_pD3DDevice->SetTransform( D3DTS_WORLD, &mtxBounds );
```

At this point we have the world matrix set on the device and we are almost ready to render, but first we will need to set some render states. We will start by disabling Z buffer writing (we do not want our box lines to obscure real geometry) and enable or disable depth testing based on the boolean parameter passed in. We will also want to disable lighting (our lines are constructed from pre-colored vertices) and set the first texture/color stage so that only the diffuse color of the vertex is used. Of course, we had better retrieve and backup the current state settings because we would not want to change something that will cause the rest of the application to render incorrectly. So we will retrieve the current states that we intend to change and store them in a local states array (OldStates) as shown below.

```
    // Retrieve old states
    m_pD3DDevice->GetRenderState( D3DRS_ZWRITEENABLE, &OldStates[0] );
    m_pD3DDevice->GetRenderState( D3DRS_ZENABLE, &OldStates[1] );
    m_pD3DDevice->GetRenderState( D3DRS_LIGHTING, &OldStates[2] );
    m_pD3DDevice->GetRenderState( D3DRS_COLORVERTEX, &OldStates[3] );
    m_pD3DDevice->GetTextureStageState( 0, D3DTSS_COLORARG1, &OldStates[4] );
    m_pD3DDevice->GetTextureStageState( 0, D3DTSS_COLOROP, &OldStates[5] );
```

With the current states currently backed up we will setup the render states we wish to use to render our box edges.

```
    // Setup new states
    m_pD3DDevice->SetRenderState( D3DRS_ZWRITEENABLE, FALSE );
    m_pD3DDevice->SetRenderState( D3DRS_ZENABLE, bZEnable );
    m_pD3DDevice->SetRenderState( D3DRS_LIGHTING, FALSE );
    m_pD3DDevice->SetRenderState( D3DRS_COLORVERTEX, TRUE );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_COLORARG1, D3DTA_DIFFUSE );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_COLOROP, D3DTOP_SELECTARG1 );
```

With the pipeline now configured, we set the FVF of our box vertices and render. Since our box vertices contain positional information and a diffuse color we will inform the pipeline by using the D3DFVF_XYZ | D3DFVF_DIFFUSE flag combination. We will then render the vertices straight from the box vertex array using the DrawPrimitiveUP function. UP stands for ‘User Pointer’ and it allows us to render straight from system memory without having to store the vertices in vertex buffers. This is a highly inefficient way to render primitives, but it is acceptable in this case since it is only a debug routine and it makes the implementation a lot easier.

```
    // Draw
    m_pD3DDevice->SetFVF( D3DFVF_XYZ | D3DFVF_DIFFUSE );
    m_pD3DDevice->DrawPrimitiveUP( D3DPT_LINELIST, 12, &Vertices, sizeof(BoxVert));
```

As you can see in the above code, we ask DrawPrimitiveUP to draw 12 lines, where each line consists of two vertices (start and end points). Thus the vertex array we pass in as the third parameter must contain at least 12*2=24 vertices, which we know ours does. The fourth parameter is the stride of the vertex structure we are using so the pipeline knows how many bytes to advance when stepping from vertex to vertex during the transformation process.

With all lines rendered for the currently passed leaf node, we restore the render states we backed up earlier and reset the world matrix to identity.

```
    // Reset old states
    m_pD3DDevice->SetRenderState( D3DRS_ZWRITEENABLE, OldStates[0] );
    m_pD3DDevice->SetRenderState( D3DRS_ZENABLE, OldStates[1] );
    m_pD3DDevice->SetRenderState( D3DRS_LIGHTING, OldStates[2] );
    m_pD3DDevice->SetRenderState( D3DRS_COLORVERTEX, OldStates[3] );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_COLORARG1, OldStates[4] );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_COLOROP, OldStates[5] );

    // Reset the matrix
    m_pD3DDevice->SetTransform( D3DTS_WORLD, &mtxIdentity );
}
```

DrawScreenTint – CBaseTree

This is utility function tints the screen a red color when the camera is positioned inside a populated leaf node. It accepts one parameter: a DWORD containing the color to tint the screen.

This technique should be familiar to you since we did the same thing in Chapter 7 of Module I when we implemented our underwater effect. We just create four transformed and lit vertices (screen space vertices with diffuse color components) and position them at the four corners of the viewport. We then render the quad to the screen with alpha blending enabled (and with the depth buffer disabled so that it is definitely rendered on top of everything else) to blend the color of the quad over the entire scene stored in the frame buffer..

The first part of the function is shown below. Note that we define a vertex structure (TintVert) which is laid out as a transformed and lit vertex. We know that when we pass a pre-transformed (viewport space) vertex to the pipeline, its positional vector is 4D, not 3D. The first two positional components of the vertex (x and y) describe the position on the viewport where the vertex is positioned. The third component (z) contains the depth buffer value in the range of 0.0 to 1.0. Since we are going to disable depth testing and writing when we render this quad, we will just set this to zero. The fourth positional component is called RHW by DirectX and should contain the reciprocal of homogenous W (i.e., 1 divided by the viewspace vertex Z component). This is all designed to work if you are performing your own transformation of geometry and merely wish DirectX to render the screen space polygons. 1/W gets closer to 1 the closer to the near plane the vertex is. It describes the depth of the vertex with respect to the camera. Recall that this value is used during rendering by the DirectX fog engine. However, we just wish to draw a quad on the screen without fog, so we will just set this to 1 which simulates a vertex very close to the near plane. However, since we are not using fog and the depth buffer is disabled, we could actually this value to anything without any ill effect.

```
void CBaseTree::DrawScreenTint( ULONG Color )
{
    struct TintVert
    {
        D3DXVECTOR4 Pos;
        ULONG       Color;
```

```
    };

    ULONG        i;
    TintVert     Vertices[4];
    ULONG        OldStates[10];
    D3DVIEWPORT9 Viewport;

    // If there is no device, we can't draw
    if ( !m_pD3DDevice ) return;

    // Retrieve the viewport dimensions
    m_pD3DDevice->GetViewport( &Viewport );

    // 4 Screen corners
    Vertices[0].Pos=D3DXVECTOR4((float)Viewport.X, (float)Viewport.Y, 0.0, 1.0f );

    Vertices[1].Pos=D3DXVECTOR4((float)Viewport.X + Viewport.Width,
                                (float)Viewport.Y, 0.0, 1.0f );

    Vertices[2].Pos  = D3DXVECTOR4( (float)Viewport.X + Viewport.Width,
                                    (float)Viewport.Y + Viewport.Height,
                                    0.0, 1.0f );

    Vertices[3].Pos  = D3DXVECTOR4( (float)Viewport.X,
                                    (float)Viewport.Y + Viewport.Height,
                                    0.0, 1.0f );

    // Set the color to that specified.
    for ( i = 0; i < 4; ++i ) Vertices[i].Color = Color;
```

The above code shows how we fetch the device viewport and retrieve the viewport rectangle. We will use this rectangle to position the vertices of our quad in the frame buffer. As you can see, the four vertices are positioned at the top left, top right, bottom right, and bottom left of the viewport. The z component of each vertex is set to 0.0 and the RHW component is set to 1.0. We then loop through each of the vertices and set its color properties to the color value passed into the function.

Next we will backup and set the render states and texture states we wish to use to render our screen effect. We will disable Z writing and testing, disable lighting, and enable alpha blending. We will set the source and destination color blending results to use the alpha component of the passed color to weight the blending between the color of the quad and the color already in the frame buffer. This means we need to set the source and destination blend render states to D3DBLEND_SRCALPHA and D3DBLEND_INVSRCALPHA and configure texture stage zero to take its alpha and color components from the diffuse vertex color. This will generate a final color for each pixel at the end of the texture stage cascade which has color and alpha components equal to the diffuse and alpha components of the passed color, respectively. We then pass this to the renderer where the alpha component will be used as the weighting factor with the blending modes we have configured.

Below we see the code that makes a backup of all the states we intend to change, sets all the new states, renders the quad, and then restores the original device states.

```
    // Retrieve old states
    m_pD3DDevice->GetRenderState( D3DRS_ZWRITEENABLE, &OldStates[0] );
    m_pD3DDevice->GetRenderState( D3DRS_ZENABLE, &OldStates[1] );
    m_pD3DDevice->GetRenderState( D3DRS_LIGHTING, &OldStates[2] );
    m_pD3DDevice->GetRenderState( D3DRS_COLORVERTEX, &OldStates[3] );
    m_pD3DDevice->GetRenderState( D3DRS_ALPHABLENDENABLE, &OldStates[4] );
    m_pD3DDevice->GetRenderState( D3DRS_ALPHATESTENABLE, &OldStates[5] );
    m_pD3DDevice->GetTextureStageState( 0, D3DTSS_COLORARG1, &OldStates[6] );
    m_pD3DDevice->GetTextureStageState( 0, D3DTSS_COLOROP, &OldStates[7] );
    m_pD3DDevice->GetTextureStageState( 0, D3DTSS_ALPHAARG1, &OldStates[8] );
    m_pD3DDevice->GetTextureStageState( 0, D3DTSS_ALPHAOP, &OldStates[9] );

    // Setup new states
    m_pD3DDevice->SetRenderState( D3DRS_ZWRITEENABLE, FALSE );
    m_pD3DDevice->SetRenderState( D3DRS_ZENABLE, FALSE );
    m_pD3DDevice->SetRenderState( D3DRS_LIGHTING, FALSE );
    m_pD3DDevice->SetRenderState( D3DRS_COLORVERTEX, TRUE );
    m_pD3DDevice->SetRenderState( D3DRS_ALPHABLENDENABLE, TRUE );
    m_pD3DDevice->SetRenderState( D3DRS_ALPHATESTENABLE, FALSE );
    m_pD3DDevice->SetRenderState( D3DRS_SRCBLEND, D3DBLEND_SRCALPHA );
    m_pD3DDevice->SetRenderState( D3DRS_DESTBLEND, D3DBLEND_INVSRCALPHA );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_COLORARG1, D3DTA_DIFFUSE );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_COLOROP, D3DTOP_SELECTARG1 );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_ALPHAARG1, D3DTA_DIFFUSE );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_ALPHAOP, D3DTOP_SELECTARG1 );

    // Draw
    m_pD3DDevice->SetFVF( D3DFVF_XYZRHW | D3DFVF_DIFFUSE );
    m_pD3DDevice->DrawPrimitiveUP(  D3DPT_TRIANGLEFAN,
                                    2,
                                    &Vertices,
                                    sizeof(TintVert) );

    // Reset old states
    m_pD3DDevice->SetRenderState( D3DRS_ZWRITEENABLE, OldStates[0] );
    m_pD3DDevice->SetRenderState( D3DRS_ZENABLE, OldStates[1] );
    m_pD3DDevice->SetRenderState( D3DRS_LIGHTING, OldStates[2] );
    m_pD3DDevice->SetRenderState( D3DRS_COLORVERTEX, OldStates[3] );
    m_pD3DDevice->SetRenderState( D3DRS_ALPHABLENDENABLE, OldStates[4] );
    m_pD3DDevice->SetRenderState( D3DRS_ALPHATESTENABLE, OldStates[5] );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_COLORARG1, OldStates[6] );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_COLOROP, OldStates[7] );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_ALPHAARG1, OldStates[8] );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_ALPHAOP, OldStates[9] );
}
```

We have now covered all the house keeping and utility building code from CBaseTree that needs to be covered in this lesson. The one exception is the Repair method that performs T-junction repair, but we will come back to that a little later in this lesson and devote an entire section to it. In the next chapter we will add a rendering system to this class, but for now we have everything we need in place to create our derived tree classes and use them to perform efficient collision queries.

Before we discuss T-junction repair and move on to look at the implementations of each of the derived classes, we will need to extend our CCollision library with a few more intersection routines that will be

used by the tree building and query functions in the derived classes. For example, we will need to be able to determine when a point is inside an AABB, when two AABBs are intersecting, and when a ray intersects an AABB. We will discuss the implementations of these functions next, and we will make them static members of the CCollision class so that they can be used even if the collision system is not being used.

14.12 Point/AABB Intersection

One of the simplest collision tests we can perform is determining whether a point is inside an AABB. Such a method is used to find out if a certain position is contained inside a leaf node's bounds, as one obvious example. Our DebugDraw routines will use this intersection test to determine whether the leaf currently being visited contains the camera position. If it does, then it renders the bounding box of the leaf a different color.

The test is easy and cheap to perform and involves nothing more than separately testing the x, y, and z components of the passed position vector to see if they fall between the minimum and maximum x, y and z extents of the AABB. If any component of the position vector is outside the range of its corresponding components in the AABB extent vectors, the point is not contained and we return false. That is, the test is essentially stating "If the x component of the point is between the minimum x extent and the maximum x extent of the box, we have passed the X axis test and the two other axes must be tested, etc."

The code to PointInAABB is just a few lines long. The function only returns true if none of the three axis tests fail.

```
bool CCollision::PointInAABB( const D3DXVECTOR3& Point,
                              const D3DXVECTOR3& Min,
                              const D3DXVECTOR3& Max,
                              bool bIgnoreX /* = false */,
                              bool bIgnoreY /* = false */,
                              bool bIgnoreZ /* = false */ )
{
    // Does the point fall outside any of the AABB planes?
    if ( !bIgnoreX && (Point.x < Min.x || Point.x > Max.x) ) return false;
    if ( !bIgnoreY && (Point.y < Min.y || Point.y > Max.y) ) return false;
    if ( !bIgnoreZ && (Point.z < Min.z || Point.z > Max.z) ) return false;

    // We are behind all planes
    return true;
}
```

Notice how this method not only accepts the point and the two AABB extents as parameters, it also accepts three booleans allowing us to instruct the function to ignore tests along any axes. For example, if we pass in true for the bIgnoreY parameter, the Y component of the point will not be tested against the Y components of the AABB extents (i.e., the function will behave as if the Y axis test has not failed and that the point always falls within the box with respect to the Y axis).

It is quite useful to have the ability to ignore certain components in the test. Indeed, you will see that this is a feature we provide in all of our AABB intersection tests. It is particularly handy when performing a collision query on a quad-tree. As discussed earlier, the vanilla quad-tree will always have leaf nodes of the same height (the max vertical range of the entire level). However, we also discussed (and will implement) the Y-variant quad-tree, where the vertical extents of each node fit the contained geometry. This can produce certain problems when querying the tree since there may be times when a given position is contained inside no leaf node. This is actually true of any tree type but is more easily demonstrated with the Y-variant tree.

For example, Figure 14.53 shows a terrain compiled into a Y-variant quad-tree. We also see a space ship hovering above the terrain.

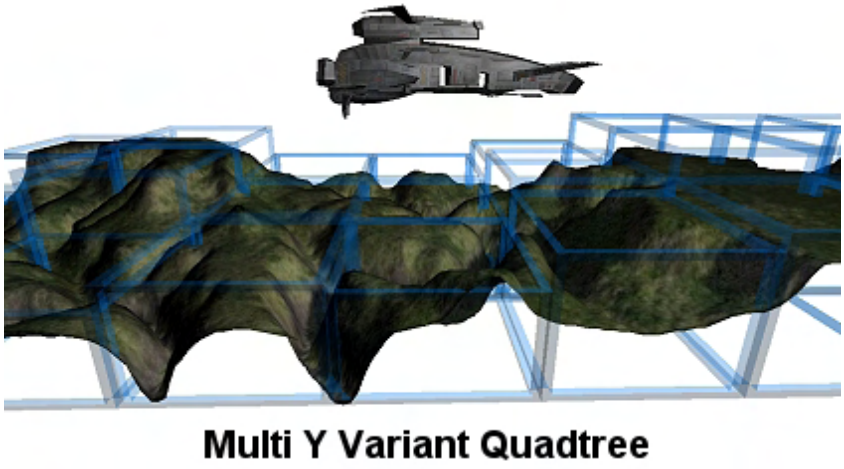

Figure 14.53

Imagine that our space ship has a spotlight mounted on the bottom of its hull, such that it illuminates the terrain immediately below it. In order to find the terrain polygons we need to illuminate, we would normally send the bounding box of the space ship down the tree and collect all the leaves it intersects. We can then fetch the polygons from those leaves and perform some custom lighting effect. However, in this case we can see that if we were to feed the bounding box of the ship into the tree, no leaves would be returned because it is not contained in any of the leaves. But, if we did the same test and ignored the Y component in each leaf (only testing the X and Z extents of the box), then the leaves beneath the ship would be returned even though the ship is not technically contained within their volume.

14.13 AABB/AABB Intersection

Another collision query that we will need to use quite a bit in our applications determines whether two AABBs intersect. This collision routine will be the heart of the CollectLeavesAABB method in our derived classes, which essentially traverses the tree with the passed query volumes and finds which leaves the passed bounding box intersects. At each leaf we will perform an AABB/AABB test and only add the leaf to the output list if there is an intersection and the collision function returns true.

Much like the PointInAABB test described above, the AABBIntersectAABB intersect function performs its tests on a per axis basis. If at any point we find an axis on which an overlap does not occur, the boxes do not overlap and the function can return false immediately. If there is overlap on each of the three axes, then the bounding boxes intersect one another and we return true. The test for an overlap on a given axis is very simple when dealing with AABBs as Figure 14.54 shows.

Figure 14.54

Figure 14.54 shows the X axis overlap test for two boxes that do indeed overlap. Since we are dealing with one axis at a time, the two boxes can be treated component-wise as lines on those axes. If Min1 and Max1 are the extent vectors of the first box and Min2 and Max2 are the extent vectors of the second box, we can see that if Min1.x is smaller than Max2.X and Max1.x is larger than Min2.x, then the boxes overlap on that axis. You should be able to imagine that if we were to move the blue line to the left so that they no longer overlapped, min2.x would no longer be smaller than Max1.x and the test would fail. That is, we would not have an overlap on the X axis which means the boxes cannot possibly be intersecting one another. When this is the case we can return false immediately without performing any other axis overlap tests.

The code is shown below. Note that it also supports the axis ignore functionality discussed in the previous function. If we choose to ignore any axis, then those axes are assumed to be overlapping.

```
bool CCollision::AABBIntersectAABB( const D3DXVECTOR3& Min1,
                                    const D3DXVECTOR3& Max1,
                                    const D3DXVECTOR3& Min2,
                                    const D3DXVECTOR3& Max2,
                                    bool bIgnoreX /* = false */,
                                    bool bIgnoreY /* = false */,
                                    bool bIgnoreZ /* = false */ )
{
    return (bIgnoreX || Min1.x <= Max2.x) && (bIgnoreY || Min1.y <= Max2.y) &&
           (bIgnoreZ || Min1.z <= Max2.z) && (bIgnoreX || Max1.x >= Min2.x) &&
           (bIgnoreY || Max1.y >= Min2.y) && (bIgnoreZ || Max1.z >= Min2.z);
}
```

The parameter list to the function includes the minimum and maximum extent vectors of the first AABB to test followed by the minimum and maximum extent vectors of the second AABB to test. Following this are three optional axis ignore booleans allowing us to ignore any of the axes during the test.

We have decided to also provide an overloaded version of this function that accepts a boolean reference as its first parameter that can be used to communicate back to the caller whether or not box 2 was completely contained inside box 1. This makes the test slower since it has to perform the containment test first, followed by the intersection test described above. However, there are times when dealing with

hierarchy traversal that this can prevent many future AABB/AABB intersection tests from needing to be performed.

For example, imagine that our application called the CollectLeavesAABB function for one of our derived tree classes. We know this function has the task of stepping through the tree and at each node testing for an intersection between the passed AABB and the AABB of the node/leaf. If the query AABB does not intersect a node's AABB then we do not have to bother traversing into any of its children, allowing us to reject portions of the tree from having to be testing and collected. However, if the query volume does intersect the node volume, we will want to step into its children. Whenever a leaf node is reached, we add its leaf structure to a list that can be passed back to the caller. However, with this new overloaded version of the function we can perform a optimization to our CollectLeavesAABB routine. If we know that the bounding box of a node is completely contained inside the query volume, then we already know that all of its child nodes (including the leaf nodes) will be contained in it also. Thus, we do not need to perform any further AABB intersection tests on any of its child nodes. Instead we can just traverse into its children searching for leaf nodes which, once found, are immediately added to the leaf list that will be returned.

The overloaded function is shown below with the containment tests performed at the beginning of the function. The passed bContained boolean is initially set to true, meaning that box 2 is fully contained in box 1 and each of the containment tests tries to find proof that box 2 pierces the bounds of box 1 and is therefore not fully contained. This is once again done of a per axis basis, so for example, when testing the X axis for containment, but we are essentially just trying to prove that either the minimum extents of box 2 are smaller then the minimum extents of box 1 or that the maximum extents of box 2 are larger than the maximum extents of box 1. If this is true for any axis, then box 2 is not contained in box1 and the containment boolean is set to false. When this is the case, we must perform the intersection test described above to test if the boxes even intersect. The intersection test at the end of the function only has to be performed if the containment test failed. As soon as we have proof that box 2 is contained in box 1 we can return true for intersection with the bContainment boolean set to true.

```
bool CCollision::AABBIntersectAABB( bool & bContained,
                                    const D3DXVECTOR3& Min1,
                                    const D3DXVECTOR3& Max1,
                                    const D3DXVECTOR3& Min2,
                                    const D3DXVECTOR3& Max2,
                                    bool bIgnoreX /* = false */,
                                    bool bIgnoreY /* = false */,
                                    bool bIgnoreZ /* = false */ )
{
    // Set to true by default
    bContained = true;

    // Is box contained totally inside
    if ( !bIgnoreX && (Min2.x < Min1.x || Min2.x > Max1.x) ) bContained = false;
    else
    if ( !bIgnoreY && (Min2.y < Min1.y || Min2.y > Max1.y) ) bContained = false;
    else
    if ( !bIgnoreZ && (Min2.z < Min1.z || Min2.z > Max1.z) ) bContained = false;
    else
    if ( !bIgnoreX && (Max2.x < Min1.x || Max2.x > Max1.x) ) bContained = false;
    else
    if ( !bIgnoreY && (Max2.y < Min1.y || Max2.y > Max1.y) ) bContained = false;
```

```
    else
    if ( !bIgnoreZ && (Max2.z < Min1.z || Max2.z > Max1.z) ) bContained = false;

    // Return immediately if it's fully contained
    if ( bContained == true ) return true;

    // Perform full intersection test
    return (bIgnoreX || Min1.x <= Max2.x) && (bIgnoreY || Min1.y <= Max2.y) &&
           (bIgnoreZ || Min1.z <= Max2.z) && (bIgnoreX || Max1.x >= Min2.x) &&
           (bIgnoreY || Max1.y >= Min2.y) && (bIgnoreZ || Max1.z >= Min2.z);
}
```

14.14 Ray/AABB Intersection

We have talked a lot about the usefulness of being able to send a ray through the tree and get back a list of intersecting leaves. One example of where such a technique will be used is in Module III when we will write a lightmap compiler. Beams of light emanating from a light source will be modelled as rays and we will need to determine as quickly as possible whether any polygons in the scene block that ray. As our scenes will likely involve of tens of thousands of polygons or more, we will be performing literally millions of these tests. To make sure that our lightmap compiler will compile its texture data as quickly as possible, the scene will first be compiled into a spatial tree so that we can query the scene efficiently by performing the ray query on the tree. There are plenty of other examples, but this should give you further indication that spatial partitioning will be an important tool in many areas.

When examining the ISpatialTree interface we saw that our derived tree classes will be expected to implement a method called CollectLeavesRay. This method will be passed a ray and will traverse the tree testing which leaves the ray intersects. These leaves will then be returned so that the calling application can access the polygon data. In the lightmap compiler discussed above, the leaves returned will contain the polygons that have the potential to block the ray. This handful of polygons can then be tested more closely using ray/polygon intersection tests.

The heart of the CollectLeavesRay function (at least for the derived classes we implement) will be the testing of a ray to see if it intersects the bounding box of a given node. If the ray does intersect a node then we have to traverse into its children and continue testing. If it does not, then we can abandon that branch of the tree and all the leaf data it contains. Whenever we enter a leaf node, the leaf object will be added to a list that will be returned to the caller. Thus, the function will return to the application a list of the leaves the ray intersected. It is clear then that we must learn how to test for an intersection between a ray and an axis aligned bounding box.

14.14.1 The Slabs Method

We will be using the slabs method for intersection testing since it will works for both axis aligned bounding boxes and oriented bounding boxes. Our implementation of this method however will be optimized to take advantage of the fact that we will only be using it for AABB testing. As such, our

function is to be used only for the testing of AABBs. Although we will be implementing a faster AABB only method, the intersection theory we discuss here should make it a fairly simple matter for you to implement a version of the function that works with OBBs as well.

The slabs method works by calculating the intersection between the ray and each set of parallel planes described by the cube faces. A slab is therefore a pair of faces that are parallel to one another. If we think of an axis aligned bounding box, it would be comprised of three slabs. The first slab might be the pair of planes described by the front and back face of the cube, whose normals are aligned to the coordinate system Z axis. The second slab might be the planes of the right and left faces whose normals are aligned with the coordinate system X axis. The third slab would be comprised of the planes of the top and bottom faces whose normals are aligned with the Y axis of the coordinate system.

The test can easily be converted to two dimensions just by dropping tests against the slab whose planes are aligned with the coordinate system Z axis. To make visualizing the slabs method a little easier, we will discuss the two dimensional case in our images. The only difference is that in the three dimensional case, we are testing three slabs instead of two.

Figure 14.55 shows the minimum and maximum extent vectors of an AABB which describe the bottom left and top right corners of a 2D axis aligned bounding box. It also shows the ray that we would like to test for intersection against the bounding box. As can be clearly seen, the ray does intersect the box; we just need some way of determining this.

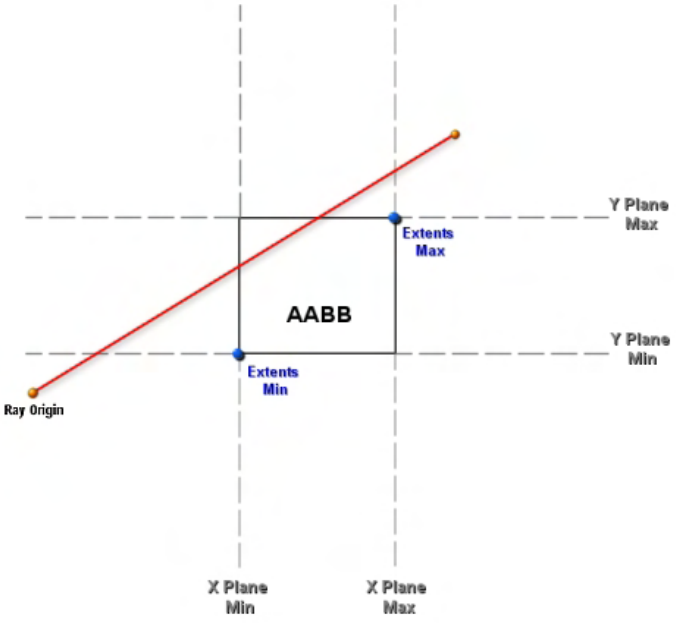

Figure 14.55

We can see that the point at the bottom left corner of the AABB (Extents Min) describes a point that is on the plane of the left face of the box. This is a plane whose normal is aligned with the coordinate system X axis. The top right corner of the box (Extents Max) describes a point that is on the same plane as the right face of the box and whose normal is also aligned to the coordinate system X axis. These two planes are parallel to one another and share the same normal, and as such, comprise a slab. This is the slab for the X axis and it contains the planes labelled ‘X Plane Min’ and ‘X Plane Max’. They are assigned the min and max names based on their distance to the ray origin; that is, based on the time of intersection between the ray and that plane. X Plane Min for example will intersect the ray closer to the ray origin, so it is called the minimum plane of the slab. We can see that a slab bounds the AABB along one axis. In this case we are describing the X slab which bounds the AABB on its left and right sides. The reason why this is important will become clear in a moment.

If we look at the same diagram (Figure 14.55) we can see that the same two extent vectors of the AABB also describe points that are on two planes aligned with the coordinate system Y axis, and thus describe

the Y slab that bounds the box on its top and bottom sides. Thus, Extents Min is also on the Y Plane Min plane and Extents Max is also on the Y Plane Max plane. Therefore, these two extents vectors actually describe four planes and two slabs. The planes of the Y slabs would each have normals aligned with the coordinate system Y axis and are once again labelled using min and max based on their distance from ray origin (the *t* value at which the ray would intersect them).

This means that we have all the information we need to define each plane in each of the slabs. We know the plane normals used by each slab since they will be aligned with the coordinate system axis. That is, one slab will have normals <1,0,0> and the other will have planes with normals <0,1,0>. In the 3D case there will be a third slab consisting of two planes with the normal <0,0,1>. Of course, we know that a normal is not enough to describe a plane since there are an infinite number of planes that share the same normal but are positioned at different distances from the origin. However, we have the points that are on each of the four planes (the two extent vectors) so we have everything we need to test the ray for intersection against each of these four planes.

The test is very simple. For each slab, we perform an intersection test between the ray and each of the planes comprising that slab. This will return us two *t* values of intersection. For example, we might process the X slab first, which would mean performing two ray/plane intersection tests between the ray and each plane in the slab (X Plane Min and X Plane Max). Once we get back these *t* values, we store them in two variables called Min and Max, sorted by value. As we test each slab and retrieve the minimum and maximum *t* values (for each plane) we compare them against two values that are keeping a record of the highest minimum *t* value and the lowest maximum *t* values found so far. If the minimum *t* value we have just calculated for the current slab is higher than the highest minimum *t* value we have found for a previous slab, we overwrite it with the new *t* value. Likewise, if the maximum *t* value for the current slab is lower than the lowest maximum *t* value we have recorded from all previously tested slabs, we overwrite the value with this new lowest maximum *t* value.

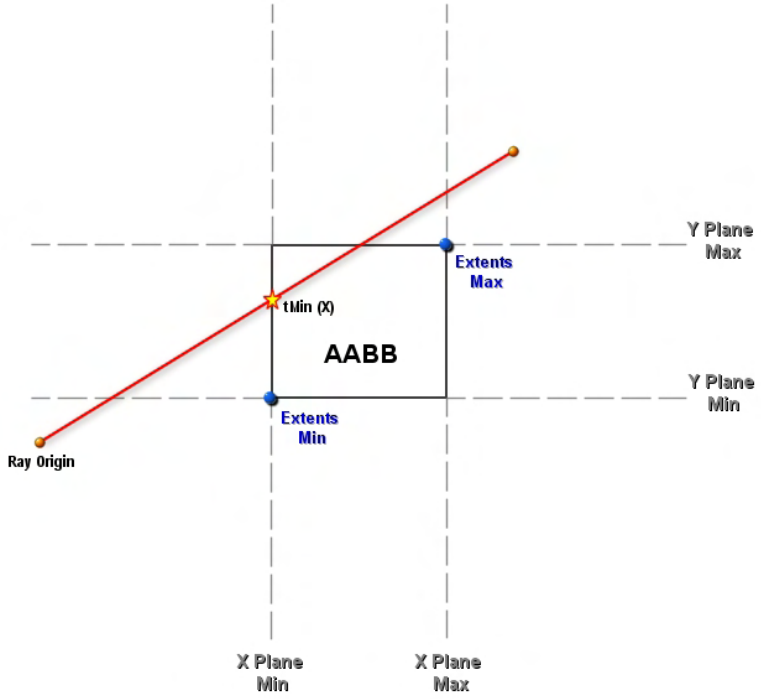

Figure 14.56

After all slabs have been evaluated, we will have two variables that contain the lowest maximum *t* value and the highest minimum *t* value we have found. If the highest minimum *t* value is larger than the lowest maximum *t* value then the ray does not intersect the box.

That might sound a little complicated, so let us have a look at an example that shows us computing the *t* values for each slab, one step at a time. In this first example, the ray does intersect the box, so the highest minimum *t* value we find for all the slabs must be lower than the lowest maximum *t* value we found from any slab according to the statement we just made a moment ago.

Let us step through the process of calculating the *t* values for the X slab first.

In Figure 14.56 we start with the X slab and calculate the *t* value of intersection between the ray and the plane that contains the minimum extents vector with a normal aligned to the coordinate system X axis (X Plane Min). The *t* value returned is shown on the diagram as tMin(x). This is the point at which the ray intersects the first plane of the X slab. Although we have already called this the minimum plane, we do not always know that this is the case. If the ray was intersecting the box from the right hand side instead, the second plane in the slab (X Plane Max) would be the first (minimum) plane of intersection.

Next we calculate the *t* value for the other plane of the slab (see Figure 14.57). This is the plane that contains the point ExtentsMax and shares the same normal (1,0,0).

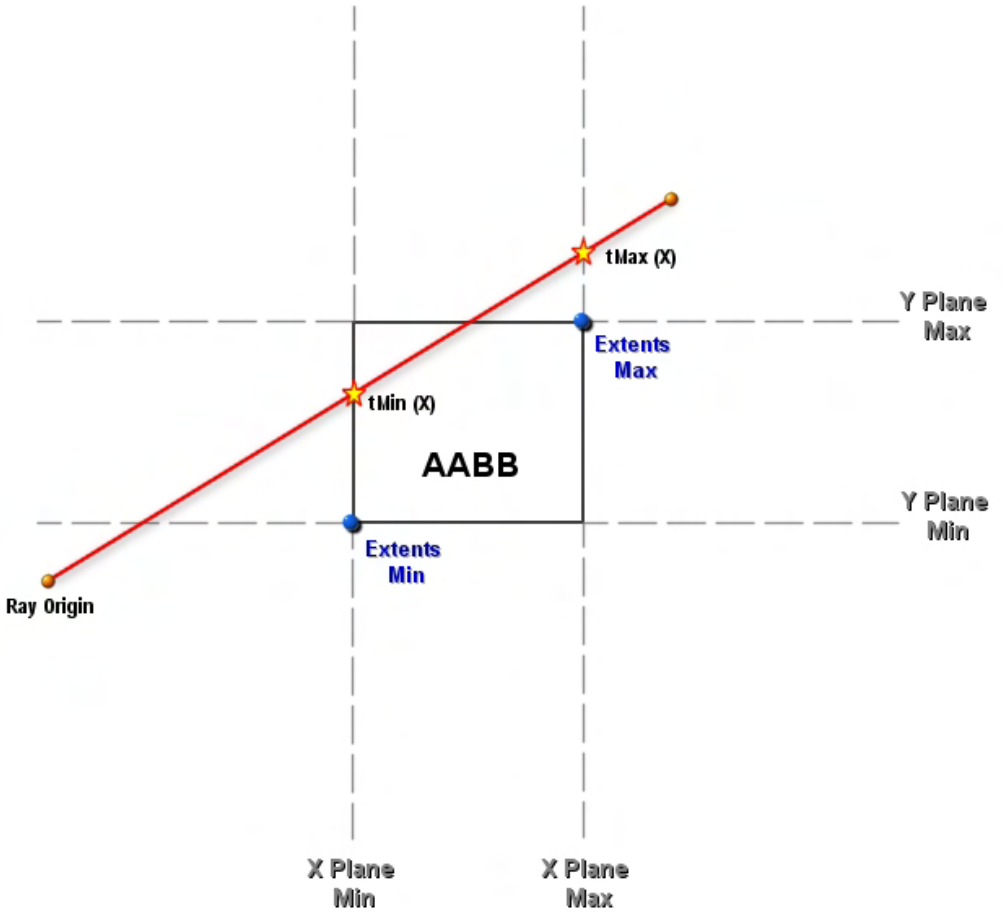

Figure 14.57

At this point we have the two *t* values for this slab, so we test which is greater and store them in the temporary variables tMin(x) and tMax(x). That is, we store in tMin(x) the plane in the slab that the ray intersects first (the smallest *t* value). In this example, we actually calculated the *t* values in this order but if the ray was intersecting from the right side of the cube, tMin(x) would contain the intersection with the X Max plane instead, and vice versa since the intersection order would be reversed.

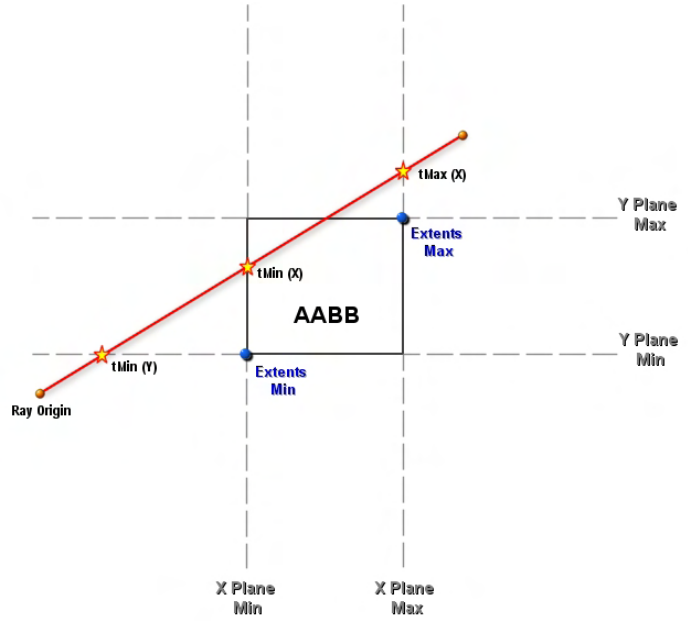

Figure 14.58

Now it is time to process the next slab (the Y slab). First we calculate the point of intersection between the ray and the first plane in the Y slab (Y Plane Min). This is shown in Figure 14.58 and is labelled tMin(y).

Our next task is to calculate another ray plane intersection test between the ray and the second plane in the Y slab (Y Plane Max). The point of intersection between the ray and second plane in the Y slab is shown in Figure 14.59 and is labelled tMax(y).

Once we have both *t* values for the Y slab, we sort them into two temporary variables as before so that tMin stores the lowest *t* value in the slab and tMax holds the highest *t* value in the slab.

The next bit of logic makes it all work. Once we have calculated the two *t* values for a slab, we see if the minimum *t* value for that slab is greater than the largest minimum *t* value we have found so far. If so, we record it. We can see in Figure 14.59 that the highest minimum *t* value from both slabs is tMin(x), which was the minimum *t* value we recorded for the first slab. In other words, this is the minimum *t* value that intersects the ray furthest from the origin compared to any other minimum *t* value calculated for other slabs. Also, when we get the maximum *t* value for a slab, we test to see if it is lower in value than any *t* value we have found so far. If it is, then we record it. At the end of testing all slabs we will have the lowest maximum *t* value found and the lowest minimum *t* value found.

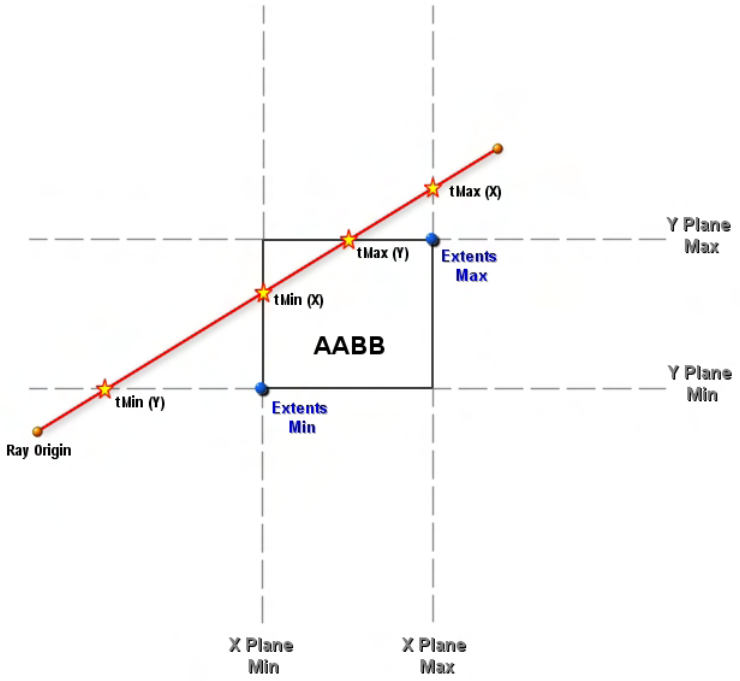

Figure 14.59

In Figure 14.59 we can see that when we calculate the maximum *t* value for the Y slab (tMax(y)), this intersection happens closer to the ray origin than the maximum *t* value found for the previous slab (yMax(x)) so we record that this is the lowest maximum *t* value we have found so far.

At the end of testing each slab we will have recorded the highest minimum value and the lowest maximum value as shown below.

tMin = tMin(X)
tMax = tMax(Y)

tMin and tMax were the temporary variables used to record the highest minimum *t* value and the lowest maximum *t* value during slab testing. We have highlighted the tMin and tMax values in Figure 14.60 below. As tMin is smaller than tMax, this means the ray intersects the box and we can return true for intersection.

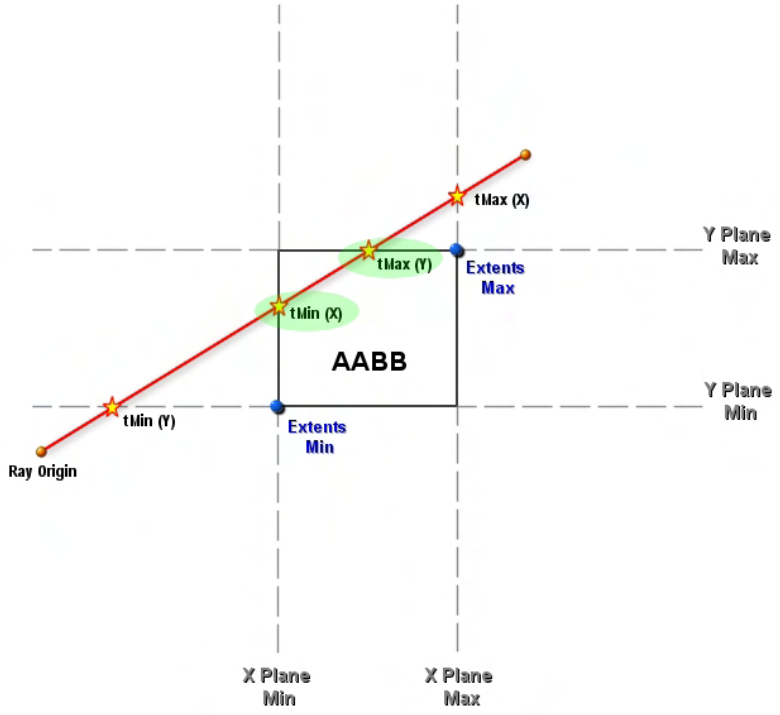

Figure 14.60

To understand why this means an intersection took place, imagine taking the red ray in the above diagram and moving it diagonally up and to the left.

As you imagine slowly moving it, you should be able to see that tMin(X) would move up its plane and tMax(Y) would move left along its plane and they would be identical values at the point where the ray just touches the top left corner. If we continue to move the ray up and to the left we can see that tMin(X) and tMax(Y) would swap around and the intersection with tMax(Y) would happen before the intersection with tMin(X). Thus we have a situation where the highest minimum *t* value is greater than the lowest maximum *t* value and thus, we have no intersection.

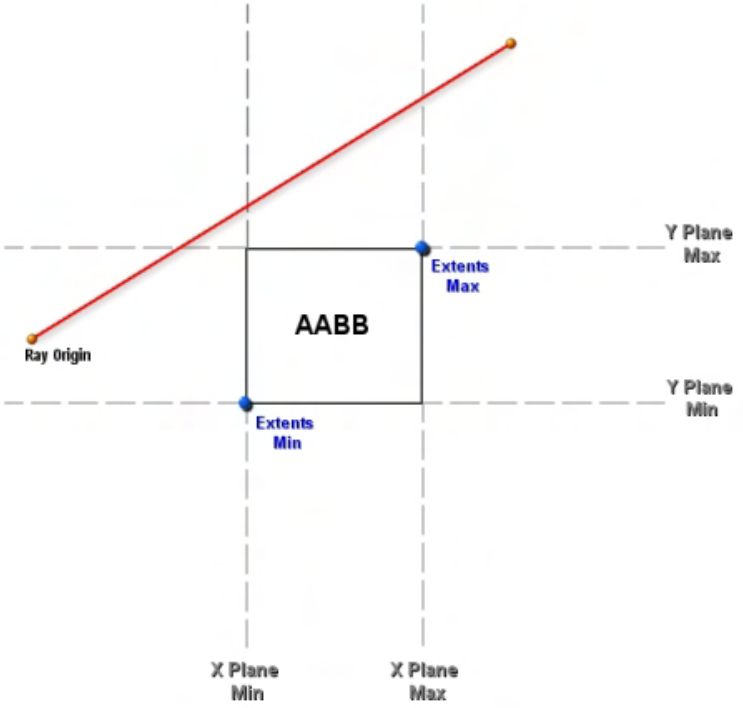

Figure 14.61

Let us try this out to make sure we are correct. Figure 14.61 shows a new example where the ray does not intersect the box. We will now quickly step through the same process and we should find that tMin is larger than tMax at the end of testing all the slabs.

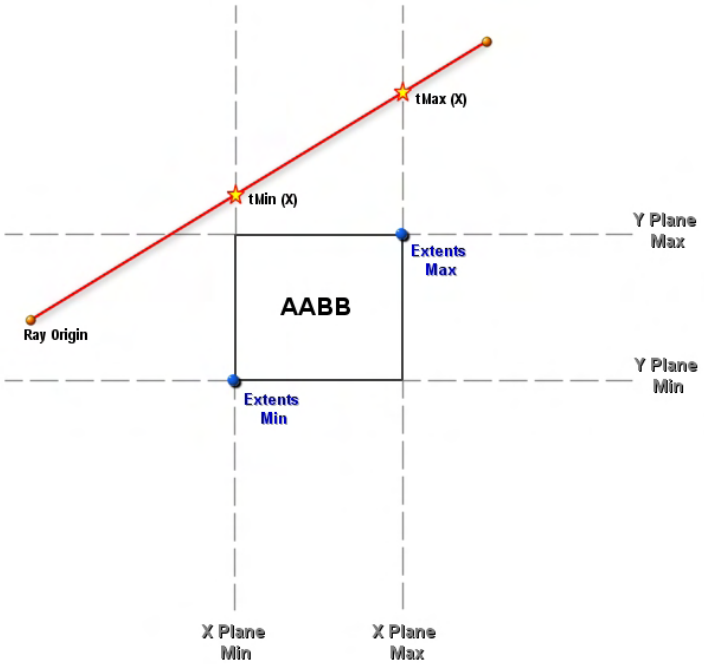

Figure 14.62

As before, we process each slab one at a time. Figure 14.62 shows the results of intersection testing the ray with the two planes comprising the X slab. Again, we test the two returned *t* values and sort them so that tMin(X) holds the first point of intersection and tMax(X) stores the second point of intersection.

Obviously, because we have only tested one slab at this point, the highest minimum *t* value we have found is tMin(X) and the lowest maximum *t* value we have found is tMax(X).

Next we move on to the Y slab and calculate the minimum and maximum intersection *t* values for both planes of that slab. These are shown in Figure 14.63 as tMin(y) and tMax(y). Notice this time however that the lowest maximum value we have found is tMax(y) which intersects the ray closer to the origin than the highest minimum *t* value (tMin(x)). As such, tMin > tMax and we know that the ray does not intersect the box. The *t* values that would end up in tMin and tMax at the end of testing all slabs are highlighted green in Figure 14.63.

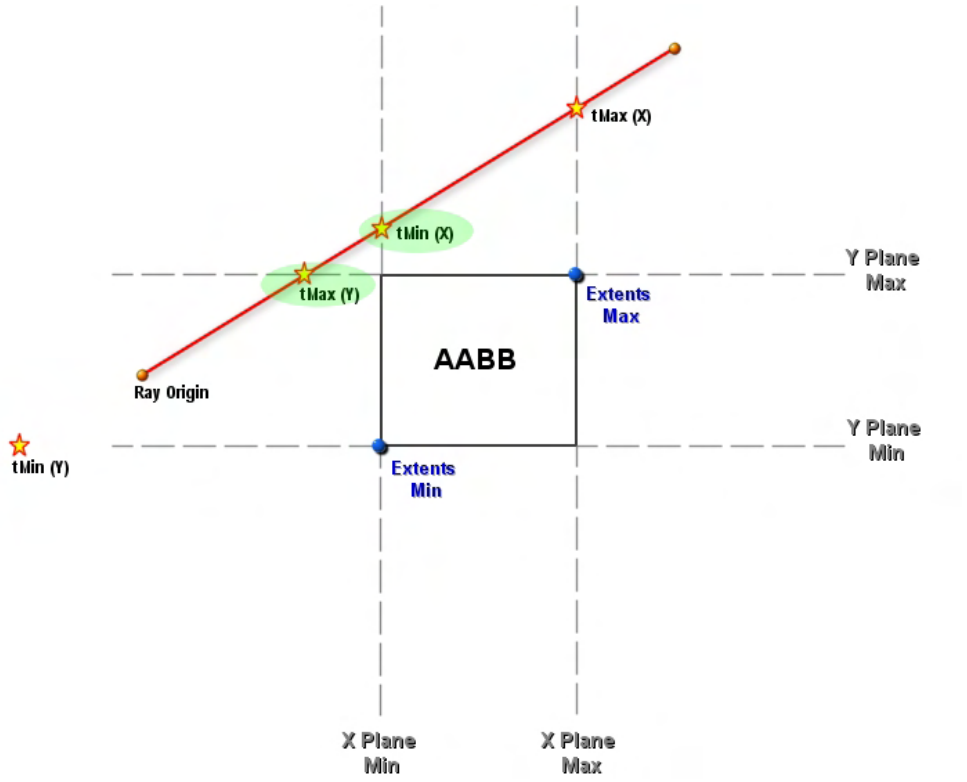

Figure 14.63

Notice that in this second example (Figure 14.63) the minimum *t* value for the Y slab (tMin(y)) is actually behind the ray origin and will thus be a negative value. This works fine since we are only interested in recording the highest minimum value found so far (so this *t* value would therefore be ignored).

Now it might not be clear why, but the process we have just described work for both OBBs and AABBs. Regardless of the orientation of the planes, as long as we have the two corner points of the box, we have points that lay on all slab planes and calculating the *t* values for each slab can be done using the CCollision::RayIntersectPlane method discussed in the previous chapter.

Next we will discuss some optimizations that can be performed that will allow our code to perform the plane intersections much quicker with axis aligned bounding boxes. Unfortunately, this will come at the cost of having a function that will not work with OBBs. However, you should be able to write your own Ray/OBB code should you need it based on the above theory.

To understand the optimizations that can be made in the case of an AABB, we will concentrate on calculating the *t* values for just one of the slabs. We will focus on the X slab for now and initially concentrate on calculating the *t* value for just one of its planes. Figure 14.64 shows the earlier example of a ray intersecting an AABB and the first plane in the X slab we need to calculate the *t* value for. As we can see, ExtentsMin describes a point on this plane and the plane normal is assumed to be aligned with the coordinate system X axis <1,0,0>.

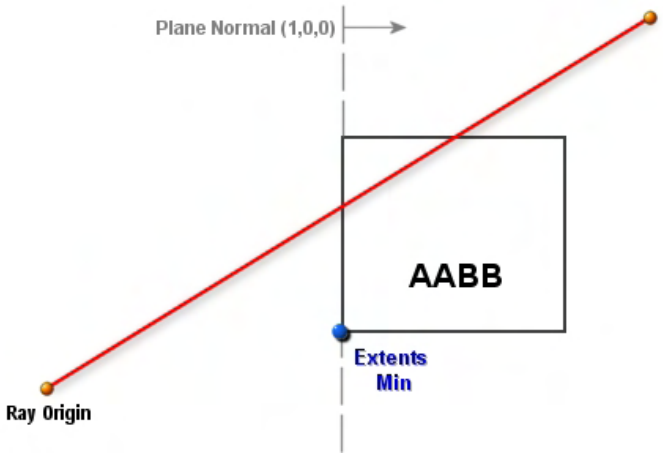

Figure 14.64

In order to find the point of intersection along the ray we first need to find the distance to the plane from the ray origin. We would normally do this by subtracting from the point known to be on the plane (ExtentsMin) from the ray origin, giving us the vector EV1 shown in Figure 14.65.

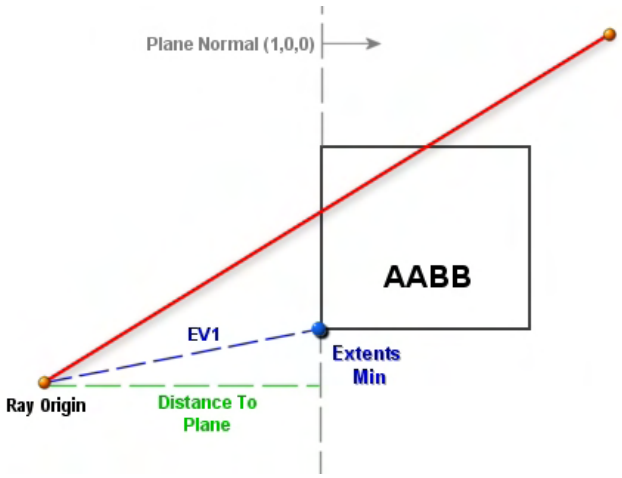

Figure 14.65

Once we have the vector EV1 we would dot it with the plane normal. Since the plane normal is unit length and the two vector origins are brought together for the dot product operation, this will scale the length of vector EV1 by the cosine of the angle between the two vectors, returning a single scalar value that describes the length of vector EV1 projected along the direction of the plane normal (the length of the green dashed line shown in Figure 14.65). This is the distance to the plane. However, why bother doing a dot product between the normal and the vector EV1 when we know that two of the components of an axis aligned plane normal will always be zero and the other will always be one? In fact, we do not have to perform a dot product between EV1 and the normal to find the distance to the plane; it is simply the value stored in EV1's x component, as shown below.

Distance To Plane **= EV1 ● Normal**
= EV1.x*Normal.x + EV1.y*Normal.y + EV1.z*Normal.z
= EV1.x*1 + EV1.y*0 + EV1.x*0
= EV1.x*1
= EV1.x

Once we have calculated vector EV1, its x component will tell us the distance to the first plane in the slab. We have just saved ourselves three multiplies and two additions per plane test.

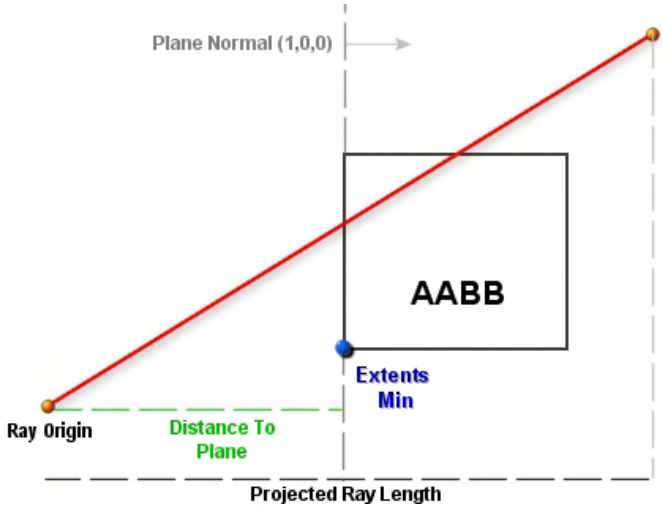

Figure 14.66

After we have found the distance from the ray origin to the plane, the next step is to project the ray length along the plane normal as shown in Figure 14.66. The ray delta vector is a vector describing the ray's direction and length from the ray origin to its end point. If we dot this with the plane normal, we will project it onto the line of the plane normal which will tell us the projected ray length. This is the length of the black dashed line at the bottom of Figure 14.66. Note that it tells us the length of the adjacent side of a triangle with the ray delta vector as the hypotenuse and the plane normal describing the direction of the adjacent side. Because we have projected the ray length along the plane normal, we can just divide the distance to the plane from the ray origin by the projected ray length to get the *t* value of intersection. In the above diagram it would be somewhere near to 0.5 as the plane intersects the ray roughly halfway along. In the last chapter we learned that we can calculate the *t* value of intersection between a ray and a plane as follows:

$$t = \frac{\text{Distance To Plane}}{V \bullet N}$$

$$t = \frac{EV1.x}{V \bullet N}$$

Where V is the ray delta vector and N is the plane normal. Once again, because we know that the plane normal of axis aligned plane will be a unit length vector with two of its components set to zero, the full dot product is not needed. This simplifies the denominator in the above equation to the following (for the X axis):

V ● N **= V.x*Normal.x + V.y*Normal.y + V.z*Normal.z**
= V.x*1 + V.y*0 + V.x*0
= V.x*1
= V.x

The final equation for calculating the *t* value for the ray and the plane shown in the above diagrams (the first plane of the X slab) has been simplified to the following:

$$t = \frac{EV1.x}{V.x}$$

We can do exactly the same for the second slab in the X plane, only this time we calculate EV1 by subtracting the ray origin from Extents Max instead of Extents Min.

This same logic works for all slabs that are axis aligned. Thus, to calculate the *t* values for the Y slab:

$$t = \frac{EV1.y}{V.y}$$

When we introduce the third dimension and a new Z aligned slab:

$$t = \frac{EV1.z}{V.z}$$

Remember that for each plane, we must calculate EV1 by subtracting the ray origin from either ExtentsMin or ExtentsMax depending on whether we are intersection testing the minimum or maximum plane of the slab.

Let us now look at the code to our new RayIntersectAABB function. The function is passed the ray origin and delta vector (Velocity) and is also passed the minimum and maximum extents of the AABB. As the fourth parameter we pass a variable by reference that will contain the *t* value of intersection between the ray and the box on function return. As with all of our AABB routines, we also offer the option to ignore any axis (slab) test. This allows us to (for example) consider a ray to intersect a box if it passes through the box in the X and Z dimensions but is above or below the box (useful when running queries against a Y-variant quad-tree).

```
bool CCollision::RayIntersectAABB(  const D3DXVECTOR3& Origin,
                                    const D3DXVECTOR3& Velocity,
                                    const D3DXVECTOR3& Min,
                                    const D3DXVECTOR3& Max,
                                    float& t,
                                    bool bIgnoreX /* = false */,
                                    bool bIgnoreY /* = false */,
                                    bool bIgnoreZ /* = false */ )
{
    float tMin  = -FLT_MAX, tMax =  FLT_MAX, t1, t2, fTemp;
    D3DXVECTOR3 ExtentsMin, ExtentsMax, P, RecipDir;
    ULONG       i;

    // Calculate required values
```

```
    ExtentsMin  = Min - Origin;
    ExtentsMax  = Max - Origin;
    RecipDir = D3DXVECTOR3( 1.0f/Velocity.x, 1.0f/Velocity.y, 1.0f/Velocity.z);
```

For efficiency we will be testing one slab at a time (two planes simultaneously), so we subtract the ray origin from both the minimum extents and maximum extents of the box. In this code, we can think of the variable ExtentsMin as describing the vector EV1 in our diagrams (the vector from the ray to the minimum plane in the slab) and we can think of ExtentsMax as describing a vector from the ray origin to the point on the second plane in the slab. At this point, the ExtentsMin <x, y, z> components contain the distances from the ray origin to the three minimum planes of each slab and ExtentsMax contains the three distances from the ray origin to the second plane in each slab. As we discussed earlier, we will calculate the *t* value by dividing the component in the ExtentsMin and ExtentsMax vectors that matches the plane we are currently testing by the matching component in the ray delta vector (Velocity). As we may have to test six planes in all, this means six divisions. Since divisions are slower than multiplications, we perform three divisions to create a reciprocal delta vector which we can then multiply with this vector. This will have the same effect as dividing by the ray's delta vector.

Now it is time to test each slab by setting up a loop to count three times. Each iteration of this loop will calculate the two t values from the planes forming that slab. As you can see below, if the slab we are currently testing is one we have chosen to ignore, we just skip any processing and advance to the next iteration.

```
    // Test box 'slabs'
    for ( i = 0; i < 3; ++i )
    {
        // Ignore this component?
        if ( i == 0 && bIgnoreX ) continue;
        else if ( i == 1 && bIgnoreY ) continue;
        else if ( i == 2 && bIgnoreZ ) continue;
```

If we get this far then this is a slab we wish to process. If we are on iteration zero then we are processing the X slab. If the matching component in the ray delta vector is zero (with tolerance) then the ray is running parallel to the current slab and could not intersect any of its planes, so we skip this slab. Therefore, the *t* value calculations for each plane in the current slab are only executed when the ray's delta vector does not have a zero in the component that matches the slab currently being tested. So if Velocity.x=0 then there is no point trying to calculate a point of intersection with the plane's comprising the X slab as the ray does not get any closer or further from the slab with distance.

```
        // Is it pointing toward?
        if ( fabsf(Velocity[i]) > 1e-3f )
        {
```

If we get inside this code block then we need to calculate the two *t* values for the planes of this slab. As discussed, this is a simple case of dividing the matching components in each of the extents vectors by the matching component in the ray delta vector.

```
            t1 = ExtentsMax[i] * RecipDir[i];
            t2 = ExtentsMin[i] * RecipDir[i];
```

At this point we have the *t* values between the ray and the planes of this slab stored in t1 and t2. We want to make sure that t1 holds the smallest *t* value, so we swap their values if this is not the case.

```
            // Reorder if necessary
            if ( t1 > t2 ) { fTemp = t1; t1 = t2; t2 = fTemp; }
```

Next we test to see if t1 (the minimum *t* value) is greater than any other minimum *t* value we have stored so far (tMin). If so, we overwrite its value with the new *t* value. Also, if the maximum *t* value (t2) is less than any maximum *t* value we have found so far (tMax), we also record its value.

```
            // Compare and validate
            if ( t1 > tMin ) tMin  = t1;
            if ( t2 < tMax ) tMax = t2;
```

At this point tMin will contain the highest minimum *t* value found so far for all previous slabs, and tMax will contain the lowest maximum *t* value. If we find (even if we are testing only the first slab) that tMin is ever greater than tMax, it means the ray cannot possibly intersect the box and we can return false immediately without testing any other slabs. Also, if we ever find that tMax is smaller that zero, then it means the box is behind the ray and we can also return false immediately. Here is the rest of the slab testing loop.

```
            if ( tMin  > tMax ) return false;
            if ( tMax < 0 ) return false;

        } // End if toward

    } // Next 'Slab'
```

If we reach this point in the function without returning then we know we have an intersection between the ray and box. All we wish to do now is return the first point of intersection. This should always be the value contained in tMin, unless it is a negative value, in which case the plane is behind the ray origin and tMax should be returned.

```
    // Pick the correct t value
    if ( tMin > 0 ) t = tMin; else t = tMax;

    // We intersected!
    return true;
}
```

That was quite a lot of explanation for what turned out to be a very small function. However, this is exactly the sort query you may have to explain at a job interview so it is good that we explored it fully.

14.15 AABB/Plane Intersection

The algorithm for classifying an AABB against a plane is not really new to us since it is something we have been doing since we first introduced frustum culling in Module I. You will recall that we introduced code to detect whether an AABB was outside a frustum plane and if so, the object which the AABB approximates was not rendered.

In this section we will cover a more generic implementation of a routine that will classify an AABB with respect to a plane and return a member of our CCollision::CLASSIFYTYPE enumeration (i.e., CLASSIFY_INFRONT, CLASSIFY_BEHIND or CLASSIFY_SPANNING). We will require a function such as this during the tree building phase where we wish to test the AABB of a detail area against the node split planes to determine which children it should be assigned to.

Classifying an AABB with respect to a plane is a simple case of finding the two corner points of the AABB that would be closest to the plane and furthest from the plane ***if the AABB was in front of the plane***. We refer to these as the *near* and *far* points. We know for example that as the near point is the closest point to the plane in a scenario where the box is in front of the plane, if this point is in front of the plane, then the whole AABB must be in the front space also. Furthermore, the far point describes the point on the box that would be farthest from the plane in the scenario (where the box was in front of the plane). If this point is behind the plane, the whole box must be behind the plane also. Finally, if the near and far points are on opposing sides of the plane, the box is spanning the plane.

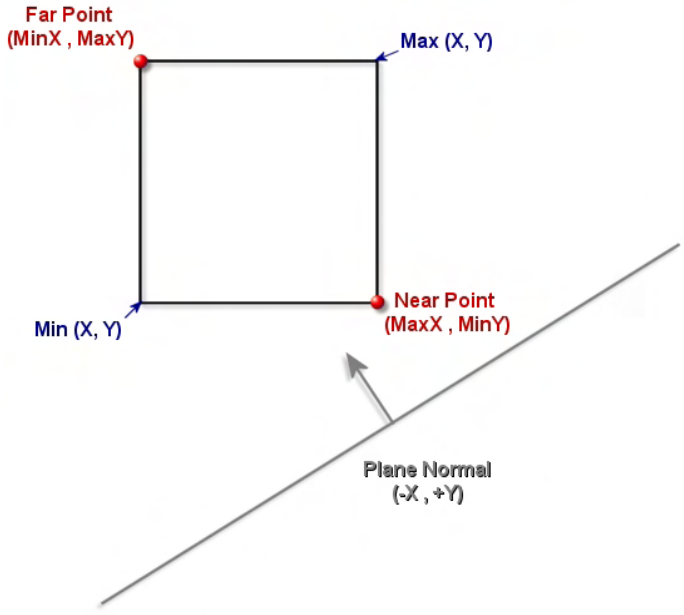

Figure 14.67

Calculating the near and far point is a simple case of analyzing the plane normal and picking the components from the AABB extents vectors to construct the point based on that normal. For example, if the x component of the normal is negative (the normal is facing in the direction of the negative X axis) then the x component of the near point will be the x component of the AABB max extents vector. If the normal is facing in the positive x direction, the x component of the AABB min extents vector describes the face of the cube that would intersect the front of the plane first were it in front of that plane. We do the same for each component of the normal. That is, for each component of the normal, if it is negative we use the maximum extents vector component for the near point and the minimum extents vector component for the far point. After doing this for each normal component, we will have constructed our two required points. In Figure 14.67 we demonstrate how this works.

Figure 14.67 depicts an AABB which is clearly in front of the plane. We also see the near and far points that have been generated based on the plane normal. Min and Max are the extent vectors of the AABB.

We can see that in this situation, if we were to move the box towards the plane, the near point would intersect the plane first and the far point would intersect the plane last. Let us examine how we generated the near and far points in this example.

The plane normal faces down the negative X axis and the Y component of the normal is positive (it is pointing up). We will keep things two dimensional for ease of illustration. Because the x component of the normal is negative, it means we use the x component from the max extents vector for the near point's x component (MaxX). Because the y component of the normal is positive, we use the y component of the AABB's minimum extents vector as the component for the near point. This gives us the point at the bottom right corner of the box shown in Figure 14.67. This is the point that would be closest to the plane if the box is in front of the plane. We can see that the reverse logic is true for the far point. If a normal component is negative, then the component from the far point is taken from the minimum extents vector of the box, otherwise it is taken from the maximum extents vector. As we can see in Figure 14.67, because the normal has a negative x component, we use MinX for its x component. Because the y component of the plane normal is positive, we take the y component from MaxY. This gives us the far point shown. Because the near point is in front of the plane, the entire box must be in front of the plane also, so we can return CLASSIFY_INFRONT.

It is important to realize that the near and far points are always calculated in this way regardless of the orientation of the plane or the position of the box. Therefore, the near point is not always the point that is nearest to the plane; it is the point that *would* be nearest to the plane *if the box was in front of the plane*.

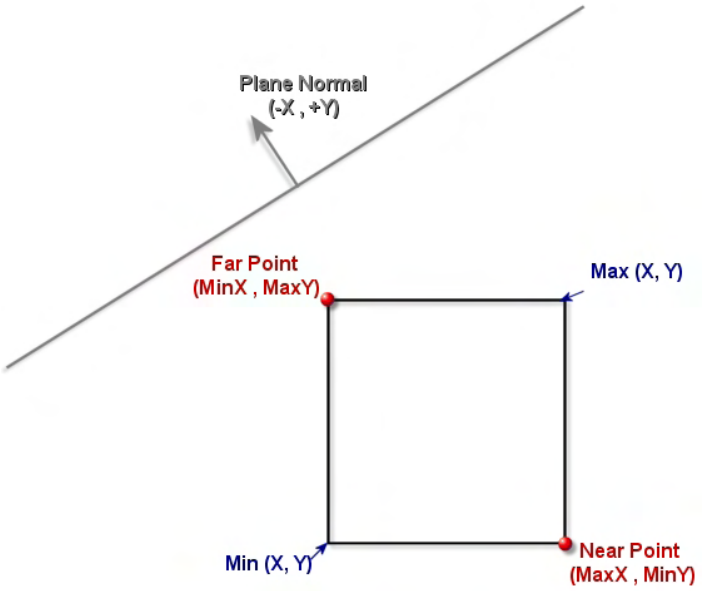

Figure 14.68

In Figure 14.68 we show the same plane being used but we have moved the box so that it is now behind the plane. Since the plane normal is the same, the near and far points of the box are calculated in exactly the same way. However, notice that because the box is behind the plane, the near point is no longer the point that is closest to the plane. We can see in this example that as the far point would be the last position on the cube to pass the plane if the cube was being moved from the planes front halfspace to its back halfspace, if the far point is behind the plane, the entire AABB must be behind the plane also and we can return CLASSIFY_BEHIND.

Of course, it is also clear to see when looking at Figures 14.67 and 14.68 that if, after calculating the near and far points, we find that they are on different sides of the plane, the box must be spanning the plane and we can return CLASSIFY_SPANNING.

The spanning case is illustrated in Figure 14.69. It demonstrates the fact that because we are now using a different plane normal, the near and far points are calculated completely differently. In this example,

because the plane normal has a negative x and y component, the near point is simply the AABB's minimum extents vector and the far point is the AABB's maximum extents vector.

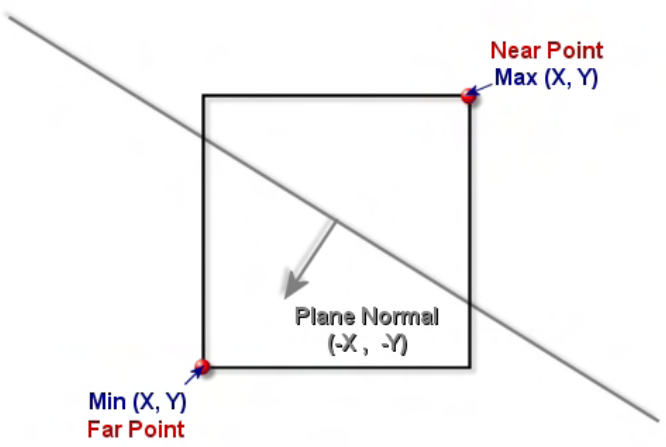

Figure 14.69

Below we see the code to the CCollision::AABBClassifyPlane function which implements the steps we have just discussed. Its parameters are the extent vectors of the AABB and the plane. The plane is passed in using ABCD format (a normal, ABC, and a distance from the plane to the origin of the coordinate system, D).

After calculating the near and far points, we classify the near point against the plane. If it is in front of the plane we can return CLASSIFY_INFRONT immediately since the whole box must be in front of the plane as well. If not, it means the near point is behind the plane so we test the far point. If the far point is in front of the plane, it means the box must be spanning the plane because the near and far points are in different half spaces. If this is the case, we return CLASSIFY_SPANNING. If not, the box must be behind the plane, so we can return CLASSIFY_BEHIND.

```
CCollision::CLASSIFYTYPE CCollision::AABBClassifyPlane( const D3DXVECTOR3& Min,
                                                        const D3DXVECTOR3& Max,
                                                  const D3DXVECTOR3& PlaneNormal,
                                                        float PlaneDistance )
{
    D3DXVECTOR3 NearPoint, FarPoint;

    // Calculate near / far extreme points
    if ( PlaneNormal.x > 0.0f ) { FarPoint.x  = Max.x; NearPoint.x = Min.x; }
    else                        { FarPoint.x  = Min.x; NearPoint.x = Max.x; }

    if ( PlaneNormal.y > 0.0f ) { FarPoint.y  = Max.y; NearPoint.y = Min.y; }
    else                        { FarPoint.y  = Min.y; NearPoint.y = Max.y; }

    if ( PlaneNormal.z > 0.0f ) { FarPoint.z  = Max.z; NearPoint.z = Min.z; }
    else                        { FarPoint.z  = Min.z; NearPoint.z = Max.z; }

    // If near extreme point is outside, then the AABB is totally outside the plane
    if ( D3DXVec3Dot( &PlaneNormal, &NearPoint ) + PlaneDistance > 0.0f )
         return CLASSIFY_INFRONT;
```

```
    // If far extreme point is outside, then the AABB is intersecting the plane
    if ( D3DXVec3Dot( &PlaneNormal, &FarPoint ) + PlaneDistance > 0.0f )
         return CLASSIFY_SPANNING;

    // We're behind
    return CLASSIFY_BEHIND;
}
```

Yet another function has now been added to our intersection library that we will find ourselves using time and time again as we progress with our studies. This concludes our discussion of the new intersection and classification routines we need to add to our library in order to build spatial hierarchies.

14.16 T-Junctions

Earlier in the lesson, we learned that any extensive clipping procedure will likely introduce T-junctions in the geometry. In this section we will examine what T-junctions are, the displeasing visual artifacts they exhibit, and a way to fix them. Since all of our trees will have the ability to produce clipped trees, all of our derived tree classes will want to have their T-junctions fixed after the build process has completed (if the tree is intended to be used for rendering). Since fixing T-junctions is exactly the same algorithm regardless of the tree type being used (it is just a repair pass on the polygons in the tree's polygon list), we have decided to place the T-junction removal code inside the Repair method of CBaseTree. This way, the same function can be used to fix the geometry built by any of our derived tree classes.

As T-junctions exhibit themselves only when the data that contains the T-junctions is being rendered, the derived class (or the application) will not have to issue the Repair call after the tree has been built as it will happen automatically. That is, the CBaseTree::PostBuild method, which is called from the derived class Build function after the tree has been built, will issue a call to the CBaseTree::BuildRenderData method. Although this method will be discussed in the following lesson, it essentially prepares the tree polygon data so that it is ready to be rendered. This includes making a call to the CBaseTree::Repair function. Of course, the BuildRenderData method returns immediately if the tree has not been given a valid 3D device pointer which means the CBaseTree::Repair method will only be called automatically for trees that you intend to render. If you are not using the tree for rendering (just collision queries) and you have not passed a 3D device pointer into the tree's constructor (avoiding the render data being built), but would still like to have the T-junctions repaired, your application can issue a call to the Repair method after the Build method has returned. Once again, remember that if a device pointer was passed to the constructor, the render data would have been built and the T-junction repair function called automatically.

14.16.1 What are T-Junctions?

A T-Junction is the meeting of geometry along a shared edge where the vertices along that shared edge are not equal in each object. This can happen a lot when clipping is being performed. A quad for example might be split into two pieces vertically at one node, and then one of those splits later gets split into two pieces horizontally at another node (see Figure 14.70). We can see in this example that the polygons (which may have originally been one quad before clipping was performed) all share a common edge. That is, the right edge of the left polygon would be butted up against the left edges of the two smaller polygons to its right. This is a classic T-junction scenario.

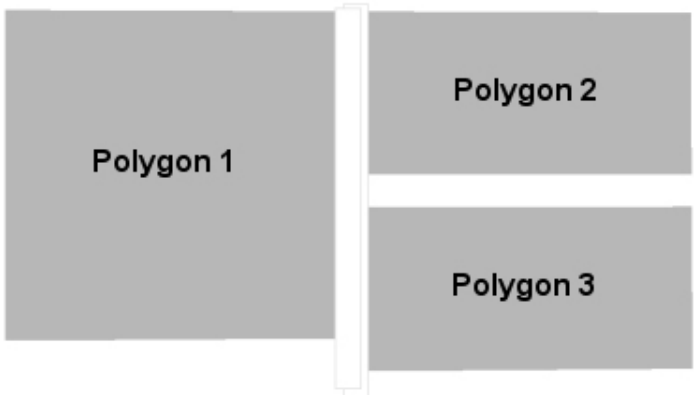

Figure 14.70

In this image we have deliberately separated the three neighboring polygons so that you can clearly see the polygon boundaries, but you should be able to recognize that if we were to slot all three polygons together so that there were no longer any gaps between them, they would look like a single large quad. Perhaps these three polygons were a single quad to begin with, but clipping broke it into three pieces. Nevertheless, we still want it to look like a single quad when rendered.

Of course, this same situation may arise simply because the artist has designed the geometry that way instead of it having been introduced by a clipping process. Either way, we have ourselves a T-junction to deal with and our scene may contain many of them.

While looking at the above image, if you tilt your head to the left, you should be able to see that the white gaps between the polygons form the letter ‘T’, which is where such a geometric configuration gets its name. If these polygons are neighbors (i.e., if their edges are touching) we would certainly have a problem that would cause lighting anomalies and other visual artifacts. In Figure 14.71 we have connected the polygons together to better show the problem. The polygon boundaries causing the T-junction are highlighted with red dashed lines.

Recall that a vertex lighting system using gouraud shading records lighting samples at the vertices for interpolation over the surface. We can see that while Polygon 1 shares its right hand edge with both Polygons 2 and 3, Polygons 2 and 3 have a vertex (shown as the red sphere) in the center of polygon 1’s right hand edge. But Polygon 1 does not have a vertex in that position since its vertices are the four corner points of the quad.

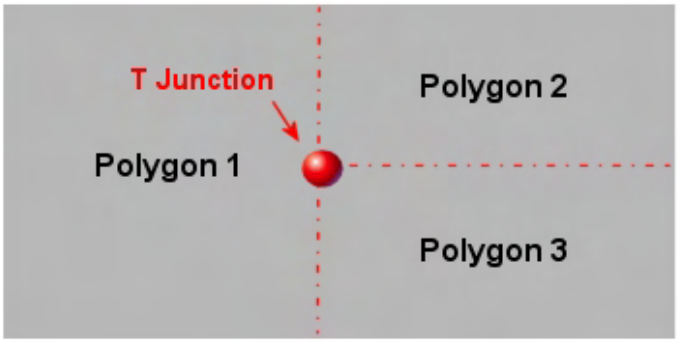

Figure 14.71

The problem occurs when a light source affects the center point of this construct where these three polygons meet. If we used a tightly focused beam (such as a small spot light for example), we would fully expect the influence of the light to affect all three polygons in the same way. However, as Figure 14.72 clearly shows, if we shine a small spot light at the center point of this construct, the bottom left vertex of Polygon 2 and the top left vertex of Polygon 3 are very close to the light source and as such, a high intensity light sample is recorded at those vertices. If Polygon 1 had a vertex in the same position, then it too would receive that same light sample which would be interpolated over its entire surface. The problem is that it does not have a vertex located there. In fact, Polygon 1's vertices are some distance from the light source. So although this construct of three polygons might seem to the user to be a large single wall polygon (for example), we have the lighting suddenly cut off as the light passes into Polygon 1's area because it does not have a vertex in a correct position to sample the light in the same way as its neighbors. This causes the lighting discontinuity illustrated in Figure 14.72.

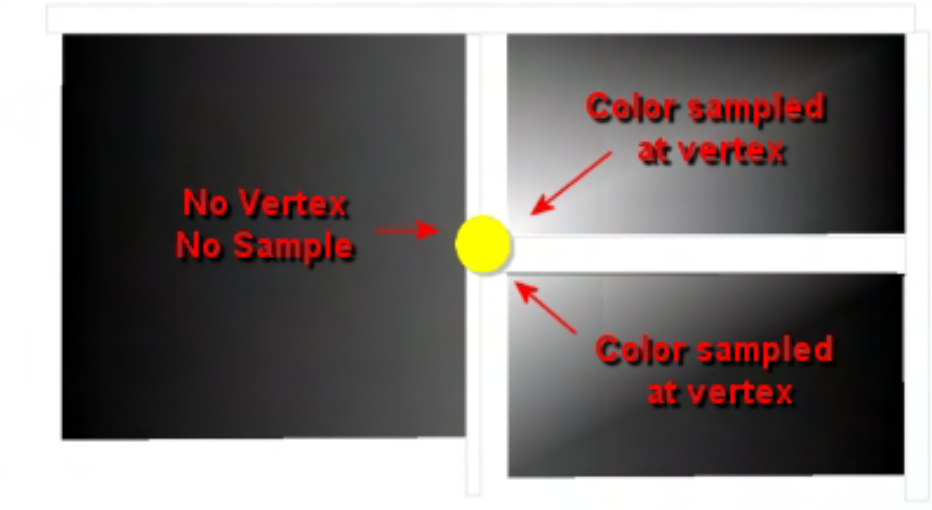

Figure 14.72

In Figure 14.73 we see the result is made much worse if the polygons are connected as they are supposed to be in this example. This is an obvious lighting discontinuity that would stick out like a sore thumb to even the most casual gamer.

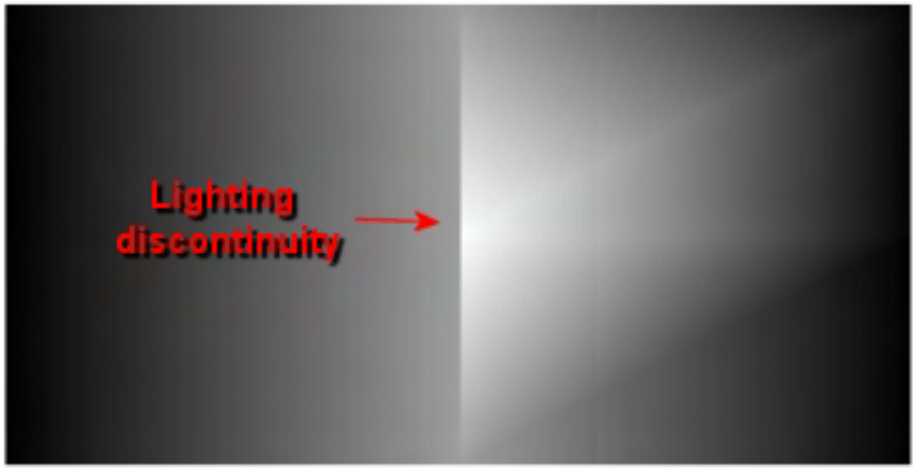

Figure 14.73

Whenever a T-junction occurs within a game level, we have the potential for a vertex lighting system to suffer these visual glitches. In fact, T-junctions are not just undesirable for a vertex lighting system; they also cause visual anomalies during rasterization. Many of you may have seen T-junctions in commercial games that did not even use a vertex lighting system. They can manifest themselves in the rasterization phase as a phenomenon called “sparklies”. Sparklies are sub-pixel gabs that appear when polygons that share edges with T-junctions are being rendered. In a T-junction scenario, rounding errors caused during rasterization occur differently along the edge that is missing the vertex versus the shared edges that have the additional vertex. The polygons appear to come apart at the shared edge ever so slightly at certain pixels, causing a gap. The difference in floating point rounding errors between the edges that do and do not contain the vertex causes a situation where neither edge renders a pixel into the frame buffer, thus allowing the background to show through. These gaps are often seen as a sparkle effect as lots of little oddly colored pixels shimmer in and out of existence on the display. These colored pixels are actually the colors of more distant polygons or the color that the frame buffer was initially cleared to before the frame was rendered.

In Figure 14.74 we see a screenshot from Lab Project 14.1 with the T-junction repair step turned off. Although it is hard to take a good screenshot of sparklies (they look much worse when the camera is actually moving), even in this image we can see some cyan colored pixels (the color the frame buffer was cleared to before the scene was rendered) showing through sub-pixel gaps on the floor.

Figure 14.74

When the player is actually walking along the floor and the level is fully animated, many of these little blue dots shimmer in and out of existence. This is very distracting to the player to say the least. In fact, it is for this reason, more so than the lighting discontinuities, that we must fix these T-junctions before the scene is rendered. Since we will be moving away from vertex lighting systems in Module III of this series and begin to favor more advanced techniques, T-junctions will no longer affect our lighting system. However, these sub-pixel gaps that occur during the rasterization of shared edges that contain T-junctions are clearly unacceptable.

As mentioned, T-junctions are not just caused by clipping geometry. They can be very easily introduced by the artist during level design. T-junctions can even exist between neighboring objects/meshes that will cause lighting anomalies (see Figure 14.75).

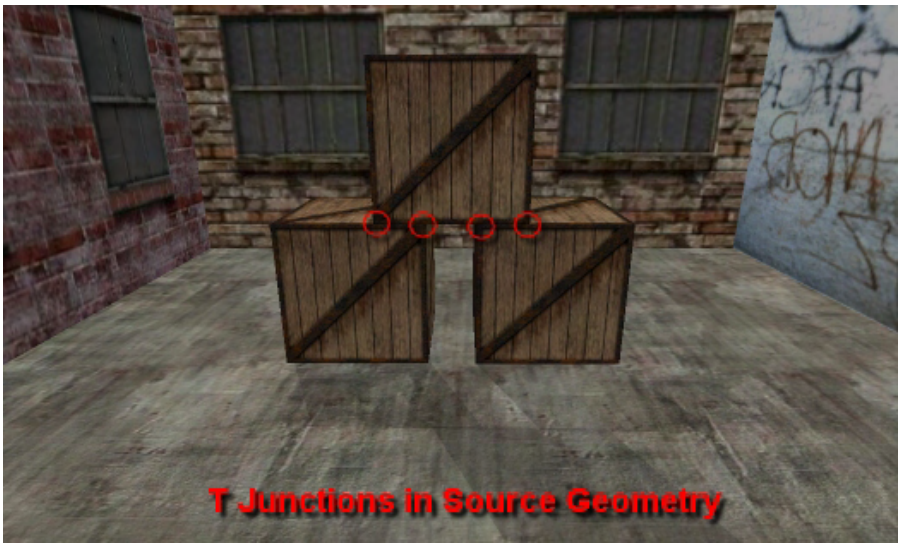

Figure 14.75

In Figure 14.75 we see how the project artist might innocently place three crates on top of each other in a staggered fashion. Because these are separate meshes, we will not have the sparklies problem, but this would still cause lighting discontinuities if a vertex lighting system was being employed.

Assuming the front face of each create is a single quad with the vertices in its four corners, we can see that top right vertex of the bottom left crate and the top left vertex of the bottom right crate partially share an edge with the bottom edge of the top crate.

Because the crates are staggered, the vertices in the bottom two crates that share the edge with the top crate have vertices in different positions versus those of the bottom edge of the top crate (and vice versa). We can also see that the bottom left and right vertices of the top crates are positioned in the middle of the top edges of the bottom crates and as such, we have four vertices that share an edge which do not each belong to both the polygons that share the edge. Take a look at Figure 14.76 and see how the vertex lighting system would light these crates if two tightly focused spot lights were set to illuminate the top left vertex of the bottom right crate and the top right vertex of the bottom left crate.

Figure 14.76

As you can see, the tightly focused beam illuminates only the points in space where the top right vertex of the bottom left crate and the top left vertex of the bottom right crate are located. The lighting color is sampled at this point and interpolated over the surfaces of the bottom two crates. However, the bottom edge of the top crate does not have vertices in these locales and its vertices (the bottom left and bottom right vertices of its quad) fall just outside the influence of the light source. As a result, the topmost crate has no vertices located in positions that receive light contributions and the create remains unlit. This has caused a very unnatural lighting result.

14.16.2 Fixing T-Junctions

Fixing T-junctions in our level is actually much simpler than you might assume. We essentially need to test the edges of each polygon in our scene, with the edges of every other polygon in the scene, searching for vertices in the edge of one polygon that exist along the edge of the first polygon. If such a vertex is found, we make a copy of the vertex and insert it into the polygon edge that has missing the vertex. Essentially, we are just finding any vertices in any polygon that may live in the middle of an edge and if found, we insert that vertex into the edge. The insertion of this extra vertex introduces another triangle primitive that will be needed to render the N-gon, so our primitive count will have grown after the T-junction repair process is complete. The basic pseudo code (lacking any optimizations) is:

```
For Each Polygon (PolygonA)
        For Each Edge (EdgeA)
                For Each Polygon (PolygonB)
                        For Each Vertex (VertexB)

                                D= Calc Distance from VertexB to EdgeA
                                ( If D !=0 [with epsilon] ) continue;

                                If  (VertexB is not between EdgeA.vertex1 and EdgeA.vertex2) continue;

                                // Vertex B is causing T junc with this EdgeA so inside it into polygon
                                PolygonA.InsertVertex( just after Edge1.vertex1);

                        End For Each Vertex
                End For Each Polygon
        End For Each Edge
End For Each Polygon
```

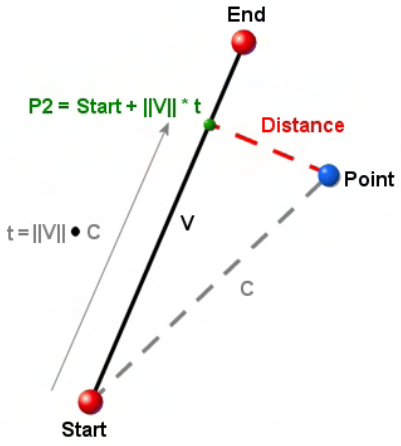
As you can see, we process each polygon and its edges one at a time. For each edge we test the vertices of every other polygon in the scene to see if that vertex causes a T-junction along the current edge. If it does, then we need to insert that vertex into the current edge so that both polygons have vertices in the same places, thus repairing the T junction. The key here is finding out whether the vertex we are currently testing is on the current edge we are testing because if it is not, it cannot possibly cause the T-junction with the current edge and we can skip it.

You can see in the above pseudo-code that for each vertex we calculate D, the shortest distance from the vertex to the infinite line on which the edge lives. If this is not zero (with tolerance) then the vertex cannot be on the edge. Obviously, if a point is on an edge, the distance from that point to the edge would be zero. If it is zero then we know that the vertex lies on the infinite line on which the edge/ray exists, but we do not know whether it lies within the line segment defined by the edge's two vertices. If it does not, then the vertex is not sharing an edge and we can ignore it. If it is between the two vertex positions then we definitely have found a vertex from another polygon that is on the edge we are currently testing in a position where the current edge does not have a vertex. When this is the case, we repair the T-junction by inserting this vertex into the edge just after the edge start vertex. This creates a new edge and a new triangle in the polygon and fixes the problem. Of course, when we insert this new vertex into the

polygon edge we must also generate its normal and texture coordinate. We can do this using interpolation based on its position between the two original vertices of the edge. Notice that testing Polygon A against Polygon B is not enough, we must also test Polygon B against Polygon A performing the same logic. The above algorithm will make sure this happens. The loops ensure that every polygon will be tested against every other polygon, so we will do ultimately perform n^2 tests (where n is the number of polygons).

It should be clear looking at the above code that the heart of this process is simply determining whether the vertex of a polygon lies on the edge of another. This process is reliant on us being able to calculate the distance from a vertex to a line segment (the edge). So we will need a function that will not only tell us the distance from a vertex to an infinite line, but will also inform us whether the point is inside the vertices of the line segment (the edge) assuming this distance is zero. Only if the distance from the vertex to the line is zero and if the point is positioned between the two edge vertices (contained within the line segment) do we wish our function to return a valid distance. So let us have a look at how we might calculate the distance from a point to a line segment.

14.16.3 Distance from a Point to a Line Segment



Calculating the Distance
from a Point to a Line Segment/Ray

Figure 14.77

Figure 14.77 illustrates the problem we are trying to solve. The blue sphere labeled Point is an arbitrary point that we would like to calculate the distance for. The line segment (the polygon edge in our example) has its two vertices shown as the red spheres labeled Start and End. The length of the red dashed line labeled Distance is what we are trying to find. If the distance is zero, then the point must lay on the same line as the edge. It may or may not be between the two vertices, but we will worry about that in a moment. For now, we are just interested in calculating the distance from the point to the infinite line on which the edge is contained.

What we are actually trying to do is calculate the position of the small green sphere in the diagram. This vector describes the projection of the point onto the line and thus, by subtracting this position from the original position, we get a vector matching the red dashed line in the diagram. The length of this vector is the distance we are seeking.

Finding the position of the green sphere is easy given the projection properties of the dot product. We first subtract the start of the line segment (the first vertex in the edge) from the point in question. This gives us vector C in the diagram. The length of this vector would tell us the distance from the origin of the ray/line segment to the point. Vector V in the diagram is calculated by the subtracting the edge start from the edge end position. V is essentially the ray delta vector with the start of the edge as the ray origin. If we normalize vector V, we can perform the dot product between unit length V and vector C to get *t*, the distance to travel in the direction of V from the ray start point to reach the green sphere.

All we have done is projected the length of vector C along the direction of V, which we know scaled it by the cosine of the angle between them. *t* now tells us how far we would have to travel along V from the start point to reach the green sphere. Therefore, we can calculate the position of this sphere simply by scaling unit length V by *t* and adding the resulting scaled V vector to the start of the edge. Now we have the position vector of the green sphere which we subtract from the position vector of the original point, which gives us the vector shown as the red dashed line in the diagram. We can then just return the length of this vector.

However, we also want our function to let the caller know when the point does exist on the infinite line for the edge, but is outside the boundaries of the edge vertices. That is no problem because we will know this as soon as we calculate *t*. Since V is unit length at this point, we know that *t* will be equal to zero at the edge start point and the pre-normalized length of V at the edge end point. Thus, as soon as we calculate *t*, we will return the highest possible distance value (FLT_MAX) if *t* is smaller than zero or greater than the original length of the edge. As our T-junction code will only take any action if the distance returned is zero, the function will only return zero if the point is indeed on the edge (and not just the infinite line on which the edge lies).

Next we see the code to the function. Because this is not a collision function, and would not really fit well in our CCollision namespace, we decided to add such a math utility function to a new cpp file called MathUtility.cpp. As we progress with our studies, we will place any functions we write which are general math utilities in this file. This function is contained in the MathUtility namespace defined in MathUtility.h.

MathUtility.h

```
namespace MathUtility
{
    float DistanceToLineSegment (   const D3DXVECTOR3& vecPoint,
                                    const D3DXVECTOR3& vecStart,
                                    const D3DXVECTOR3& vecEnd );
};
```

MathUtility.cpp – DistanceToLineSegment function code

```
float MathUtility::DistanceToLineSegment(       const D3DXVECTOR3& vecPoint,
                                                const D3DXVECTOR3& vecStart,
                                                const D3DXVECTOR3& vecEnd )
{
    D3DXVECTOR3 c, v;
    float       d, t;

    c = vecPoint  - vecStart;
    v = vecEnd - vecStart;
    d = D3DXVec3Length( &v );

    // Normalize V
    v /= d;

    // Calculate final t value
    t = D3DXVec3Dot( &v, &c );

    // Check to see if 't' is beyond the extents of the line segment
```

```
    if (t < 0.01f)     return FLT_MAX;
    if (t > d - 0.01f) return FLT_MAX;

    // Calculate intersection point on the line
    v.x = vecStart.x + (v.x * t);
    v.y = vecStart.y + (v.y * t);
    v.z = vecStart.z + (v.z * t);

    // Return the length
    return D3DXVec3Length( &(vecPoint - v) );
}
```

The function above mirrors Figure 14.77. It is passed the two position vectors of the line segment (the start and end points) and the point we wish to classify. We first calculate c and v as discussed, then store the length of the line segment (edge) in d. We will need this value later and we are just about to normalize it. We then normalize vector V by dividing it by its length and calculate *t* by dotting unit length vector v with c. This projects the length of c onto v (scaled by the cosine between them), returning a *t* value in the range [0, d] for points that are contained between the two end points.

If *t* is less than zero or larger than the length of the line segment, then it does not matter what the distance to the infinite line is; this point could not possibly be contained in the line segment. Its projection places it on the infinite line either prior to the start vertex or after the end vertex. When this is the case we return a distance of FLT_MAX (the maximum value that can be stored in a float). If this is not the case, then we know that the projection of the point onto the line segment did indeed produce a point (the green sphere in Figure 14.77) that is on the edge. However, we have no idea how far it is from that edge; only if it is at a distance of zero is the point truly on the edge.

Next we calculate the position of the green sphere in Figure 14.77 and store the result in v. We calculate it by scaling v by *t* and adding the result to the start vector of the edge. Now that we have the projected position stored in v, we can simply subtract it from the position of the original point and return the length of the resulting vector. If this length is zero, the point is on the edge and we have ourselves a T-junction that needs repair.

14.16.4 The T-Junction Repair Code

We now have everything we need to write our T-junction repair code. However, when we examine the pseudo-code discussed previously, we realize immediately that it will be an incredibly slow operation. In that vanilla description of the algorithm, we had to test each edge of every polygon against every vertex in every other polygon. Since most of us will be reluctant to wait for an extended amount of time for our T-junctions to be repaired, we need to speed this up as much as possible.

As it happens, by the time the repair process is invoked, the spatial tree will have already been built. Therefore we can reduce the time it takes to compute this process down to a mere fraction of the time it would otherwise take if we incorporate a spatial hierarchy into the process. At the point the repair process is called, each polygon will have already been assigned to its leaves and each polygon will have

a bounding box of its own. Therefore, much like we will implement the broad phase collision step, we will only have to test a mere handful of vertices during the repair process for each polygon's edge.

For each polygon, we will call the CollectLeavesAABB function which will be discussed in detail shortly. This is the function we will implement in our derived classes that will traverse the tree and return any leaves whose AABB intersects the query AABB. In this instance, the query AABB will be the AABB of the polygon we are currently repairing. The CollectLeavesAABB function will return a list of all leaves that intersect the polygon's AABB, allowing us to reject virtually every other polygon in the scene from consideration. Only the polygons in the returned leaves will need to be tested against each other. These are the polygons that are in close proximity to the polygon currently being repaired and might possibly share an edge with it. We will then loop through each polygon in the returned leaves and compare the bounding box of the polygon with the bounding box of the polygon we are currently repairing. Only when the two bounding boxes intersect will we test each vertex in that polygon against each edge in the polygon currently being repaired.

Repair - CBaseTree

The CBaseTree::Repair function is actually a wrapper around the core T-junction repair process. It takes care of looping through each polygon and collecting the leaves that intersect its bounding box. It also takes care of comparing the AABBs of the two polygons to determine whether a T-junction repair test should be done on them. Once it finds two polygons that have intersecting AABBs (and thus the potential to share an edge), it calls the CBaseTree::RepairTJunctions function to actually repair it. We will look at this method after we have examined the code to the main Repair function. This code is an excellent example of how hierarchies can speed up virtually any task done at the scene level.

In the first section of the code we set up a loop to iterate through all the CPolygon pointers stored in the tree's m_Polygons linked list. Remember, this list will contain every polygon being used by the tree. For each polygon in the list we will then extract its AABB. This is our current polygon being tested for repair.

```
bool CBaseTree::Repair( )
{
    ULONG                   SrcCounter, DestCounter, i;
    CPolygon               *pCurrentPoly, *pTestPoly;
    PolygonList::iterator   SrcIterator, DestIterator;
    LeafList::iterator      LeafIterator;
    LeafList                LeafList;

    // No-Op ?
    if (m_Polygons.size() == 0 ) return true;

    try
    {
        // Loop through Faces
        for ( SrcCounter = 0,
              SrcIterator = m_Polygons.begin();
              SrcIterator != m_Polygons.end();
              ++SrcCounter,
```

```
              ++SrcIterator )
        {
            // Get poly pointer and bounds references for easy access
            pCurrentPoly = *SrcIterator;
            if ( !pCurrentPoly ) continue;

            D3DXVECTOR3 & SrcMin = pCurrentPoly->m_vecBoundsMin;
            D3DXVECTOR3 & SrcMax = pCurrentPoly->m_vecBoundsMax;
```

At the head of the function we declared a local variable LeafList, which is a variable of an STL list that stores ILeaf pointers. We make sure this list is empty and then send this list along with the AABB of the current polygon into the CollectLeavesAABB method.

```
            // Retrieve the list of leaves intersected by this poly
            LeafList.clear();
            CollectLeavesAABB( LeafList, SrcMin, SrcMax );
```

The CollectLeavesAABB code will be discussed in a moment since it is implemented in the derived classes. The method fills the passed leaf list with any leaves in the tree which intersect the bounding box of the polygon. On function return, LeafList will contain a list of ILeaf pointers which contain polygons that have the potential to cause T-junctions with the current polygon (i.e., a broad phase).

We will now loop through each leaf in the returned list and extract its pointer so that we can access its data. Notice how LeafList is defined to store ILeaf pointers, but we know that they will contain pointers to CBaseLeaf objects because this is the type of leaf we will allocate and store during the build process. Therefore, we cast the current ILeaf pointer to a CBaseLeaf.

```
            // Loop through each leaf in the set
            for ( LeafIterator = LeafList.begin();
                  LeafIterator != LeafList.end(); ++LeafIterator )
            {
                CBaseLeaf * pLeaf = (CBaseLeaf*)(*LeafIterator);
                if ( !pLeaf ) continue;
```

For the current leaf, we will set up a loop that allows us to retrieve each of its polygon pointers one at a time and perform an AABB/AABB test between it and the current polygon being repaired. Notice how we use our new CCollision::AABBIntersectAABB function to perform the AABB test between the two polygons. If it returns true, the polygon do have intersecting bounding volumes and we will have to feed them both into CBaseTree::RepairTJunctions where they will be tested at the edge/vertex level. The remaining code of the Repair method is shown below.

```
                // Loop through Faces
                DestCounter = pLeaf->GetPolygonCount();

                for ( i = 0; i < DestCounter; ++i )
                {
                    // Get poly pointer and bounds references for easy access
                    pTestPoly = pLeaf->GetPolygon( i );
                    if ( !pTestPoly || pTestPoly == pCurrentPoly ) continue;
                    D3DXVECTOR3 & DestMin = pTestPoly->m_vecBoundsMin;
                    D3DXVECTOR3 & DestMax = pTestPoly->m_vecBoundsMax;
```

```
                    // Do polys intersect
                    if ( !CCollision::AABBIntersectAABB( SrcMin,
                                                         SrcMax,
                                                         DestMin,
                                                         DestMax ) ) continue;

                    // Repair against the testing poly
                    RepairTJunctions( pCurrentPoly, pTestPoly );

                } // Next Test Face

            } // Next Leaf

        } // Next Current Face

    } // End Try Block

    catch ( ... )
    {
        // Clean up and return (failure)
        return false;

    } // End Catch Block

    // Success!
    return true;
}
```

So we have seen that While the CBaseTree::Repair method is called post-build to repair T-junctions, the actual function code really just implements a broad phase testing process for the real T-junction repair code. Our collision system will use the hierarchy in a very similar way. The only polygons we have to test at the edge/vertex level are polygons that have intersecting bounding volumes. This will typically be a few polygons at most for each polygon being tested. That is certainly a lot more efficient than testing every single vertex and every single polygon against every edge of every other polygon in the scene.

RepairTJunctions - CBaseTree

The code to this function is quite small and straightforward. It is passed two polygon pointers. The first polygon is the polygon currently having its edges tested for T-junctions. It is the polygon that will have vertices added to it if a T-junction is identified. The second polygon is the polygon that is going to have each of its vertices tested against each of the edges of the first polygon to see if any of them share that edge and cause a T-junction.

The function begins by setting up a loop to iterate through every edge in the polygon. The loop will step through each vertex and the vertex ahead of it in the array for the edge that is currently being tested.

```
void CBaseTree::RepairTJunctions( CPolygon * pPoly1, CPolygon * pPoly2 )
```

```
{
    D3DXVECTOR3 Delta;
    float       Percent;
    ULONG       v1, v2, v1a;
    CVertex     Vert1, Vert2, Vert1a;

    // Validate Parameters
    if (!pPoly1 || !pPoly2) return;

    // For each edge of this face
    for ( v1 = 0; v1 < pPoly1->m_nVertexCount; v1++ )
    {
        // Retrieve the next edge vertex (wraps to 0)
        v2 = ((v1 + 1) % pPoly1->m_nVertexCount);

        // Store verts (Required because indices may change)
        Vert1 = pPoly1->m_pVertex[v1];
        Vert2 = pPoly1->m_pVertex[v2];
```

v1 is always the index of the current vertex and v2 is the index of the next one in the winding of the polygon. These two vertex indices form the current edge that is to be tested against. Notice that v2 is calculated using the modulus operator so that when v1 is equal to the last vertex in the winding, v2 will wrap around to vertex 0 (the final edge in a polygon is formed by vertex N and vertex 0, where N is the number of vertices in the polygon). In the above code you should notice that once these indices are calculated, we use them to fetch the actual vertex data from the CPolygon's vertex array.

We now have the two vertices of the edge we wish to test, so now we need to loop through each vertex in the second polygon and calculate its distance from the edge. If the DistanceToLineSegment method that we just wrote is passed the two vertices of the edge and the vertex from polygon 2, and it returns zero (with tolerance), the vertex of the second polygon causes a T-junction with the edge and steps must be taken to repair it.

```
        // Now loop through each vertex in the test face
        for ( v1a = 0; v1a < pPoly2->m_nVertexCount; v1a++ )
        {
            // Store test point for easy access
            Vert1a = pPoly2->m_pVertex[v1a];

            // Test if this vertex is close to the test edge
            if ( MathUtility::DistanceToLineSegment(  (D3DXVECTOR3&)Vert1a,
                                                      (D3DXVECTOR3&)Vert1,
                                                      (D3DXVECTOR3&)Vert2 )<0.01f )
            {
```

In this next code block we repair the T-junction. This is done by simply inserting a new vertex in the polygon immediately after the first vertex in the edge we are testing (v1). That is, we must insert it at the position in the vertex array currently occupied by the second vertex v2. This will nudge all vertices in the winding order up by one position in the array, creating the current edge between v1 and the new vertex we have just inserted. It also adds a new edge to the polygon between the new vertex and what used to be the second vertex in the current edge.

The following code demonstrates inserting a new vertex into the polygon and setting its position equal to the vertex in the second polygon that caused the T-junction.

```
                // Insert a new vertex within this edge
                long NewVert = pPoly1->InsertVertex( (USHORT)v2 );
                if (NewVert < 0) throw std::bad_alloc();

                // Set the vertex pos
                CVertex * pNewVert = &pPoly1->m_pVertex[ NewVert ];

                pNewVert->x = Vert1a.x;
                pNewVert->y = Vert1a.y;
                pNewVert->z = Vert1a.z;
```

Because our polygon has a vertex in exactly the same position as the one that caused the T-junction in the second polygon, we have repaired it. However, we also have to generate the texture coordinate information and normal for this newly inserted vertex.

Just as we did in the polygon splitting routine, we create the new normal and texture coordinates for the vertex by interpolating the texture coordinates and normal vectors stored in the original edge vertices based on the distance along that edge where we have inserted the new vertex. In the following code we divide the length of the new edge (vert1 to new vertex) by the length of the original edge (Vert1 to Vert2) to get a *t* value back that describes the position of the new vertex parametrically along the original edge. We use this to weight the interpolation as we have done so many times before. Below we see the remainder of the function.

```
                // Calculate the percentage for interpolation calcs
                Percent = D3DXVec3Length( &(*(D3DXVECTOR3*)pNewVert –
                                            (D3DXVECTOR3&)Vert1) )
                          /
                          D3DXVec3Length( &((D3DXVECTOR3&)Vert2 –
                                           (D3DXVECTOR3&)Vert1) );

                // Interpolate texture coordinates
                Delta.x      = Vert2.tu - Vert1.tu;
                Delta.y      = Vert2.tv - Vert1.tv;
                pNewVert->tu = Vert1.tu + ( Delta.x * Percent );
                pNewVert->tv = Vert1.tv + ( Delta.y * Percent );

                // Interpolate normal
                Delta            = Vert2.Normal - Vert1.Normal;
                pNewVert->Normal = Vert1.Normal + (Delta * Percent);
                D3DXVec3Normalize( &pNewVert->Normal, &pNewVert->Normal );

                // Update the edge for which we are testing
                Vert2 = *pNewVert;

            } // End if on edge
        } // Next Vertex v1a
    } // Next Vertex  v1
}
```

Not only have we learned how to fix T-junctions, we have also finished our coverage of CBaseTree for this chapter. In the next chapter we will add a few more functions and variables to CBaseTree so that it offers an efficient rendering strategy. For now though, we will remain focused on tree building and using trees to perform collision queries.

With the base functionality in place, we can now finally look at the code to the derived classes. For the most part, these classes will contain only a few methods. This is due to the fact that, apart from the building and traversal functions, everything else has already been implemented in CBaseTree.

In the following sections of the textbook we will cover the source code to the quad-tree, the oct-tree and the kD-tree, one at a time and in that order. Most of their implementations will be identical, with only slightly different traversal and build logic. Thus, covering the building process for each tree should be a relatively painless affair after we have covered the build function for the first. Let us start by looking at our first derived class, CQuadTree. This is the class that implements the vanilla quad-tree and it is the first tree class we have developed so far that is designed to be instantiated by the application.

14.17 CQuadTree - Implementation

Contained in the source files CQuadTree.cpp and CQuadTree.h is the code for our vanilla quad-tree implementation. It is derived from CBaseTree as all tree classes will be and as such, there are several functions that we must implement because they are required by ISpatialTree but not implemented in CBaseTree. For example, we must implement the Build method. This method will recursively build a tree of quad-tree nodes using the polygon and detail area data that has been registered with the tree and populate the leaf lists with CBaseLeaf objects. After the Build function has returned, the quad-tree will be complete and we will have a tree of quad-tree nodes. Each node will contain a bounding box large enough to contain the polygon data and detail areas that are assigned to any of its child nodes. At each point during the build process, a node will be divided into four equal quadrants and each quadrant assigned to a child of that node.

Other functions that are specified in ISpatialTree but not implemented in CBaseTree are the collision functions, such as CollectLeavesAABB and CollectLeavesRay. These must also be implemented in this class to provide the traversal logic that steps through the nodes of a quad-tree searching for leaf nodes. These will be small and simple methods since the collision code and much of the core logic resides in CBaseTree and CCollision.

14.17.1 CQuadTree Node – The Source Code

Although CBaseTree implements the CBaseLeaf object that all trees will use to contain the polygon and detail area data at a leaf node, it does not implement a node object that will be used to link the nodes of the hierarchy together. This is because the node structure of each derived class will be different since they have different child counts. A quad-tree for example must store pointers to four child nodes, an oct-tree must store pointers to eight children, and a kD-tree will store only two child node pointers. This

means it is up to the programmer who implements the derived class to also define the node structure the tree will use. The structure we use for the quad-tree nodes is shown below.

```
class CQuadTreeNode
{
public:

    // Constructors & Destructors for This Class.
     CQuadTreeNode( );
    ~CQuadTreeNode( );

    // Public Functions for This Class
    void SetVisible( bool bVisible );

    //Public Variables for This Class
    CQuadTreeNode * Children[4];        // The four child nodes
    CBaseLeaf     * Leaf;               // If this is a leaf, store here.
    D3DXVECTOR3     BoundsMin;          // Minimum bounding box extents
    D3DXVECTOR3     BoundsMax;          // Maximum bounding box extents
    signed char     LastFrustumPlane;   // The frame-to-frame coherence plane
};
```

This very simple structure contains pointers to four children and a CBaseLeaf pointer. The only nodes that will not have NULL assigned to their leaf pointer will be terminal nodes (nodes at the ends of branches that have been made into leaf nodes). When traversing the tree searching for leaf nodes, we know that a leaf node is any node that does not have NULL assigned to its leaf pointer. If it is leaf node, the attached CBaseLeaf object will contain all the polygon data and detail area data assigned to that terminal node. Following the leaf pointer in the declaration are two vectors in which the node's bounding box will be stored and a fifth member that will be explained in detail in the next lesson.

Finally, notice that this class has a method called SetVisible which the tree can call to make all its children visible. A node does not hold a visible status but this function is a recursive function that traverses the children of the node and sets the visibility status of any leaves underneath it to true. This will be used in our visibility testing methods. For example, if a node's volume is completely contained inside the frustum, then all direct and indirect children of that node must also be inside it. When this is the case, we no longer have to perform frustum/AABB tests on each of its children since we know the entire branch starting at that node must be contained in the frustum. When this is the case, this method is called to immediately set the visibility status of all child leaves to true.

Constructor - CQuadTreeNode

The quad-tree node constructor makes sure that its leaf and child pointers are set to NULL and that the last frustum plane index is set to -1 (no plane).

```
CQuadTreeNode::CQuadTreeNode()
{
    unsigned long i;

    // Reset / Clear all required values
```

```
    Leaf             = NULL;
    LastFrustumPlane = -1;

    // Delete children
    for ( i = 0; i < 4; ++i ) Children[i] = NULL;
}
```

Destructor - CQuadTreeNode

The destructors for all of our derived node types will work the same way. When a node is destroyed, it deletes its child nodes, which causes their destructors to trigger, which then deletes their child nodes, and so on down the tree. This causes a cascade effect that removes every node of the tree from memory. Thus, the tree just has to delete the root node to kick off this process. The code is shown below.

```
CQuadTreeNode::~CQuadTreeNode()
{
    unsigned long i;

    // Delete children
    for ( i = 0; i < 4; ++i )
    {
        if ( Children[i] ) delete Children[i];
        Children[i] = NULL;

    } // Next Child

    // Note : We don't own the leaf, the tree does, so we don't delete it here

    // Reset / Clear all required values
    Leaf = NULL;
}
```

Note that if the node is a terminal node and has a leaf attached to it, we do not delete the leaf from memory, we simply set its pointer to NULL. The reason we do not worry about the node deleting its leaf is because the leaf pointers are also stored in the tree's m_Leaves STL list. The tree can delete all the leaves in one go afterwards simply by emptying this list.

Since the constructor and destructor for all of our various node types will be the same as this one (just with more or less children to delete) we will not show the code to the constructors and destructors of other node types from this point forwards.

SetVisible - CQuadTreeNode

Although we will not see the SetVisible method being used until we cover the rendering system of CBaseTree (in the next lesson), its code is very simple so we will cover it here. As you can see, it first tests to see if its leaf pointer is non NULL. If it is, then this is a leaf and we set the leaf's visible status to that of the boolean passed. This means this recursive function can be used to turn on or off the visibility

status of all leaves down a given branch of the tree (using the boolean parameter). If the current node is a leaf node then our job is done and we return. If the current node is not a leaf, then the function calls itself recursively for each of its children.

```
void CQuadTreeNode::SetVisible( bool bVisible )
{
    unsigned long i;

    // Set leaf property
    if ( Leaf  ) { Leaf->SetVisible( bVisible ); return; }

    // Recurs down if applicable
    for ( i = 0; i < 4; ++i )
    {
        if ( Children[i] ) Children[i]->SetVisible(bVisible);

    } // Next Child
}
```

14.17.2 CQuadTree – The Source Code

Below we see the CQuadTree class declaration (see CQuadTree.h) which shows the functions and members we added beyond those inherited from CBaseTree. In the following listing you can see that the first group of methods are those that must be implemented to support the ISpatialTree interface. For example, we know that every derived class must provide the implementation for the Build, CollectLeavesAABB, and the CollectLeavesRay methods since these are the application's only means to build and query the tree. Even methods in CBaseTree, such as the Repair method, rely on the CollectLeavesAABB method being implemented in the derived class so that polygon neighbors can be quickly determined.

Let us look at the public methods implemented to the support the base class first.

```
class CQuadTree : public CBaseTree
{
public:

    // Constructors & Destructors for This Class.
    virtual ~CQuadTree( );
             CQuadTree( LPDIRECT3DDEVICE9 pDevice, bool bHardwareTnL );

    // Public Virtual Functions for This Class (from base).
    virtual bool Build                  ( bool bAllowSplits = true );
    virtual void ProcessVisibility      ( CCamera & Camera );

    virtual bool CollectLeavesAABB      ( LeafList & List,
                                          const D3DXVECTOR3 & Min,
                                          const D3DXVECTOR3 & Max );

    virtual bool CollectLeavesRay       ( LeafList & List,
                                          const D3DXVECTOR3 & RayOrigin,
```

```
                                        const D3DXVECTOR3 & Velocity );
    virtual void DebugDraw              ( CCamera & Camera );

    virtual bool GetSceneBounds         ( D3DXVECTOR3 & Min, D3DXVECTOR3 & Max );
```

The ProcessVisibility method is specified in ISpatialTree and should be called by the application prior to calling the ISpatialTree::DrawSubset method. Although we will not discuss the rendering system until the next chapter, the purpose of this function is to traverse the quad-tree with the passed camera and set the visible status of any leaves according to whether they are currently inside or outside the frustum. The GetSceneBounds function should return the bounding box of the entire area compiled into the quad-tree (which is the bounding volume of the root node). Finally, the DebugDraw method does not have to be implemented in any derived class as it has a default implementation in ISpatialTree which does nothing. However, each of our derived classes will override this method so that we can traverse the tree and render their leaf node bounding boxes to visualize what we have created.

Below we see the private class methods. These are basically the methods that the public methods shown above use to accomplish their tasks. The functions listed above are really just doorways to the private recursive procedures. For example, the Build method creates the root node and builds the initial polygon list for that node and then calls the BuildTree function which recursively calls itself until the tree is complete. The same is true of the CollectLeavesAABB method which is really a one line function that makes sure the CollectAABBRecurse method is first called using the root node.

```
private:

    // Private Functions for This Class
    bool         BuildTree              ( CQuadTreeNode * pNode,
                                          PolygonList PolyList,
                                          DetailAreaList AreaList,
                                          const D3DXVECTOR3 & BoundsMin,
                                          const D3DXVECTOR3 & BoundsMax );

    void         UpdateTreeVisibility   ( CQuadTreeNode * pNode,
                                          CCamera & Camera,
                                          UCHAR FrustumBits = 0x0 );

    bool         DebugDrawRecurse       ( CQuadTreeNode * pNode,
                                          CCamera & Camera,
                                          bool bRenderInLeaf );

    bool         CollectAABBRecurse     ( CQuadTreeNode * pNode,
                                          LeafList & List,
                                          const D3DXVECTOR3 & Min,
                                          const D3DXVECTOR3 & Max
                                                bool           bAutoCollect = false
);

    bool         CollectRayRecurse      ( CQuadTreeNode * pNode,
                                          LeafList & List,
                                          const D3DXVECTOR3 & RayOrigin,
                                          const D3DXVECTOR3 & Velocity );
```

Because CBaseTree provides us with the leaf list, detail area list, and polygon list in which to store our data, we only need to add a few more members in this class. The first is a CQuadTreeNode pointer which will point to the root node of the tree once it has been built. Given our extensive exposure to hierarchies in this course, we know that we only need to store the root node to a tree/hierarchy for its methods to be able to perform a complete traversal of every node in the tree. We also add a boolean member called m_bAllowSplits which simply stores whether a clipped tree is being built. This is determined by the value of the boolean parameter passed into the build function, which is stored in this member. The remainder of the class declaration is shown below.

```
      //-----------------------------------------------------------------------
      // Private Variables for This Class
      //-----------------------------------------------------------------------
      CQuadTreeNode * m_pRootNode;      // The root node of the tree
      bool            m_bAllowSplits;   // Is splitting allowed?

      // Stop Codes
      float          m_fMinLeafSize;     // Min leaf size stop code
      ULONG          m_nMinPolyCount;    // Min polygon count stop code
      ULONG          m_nMinAreaCount;    // Min detail area count stop code
};
```

Notice that we now have three members at the very bottom which store a minimum leaf size, a minimum polygon count, and a minimum detail area count. The values of these members will be passed in as parameters to the constructor by the application to provide a degree of control over the way the tree is built. When the tree is being compiled, a decision must be made at each node as to whether the node satisfies the requirements to become a leaf node. We implement three stop codes to that can be set by the application to influence this decision. If any of these stop codes are reached, the current node will have no children generated for it and will be made a leaf node. The three stop codes we use for the quad-tree are defined in CQuadTree.h and are discussed next.

The first stop code is the size of the leaf. We currently set our default such that, if the bounding volume of a node is determined to have a diagonal length (e.g., bottom left to top right) of less than 300 world space units, we decide that this node's volume is so small that we do not wish to further subdivide and create any more children down that branch of the tree. When this is the case, the node's child pointers are set to NULL and a new CBaseLeaf object is created and attached to the node. The leaf is also added to the tree's leaf list and the leaf itself has the pointers for all polygons and detail areas that made it into that node added to its internal arrays.

The second stop code occurs during the creation of a node when we determine that less than a specified number of polygons have made it into that node. The default value for this is 600. This means that regardless of how large a node's volume might be, if it contains less than 600 polygons we decide that further subdividing this polygon set would be futile and the node is made a leaf, exactly as described in the previous paragraph.

The third stop code is one that allows us to stop subdividing a node's volume if less than a certain number of detail areas exist in that node. By default we set this to zero so that detail areas play no part in determining whether a node should be made a leaf node. However, if you were to set this value to 1 (for example) then whenever a node was encountered that had only one detail area in it and the polygon list was lower than the polygon count stop code, a leaf node will be created. This stop code may be a little

hard to understand, and most of the time it will go unused and be set to zero. However, it can become very useful when you are building a tree that has no polygon data and consists only of detail areas, since it allows us to control the size of the leaf nodes under those conditions. For example, consider what happens if we compiled our terrain into a quad-tree. As discussed previously in this lesson, we will not want to compile every terrain polygon into the tree since the terrain data is already organized into a series of render ready terrain blocks (sub-meshes). What we might decide to do instead is just build a tree of detail areas. We could for example create a bounding box around each terrain block and register each of these volumes as detail areas with the tree. When the tree is compiled (which contains no polygon data) the only stop code would be the leaf size. However, this might carve up the space into many more leaves than necessary such that a given terrain block's volume could be contained in many leaves. If all we are using the tree for is quickly querying which terrain block is visible, we would rather have each terrain block fit into a single leaf equal to its size. Ideally, if the terrain was divided into a 10x10 grid of terrain blocks, we would like that space divided up into a grid of 10x10 terrain block sized leaf nodes. In this situation we could set the detail area count stop code to 1, and as soon as a node had only one detail area assigned to it, it would be made into a leaf node containing that single detail object. This means our tree would contain a leaf node for each terrain block allowing us to keep the tree as shallow as possible and therefore speeding up tree traversals.

The Constructor - CQuadTree

The CQuadTree constructor accepts two required parameters and three optional parameters. The first is a pointer to a Direct3D device which the rendering system will use to render the tree. The second is a boolean describing whether this is a hardware or software device. This information will be needed by the rendering system when creating the index and vertex buffers that will store the geometry for the render system.

```
CQuadTree::CQuadTree( LPDIRECT3DDEVICE9 pDevice,
                      bool bHardwareTnL
                      float fMinLeafSize /* = 300.0f */,
                      ULONG nMinPolyCount /* = 600 */,
                      ULONG nMinAreaCount /* = 0 */ ) : CBaseTree( pDevice, bHardwareTnL )
{
    // Clear required variables
    m_pRootNode = NULL;

    // Store stop code values
    m_fMinLeafSize  = fMinLeafSize;
    m_nMinPolyCount = nMinPolyCount;
    m_nMinAreaCount = nMinAreaCount;
}
```

The device pointer and its boolean hardware status are immediately sent to the CBaseTree constructor where they are stored in CBaseTree member variables. These will be used after the tree is built to set up the render system. The final three parameters contain the stop codes that the application can pass to influence which nodes are candidates for becoming leaf nodes during a build. We simply store these values in their corresponding member variables.

In our coverage of CBaseTree we learned that the CBaseTree::PostBuild method was to be called after the derived class's Build method completed its task and built the tree (CBaseTree::PostBuild will be called from the CQuadTree::Build function just before it returns). The PostBuild method issues a call to the CBaseTree::BuildRenderData method which we will cover in the next lesson. This method will build the render data if NULL was not passed as the device pointer. Therefore, we can inform the tree that it will not be used for rendering by passing NULL as the first parameter and save the memory that would otherwise be allocated to prepare and contain the tree data in a renderable format.

Destructor – CQuadTree

At first glance, the CQuadTree destructor appears to neglect to free a lot of its memory. It simply deletes the root node, which triggers the deletion of every node in the tree.

```
CQuadTree::~CQuadTree()
{
    // Release any resources
    if ( m_pRootNode ) delete m_pRootNode;

    // Clear required variables
    m_pRootNode = NULL;
}
```

What about the leaves, the polygons and the detail area? Keep in mind that our classes all have virtual destructors, so the base class's destructor will automatically be called. CBaseClass actually manages the polygon, detail area, and leaf list data, so it is this destructor that releases them (shown below).

As you can see, the base class destructor first loops through the linked list of polygons used by the tree and deletes each one before emptying the pointer list and freeing up its memory.

```
CBaseTree::~CBaseTree()
{
    PolygonList::iterator       PolyIterator = m_Polygons.begin();
    LeafList::iterator          LeafIterator = m_Leaves.begin();
    DetailAreaList::iterator    AreaIterator = m_DetailAreas.begin();
    ULONG                       i;

    // Iterate through any stored polygons and destroy them
    for ( ; PolyIterator != m_Polygons.end(); ++PolyIterator )
    {
        CPolygon * pPoly = *PolyIterator;
        if ( pPoly ) delete pPoly;

    } // Next Polygon

    m_Polygons.clear();
```

We then iterate through every detail area in the tree's detail area STL list, delete each one and empty that list too.

```
    // Iterate through any stored detail area objects and release
    for ( ; AreaIterator != m_DetailAreas.end(); ++AreaIterator )
    {
        TreeDetailArea * pDetailArea = *AreaIterator;
        if ( pDetailArea ) delete pDetailArea;

    } // Next detail area
    m_DetailAreas.clear();
```

And of course, we do the same for the list of leaves.

```
    // Iterate through the leaves and destroy them
    for ( ; LeafIterator != m_Leaves.end(); ++LeafIterator )
    {
        CBaseLeaf * pLeaf = (CBaseLeaf*)(*LeafIterator);
        if ( pLeaf ) delete pLeaf;

    } // Next Leaf

    m_Leaves.clear();
```

We then release the 3D device that the base tree render system will use. This device was passed in and stored in the constructor. We will see it being used in the following lesson.

```
    // Release other D3D Objects
    if ( m_pD3DDevice ) m_pD3DDevice->Release();

    // Clear required variables
    m_pD3DDevice        = NULL;
}
```

Just remember later when examining the destructors of each derived class, that this base class constructor will always be called too. This is how the main memory for much of the tree gets released. All the derived class has to do in its destructor is delete the root node.

Build - CQuadTree

We finally find ourselves at the point where we can discuss the code that actually builds a tree. The application should call the CQuadTree::Build function only after it has registered all static polygon and detail area data with the tree (using the AddPolygon and AddDetailArea methods inherited from the base class). It is important that at the time this function is called, the object's m_Polygons STL list contains all of the static polygon data we wish to compile into the tree and the m_DetailAreas array contains all of the detail areas that we would like compiled into the tree.

This function is not the recursive function that calls itself until the tree is fully built, but it is the function that allocates the root node and prepares the scene data for the recursive process (invoked by a call to the CQuadTree::BuildTree method). This function has the following tasks to perform:

1. Allocate a new CQuadTreeNode for the root node of the tree.

2. Loop through each polygon in its list and compile an AABB for the data.

3. Loop through each detail area and possibly adjust the AABB computed in step 2 so that all polygon data and detail areas are contained inside the bounding box (this will be the bounding box of the root node).

4. Build a list of all the polygons contained in this node (which will actually be a new temporary list containing all the polygons in the entire scene). Since this is the root node, this list will initially be a copy of the complete m_Polygons list (more on this in a moment). It is this list that will be passed down the tree and divided into four child lists at each node.

5. Compile a list of all the detail area in the root node. This list will initially be an exact copy of the m_DetailAreas list to begin with since this is the root node. As this list is passed down the tree, it will be divided into four lists at each node, one for each child.

6. Call the recursive BuildTree function passing the node pointer (step 1), the list of polygons and detail areas (steps 4 and 5) and the bounding box (steps 2 and 3). The recursive function will then store that passed AABB in the node and will sort the passed polygon and detail area lists into four lists, one for each child it creates. Then it will call itself recursively for each child, passing in the child node and the polygon and detail area lists for that node.

7. When the recursive function returns, call the CBaseTree::PostBuild method. This will instruct the base class to calculate the polygon bounding boxes and initialize the render system. If a valid device pointer was passed to the constructor, the initialization of the render system will be triggered which will also issue a call to the CBaseTree::Repair method to repair all T-junctions that exist in the tree's polygon set.

Before we look at the code, we have one more small matter to address. If a clipped tree is not being compiled, then after the build is finished, the m_Polygons list should and will contain the same polygon pointers that were originally registered with the tree (i.e., the building process will not alter the polygons stored in this list). The CPolygon pointers stored in this list will be passed down the tree and a copy of each polygon pointer will be stored in the leaves in which it is contained. As the polygon data is never clipped or altered, the m_Polygons array will not be altered by the build process and will always contain the polygons contained in the tree even after the build process.

However, if we pass true as the (only) parameter into the Build function, we are informing the tree that we would like the polygon data clipped to the leaf nodes so that no polygon will ever be stored in more than one leaf. We know that when we clip a polygon, we get back two new polygons and the original polygon is deleted and replaced by the two new clips. After the build process has completed in the case of a clipped tree, we do not want the m_Polygons array to contain the same polygons that were registered with the scene as these will no longer describe the polygons being used by the tree. Several polygons in that list will have been deleted the moment they were split, and many new polygons would have been added.

Fortunately there is not much to worry about. As we discussed in the steps above, we copy the polygon pointers into a temporary polygon list for the root node anyway, and it is this list that is passed down the tree. Therefore, in the clipped case, once we have made that temporary copy of the list, we will empty the m_Polygons list so that it contains no data. During the build process, polygons in the temporary list that gets passed to each node will be deleted and split into two new polygons which will all be added to these temporary lists. However, as soon as we find a leaf node, we will be passed a list of clipped polygons that fit exactly inside that leaf. We will then add these pointers to the m_Polygons list as and when they make it into a leaf. That way, as each leaf is created, its new split polygons are added back into the m_Polygons list, leaving us with an m_Polygons list at the end of the build process which contains all the polygons actually being used by the tree. This will be a very different list versus the original polygon set prior to the build process.

Let us now look at the code a section at a time.

The function is passed a single parameter which determines whether a clipped or non-clipped tree should be built. If this boolean is set to false (the default) a non-clipped tree will be built. Take a look at the variables we declare on the stack at the head of the function.

```
bool CQuadTree::Build( bool bAllowSplits /* = false */ )
{
    PolygonList::iterator       PolyIterator = m_Polygons.begin();
    DetailAreaList::iterator    AreaIterator = m_DetailAreas.begin();
    PolygonList                 PolyList;
    DetailAreaList              AreaList;
    unsigned long               i;

        // Reset our tree info values.
    D3DXVECTOR3 vecBoundsMin( FLT_MAX, FLT_MAX, FLT_MAX );
    D3DXVECTOR3 vecBoundsMax( -FLT_MAX, -FLT_MAX, -FLT_MAX );
```

We declare two iterators that will be used to step through the m_Polygons and m_DetailAreas lists. These lists contain the data we wish to compile. However, we also instantiate a local scope polygon list and detail area list that will be used to contain copies of the m_Polygons and m_DetailAreas lists respectively. We then set the vecBoundsMax and vecBoundsMin vectors which will be used to record the size of the root node's volume (an inside out box initially).

Next we allocate the root node of the tree and store its pointer in the CQuadTree member variable. We also copy the value of the bAllowSplits boolean into the m_bAllowSplits member variable.

```
    // Allocate a new root node
    m_pRootNode = new CQuadTreeNode;
    if ( !m_pRootNode ) return false;

    // Store the allow splits value for later retrieval.
    m_bAllowSplits = bAllowSplits;
```

Our next task is to loop through every polygon in the m_Polygons list and adjust the extents of the bounding box such that it is large enough to contain the vertices of all polygons in the scene. At the end of the following loop, vecBoundsMin and vecBoundsMax will represent a box that bounds all the

polygon data in the root node. Note that as we process each CPolygon pointer in m_Polygons and adjust the box to fit it, we add its pointer to the local polygon list declared at the top of the function. Therefore, at the end of this loop, we will have also made a copy of all the polygon pointers contained in m_Polygons into the local PolyList.

```
    // Loop through all of the initial polygons
    for ( ; PolyIterator != m_Polygons.end(); ++PolyIterator )
    {
        // Retrieve the polygon
        CPolygon * pPoly = *PolyIterator;
        if ( !pPoly ) continue;

        // Calculate total scene bounding box.
        for ( i = 0; i < pPoly->m_nVertexCount; ++i )
        {
            // Store info
            CVertex * pVertex = &pPoly->m_pVertex[i];
            if ( pVertex->x < vecBoundsMin.x ) vecBoundsMin.x = pVertex->x;
            if ( pVertex->y < vecBoundsMin.y ) vecBoundsMin.y = pVertex->y;
            if ( pVertex->z < vecBoundsMin.z ) vecBoundsMin.z = pVertex->z;
            if ( pVertex->x > vecBoundsMax.x ) vecBoundsMax.x = pVertex->x;
            if ( pVertex->y > vecBoundsMax.y ) vecBoundsMax.y = pVertex->y;
            if ( pVertex->z > vecBoundsMax.z ) vecBoundsMax.z = pVertex->z;

        } // Next Vertex

        // Store this polygon in the top polygon list
        PolyList.push_back( pPoly );

    } // Next Polygon

    // Clear the initial polygon list if we are going to split the polygons
    // as this will eventually become storage for whatever gets built
    if ( bAllowSplits ) m_Polygons.clear();
```

Notice what we do in the very last line of code show above. If a clipped tree is being built, we empty m_Polygons so that it no longer contains any polygon data. We can do this because we now have a copy of each pointer in the local list. m_Polygons will be repopulated with the clipped polygon data as each leaf node is encountered and created. If a clipped tree is not being built, we do not empty this list since it will be unchanged during the build process.

We now have a bounding box for the root node polygon data but we must also make sure that it is large enough to also bound any registered detail areas. So we now loop through each registered detail area and adjust the root node's bounding box to contain the bounding boxes of all detail areas. As with the above loop, as we process each detail area, we also copy its pointer into the local detail area list (DetailList) so that we have a complete list of detail areas which can be passed into the recursive process.

```
    // Loop through all of the detail areas
    for ( ; AreaIterator != m_DetailAreas.end(); ++AreaIterator )
    {
        // Retrieve the detail area
        TreeDetailArea * pDetailArea = *AreaIterator;
```

```
        if ( !pDetailArea ) continue;

        // Calculate total scene bounding box.
        D3DXVECTOR3 & Min = pDetailArea->BoundsMin;
        D3DXVECTOR3 & Max = pDetailArea->BoundsMax;

        if ( Min.x < vecBoundsMin.x ) vecBoundsMin.x = Min.x;
        if ( Min.y < vecBoundsMin.y ) vecBoundsMin.y = Min.y;
        if ( Min.z < vecBoundsMin.z ) vecBoundsMin.z = Min.z;
        if ( Max.x > vecBoundsMax.x ) vecBoundsMax.x = Max.x;
        if ( Max.y > vecBoundsMax.y ) vecBoundsMax.y = Max.y;
        if ( Max.z > vecBoundsMax.z ) vecBoundsMax.z = Max.z;

        // Store this in the top detail area list
        AreaList.push_back( pDetailArea );

    } // Next Polygon
```

At this point we have a root node pointer, a bounding box large enough to contain all the data contained in that node, and a complete list of all the registered polygons and detail areas stored in the PolyList and AreaList local lists. We are now ready to start the internal build process, so we pass this information into the BuildTree recursive function.

```
    // Build the tree itself
    if ( !BuildTree(m_pRootNode, PolyList, AreaList, vecBoundsMin, vecBoundsMax ))
         return false;
```

This function call will store the passed bounding box in the passed node, which means in its first iteration it will store the bounding box we have just compiled in the root node. It will then divide this bounding box into four quadrants creating the bounding boxes for each of the four child nodes. Then it will classify the polygon list and the detail area list against each bounding box, creating four separate polygon and detail area lists for each child. The four child nodes are then created and the BuildTree function calls itself recursively for each child and the process repeats until the function determines it has been passed a node that should be made into a leaf. This function will be covered in a moment, but for now just know that when it returns program flow back to CQuadTree::Build, the entire hierarchy of nodes will have been created and m_Polygons will contain the polygon data being used by the tree.

At this point, the tree is fully constructed. Before we return program flow back to the application, we issue a call to the CBaseTree::PostBuild function which instructs the base class to calculate the bounding boxes of each polygon and prepare the data for rendering (which includes T-junction repair).

```
    // Allow our base class to finish any remaining processing
    return CBaseTree::PostBuild();
}
```

The recursive CQuadTree::BuildTree function is true core of this system, so let us cover that next.

BuildTree – CQuadTree

BuildTree is the main tree compilation function. It is passed a node, a list of polygons and detail areas that fit in the bounding volume of that node, and the extent vectors of its volume. The function will first assign the passed volume to the passed node. Thus, the first time this function is called, BoundsMin and BoundsMax will be assigned to the root node as its bounding volume. It also means that the first time it is called, PolyList and AreaList will contain the entire scene since the root node's volume bounds everything (assuming you are using the tree for an entire scene of course). In the case of the root node, its bounding volume was calculated in the previously discussed function and passed in along with the node. For all other nodes however, this function will generate the bounding boxes and polygon lists for each of its child nodes and call itself recursively. Therefore, the second time this function is called it will be called by the previous instance of the function. The node pointer passed will not be the root, it will be the first child of the root. The PolyList and AreaList will contain only the geometry that was contained in the root node's first child, and BoundsMax and BoundsMin will be the bounding volume of that child node quadrant.

Let us first look at the variables that are allocated on the stack. We will need to be able to iterate through the passed polygon and detail area lists so that we can divide them into four sub-lists (one per child), so we instantiate two iterators for this purpose. We will also need four temporary lists to hold the polygon data for each child node and the detail areas for each child node, so you can see that we instantiate an array of four PolygonLists (an STL list of CPolygons) and four DetailAreaLists (an STL list of detail area structures). We allocate two D3DXPLANE structures that will be used to create and store the two split planes at this node that divide the node into four quadrants. We will see these being used in a moment.

Again, the first thing we do in the following code is assign the passed volume to the passed node.

```
bool CQuadTree::BuildTree( CQuadTreeNode * pNode,
                           PolygonList PolyList,
                           DetailAreaList AreaList,
                           const D3DXVECTOR3 & BoundsMin,
                           const D3DXVECTOR3 & BoundsMax )
{
    D3DXVECTOR3                 Normal;
    PolygonList::iterator       PolyIterator;
    DetailAreaList::iterator    AreaIterator;
    CPolygon                  * CurrentPoly, * FrontSplit, * BackSplit;
    PolygonList                 ChildList[4];
    DetailAreaList              ChildAreaList[4];
    CCollision::CLASSIFYTYPE    Location[2];
    D3DXPLANE                   Planes[2];
    unsigned long               i;
    bool                        bStopCode;

    // Store the bounding box properties in the node
    pNode->BoundsMin = BoundsMin;
    pNode->BoundsMax = BoundsMax;
```

Before we start subdividing space we need to determine whether or not the leaf is so small or its polygon list contains so few polygons that this node should be made a terminal node (a leaf). We discussed earlier that there are three stop codes that if true, prevent us creating any more children. We simply store the passed polygon data in the node, making it a leaf. Therefore, we first calculate the diagonal length of the current node's bounding box and test this against the m_fMinLeafSize stop code.

```
    // Calculate 'Stop' code
    D3DXVECTOR3 vecLeafSize = D3DXVECTOR3( BoundsMax.x - BoundsMin.x,
                                           0,
                                           BoundsMax.z - BoundsMin.z );

    bStopCode  = (AreaList.size() == 0 && PolyList.size() == 0) ||
                 (AreaList.size() <= m_nMinAreaCount  &&
                  PolyList.size()<= m_nMinPolyCount ) ||
                  D3DXVec3Length( &vecLeafSize ) <= m_fMinLeafSize;
```

Let us analyze the multiple conditionals being used above. First, if there are no detail areas in the passed area list and no polygons in the passed polygon list, the node is totally empty and the boolean bStopCode will be set to true. In that case, we will create a leaf here. This boolean is also set to true if the number of detail areas is less then or equal to the m_nMinAreaCount stop code or if the number of polygons is less than or equal to the minimum polygon count amount. So, if we have too few polygons and too few detail areas in this node (as defined by the stop codes), we set bStopCode to true since we wish to halt subdivision and make this node a leaf. The final test that sets bStopCode to true happens when the length of the diagonal vector from the node's extents is less than or equal to the minimum leaf size stop code. Notice that because we are using a quad-tree, all nodes will have the same height and we do not factor in the y components of the extents (we set the vecLeafSize vector's Y component to zero). For a quad-tree, the diagonal vector projected on to the XZ plane is all we are concerned with.

At this point we have a boolean that tells us whether we should continue to divide this node into four children or whether we should just make a new leaf here and return.

In the next section of code we see what happens if this node is to become a leaf. We first allocate a new CBaseLeaf structure, passing in a pointer to the current tree instance, and then loop through every polygon in the passed list and add it to the leaf's polygon array using the CBaseLeaf::AddPolygon function. At the end of this loop all the polygons that made it into the node will be stored in a new CBaseLeaf.

```
    // If we reached our stop limit, build a leaf here
    if ( bStopCode )
    {
        // Build a leaf
        CBaseLeaf * pLeaf = new CBaseLeaf( this );
        if ( !pLeaf ) return false;

        // Store the polygons
        for ( PolyIterator = PolyList.begin();
              PolyIterator != PolyList.end();
              ++PolyIterator )
        {
            // Retrieve poly
```

```
            CurrentPoly = *PolyIterator;
            if ( !CurrentPoly ) continue;

            // Add to full tree polygon list ONLY if splitting is allowed
            if ( m_bAllowSplits ) AddPolygon( CurrentPoly );

            // Also add a reference to the leaf's list
            pLeaf->AddPolygon( CurrentPoly );

        } // Next Polygon
```

Notice something very important in the above code. If a clipped tree is being built, we need to repopulate the tree's m_Polygons array which was emptied at the start of the build process. We do this using the CBaseTree::AddPolygon function. This way, when all leaves have been created for the tree, the m_Polygons list will be fully populated with all the polygon fragments that made it into each clipped leaf. Obviously, we do not add the polygons to the tree's list if we are not building a clipped tree as they are already stored there.

Our next task is to loop through each detail area that made it into this node's list and add each of those to the new leaf's detail area array. The CBaseLeaf::AddDetailArea method which we covered earlier will be used to perform this task.

```
        // Store the area lists
        for ( AreaIterator = AreaList.begin();
              AreaIterator != AreaList.end(); ++AreaIterator )
        {
            // Retrieve detail area item
            TreeDetailArea * pDetailArea = *AreaIterator;
            if ( !pDetailArea ) continue;

            // Add a reference to the leaf's list
            pLeaf->AddDetailArea( pDetailArea );

        } // Next Polygon
```

At this point we have a new leaf and it contains (in its internal arrays) a list of all the CPolygon pointers and detail area pointers that made it into this node. We will now assign the node's Leaf pointer to point at our new leaf object and set the bounding box of the leaf to be the same as the node's bounding box (using the CBaseLeaf::SetBoundingBox method to perform this task). Finally, with the leaf attached the node and its internal structures populated with the node's data, we add this leaf object's pointer to the tree's leaf list for easier access and cleanup. We implemented the CBaseTree::AddLeaf method earlier to take care of adding a leaf pointer to the tree's leaf list.

At this point the leaf has been created and the node's child pointers will still be NULL, and that is how they should remain. This is an end of branch of the tree and we can simply return because our terminal node has been created. This halts the recursive process down this particular branch of the tree.

```
        // Store pointer to leaf in the node and the bounds
        pNode->Leaf = pLeaf;

        // Store the bounding box in the leaf
```

```
        pLeaf->SetBoundingBox( pNode->BoundsMin, pNode->BoundsMax );

        // Store the leaf in the leaf list
        AddLeaf( pLeaf );

        // We have reached a leaf
        return true;

    } // End if reached stop code
```

If we reach this point in the code, then it means we are not in a leaf node and as such, we need to divide the node's volume into four quadrants so that we can build appropriate polygon and detail area lists as well as new bounding volumes.

These four quadrants describe the bounding volumes of the four child nodes we will create and attach to this node.

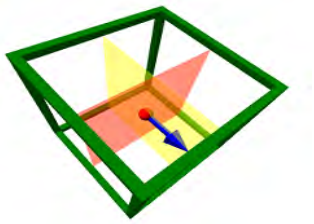


Figure 14.78

As discussed earlier in the lesson, we will determine which quadrant each polygon is in by creating two split planes that are aligned with the world X and Z axes and pass through the center point of the current node's bounding volume. The two split planes are shown in Figure 14.78. We will classify each polygon in this node's list against these two planes to determine in which quadrants they exist and to which child polygon list they should be assigned.

The next section of code generates the two split planes and stores them in the two element local Planes array. Plane[0] has its normal pointing in the direction of the Z axis (XY plane) and Plane[1] is aligned with the world YZ plane with its normal pointing down the X axis. The point on each plane which helps fully describe the plane to the D3DXPlaneFromPointNormal function is the same for each plane: the center point of the node's volume calculated by adding its maximum extents to its minimum extents and dividing the result by two. The D3DXPlaneFromPointNormal function will return a D3DXPLANE structure that describes the plane, not in point/normal format, but in normal/distance format.

```
    // Generate the two split planes
    D3DXPlaneFromPointNormal( &Planes[0], &((BoundsMin + BoundsMax) / 2.0f),
                                          &D3DXVECTOR3( 0.0f, 0.0f, 1.0f ) );

    D3DXPlaneFromPointNormal( &Planes[1], &((BoundsMin + BoundsMax) / 2.0f),
                                          &D3DXVECTOR3( 1.0f, 0.0f, 0.0f ) );
```

> **Note:** Because we have to give some descriptive names to the quadrants of our node to make things a little easier to explain, we will refer to each quadrant using a name that is relative to an imaginary individual positioned at the center of the node looking in the direction of Plane[0]'s normal. As Plane[0] faces down the positive Z axis, the quadrants behind this plane will be referred to as 'BehindLeft' and 'BehindRight'. The two quadrants in front of Plane[0] will be labelled 'InfrontLeft' and 'InfrontRight'.

If we were only supporting non-clipped trees, then our next task would be to loop through each polygon in the node's list, classify it against both planes and use the two results to determine which quadrants the polygon falls into. The polygon would then have its pointer added to the appropriate lists for those quadrants (remember that we allocated an array of four empty polygon lists on the stack which we will

fill in this function with the polygon contained in each quadrant). However, if the m_bAllowSplits member is set to true, it means the application would like this tree built so that no polygon is ever spanning node boundaries. As such, all the polygons in the node's list that are spanning any of the two node planes should be split. The original polygon that was spanning the plane should then be deleted from the list and replaced with the two new polygons that it was split into.

The next section of code is executed only in the case when a clipped tree is being built. It loops through each polygon in this node's list and classifies each polygon against the current plane being tested. If a polygon is found to be spanning the current plane we are testing, we split it into two, delete it, set its pointer entry in the list to NULL and then add the two new child polygons to the list. These child polygons will possibly be split again when the second plane is tested. We discussed code almost identical to this at the beginning of this lesson, so you should have no problem understanding how it works. Notice that the task is made very easy due the functions we have previously written (CPolygon::Split and CCollision::PolyClassifyPlane).

```
    // Split all polygons against both planes if required
    if ( m_bAllowSplits )
    {
        for ( i = 0; i < 2; ++i )
        {
            for ( PolyIterator = PolyList.begin();
                  PolyIterator != PolyList.end(); ++PolyIterator )
            {
                // Store current poly
                CurrentPoly = *PolyIterator;
                if ( !CurrentPoly ) continue;

                // Classify the poly against the first plane
                Location[0] = CCollision::PolyClassifyPlane
                            (
                               CurrentPoly->m_pVertex,
                               CurrentPoly->m_nVertexCount,
                               sizeof(CVertex),
                               (D3DXVECTOR3&)Planes[i],
                               Planes[i].d
                            );

                if ( Location[0] == CCollision::CLASSIFY_SPANNING )
                {
                    // Split the current poly against the plane,
                    // delete it and set it to NULL in the list
                    CurrentPoly->Split( Planes[i], &FrontSplit, &BackSplit );
                    delete CurrentPoly;
                    *PolyIterator = NULL;

                    // Add these to the end of the current poly list
                    PolyList.push_back( FrontSplit );
                    PolyList.push_back( BackSplit );

                } // End if Spanning

            } // Next Polygon
```

```
        } // Next Plane

    } // End if allow splits
```

At this point, if we are building a clipped tree, any polygons in the list that were spanning the node planes will have been deleted and replaced with polygons that fit neatly into each leaf. If this is not a clipped tree, then it does not matter if a polygon is spanning a node plane as we will just assign it to all the child node lists in which it belongs.

Our next task is to loop through each polygon in the list and classify it against both of the node's split planes. We store the classification results in a local ClassifyType array called Location.

```
    // Classify the polygons and sort them into the four child lists.
    for ( PolyIterator = PolyList.begin();
          PolyIterator != PolyList.end(); ++PolyIterator )
    {
        // Store current poly
        CurrentPoly = *PolyIterator;
        if ( !CurrentPoly ) continue;

        // Classify the poly against the planes
        Location[0] = CCollision::PolyClassifyPlane( CurrentPoly->m_pVertex,
                                                     CurrentPoly->m_nVertexCount,
                                                     sizeof(CVertex),
                                                     (D3DXVECTOR3&)Planes[0],
                                                     Planes[0].d );

        Location[1] = CCollision::PolyClassifyPlane( CurrentPoly->m_pVertex,
                                                     CurrentPoly->m_nVertexCount,
                                                     sizeof(CVertex),
                                                    (D3DXVECTOR3&)Planes[1],
                                                     Planes[1].d );
```

At this point we know the current polygon's relationship to both the split planes and have the results stored, so we can figure out which quadrant it is in and which of the child polygon lists to add it to. Location[0] tells us whether it is in the back or front halfspace of the node, while Location[1] tells us in which halfspace within that halfspace (left or right) the polygon belongs.

Since the first plane split plane is aligned to the world XY plane, we know that if it is spanning the plane (only possible in the non-clipped tree case) or it is behind this plane, then it will need to have its pointer assigned to either the BehindLeft or BehindRight lists. Once we know it is behind the XY plane, we then test its classification against the YZ plane. If it is behind this plane then it must be in the BehindLeft quadrant; otherwise it must be in the BehindRight quadrant. In either case, we add it to the relevant list. ChildList[0] will contain the polygons found to be in the BehindLeft quadrant and ChildList[1] is assigned polygons that are contained in the BehindRight quadrant.

```
        // Position relative to XY plane
        if ( Location[0] == CCollision::CLASSIFY_BEHIND ||
             Location[0] == CCollision::CLASSIFY_SPANNING )
        {
```

```
            // Position relative to ZY plane
            if ( Location[1] == CCollision::CLASSIFY_BEHIND ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                                ChildList[0].push_back( CurrentPoly );

            if ( Location[1] == CCollision::CLASSIFY_INFRONT ||
                 Location[1] == CCollision::CLASSIFY_ONPLANE ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                                ChildList[1].push_back( CurrentPoly );

        } // End if behind or spanning
```

Notice in the above code that if a polygon is found to lie on the plane YZ plane we assign it to the node in front of the plane. An on plane polygon is essentially on the border between two nodes and we need to assign it somewhere. It does not really matter which node we choose to assign it to because if that polygon is visible, it would mean that the leaves both in front and behind that node would always be collected anyway. Likewise, if a collision query is performed and the swept sphere did intersect that polygon, it would automatically mean that it is spanning those leaves and those leaves would be collected.

If the above code was not executed it must mean the polygon is in front of the XY node plane (Plane[0]), so we must include similar code that will add the polygon to either front left or right quadrants. However, the next section of code is also executed in the spanning case as well, just as the above code was. This means that in the case of a non-clipped tree where we have a polygon spanning the XY plane, both code blocks will be executed and the polygon will be added to nodes both in front and behind this plane. This is correct, because if a polygon spans the boundaries of two nodes (which is only possible at this point in the non-clipped tree), we wish to add it to both nodes.

The next section of code handles the list assignments for polygons that are either spanning or are contained in the front halfspace of the XY plane. It is executed if the polygon is in front of the XZ plane or (as discussed above) if the polygon is on the plane. For our spatial trees, we can safely treat the on plane case as being identical to the in front case.

```
        if ( Location[0] == CCollision::CLASSIFY_INFRONT ||
             Location[1] == CCollision::CLASSIFY_ONPLANE ||
             Location[0] == CCollision::CLASSIFY_SPANNING )
        {
            // Position relative to ZY plane
            if ( Location[1] == CCollision::CLASSIFY_BEHIND ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                                ChildList[2].push_back( CurrentPoly );

            if ( Location[1] == CCollision::CLASSIFY_INFRONT ||
                 Location[1] == CCollision::CLASSIFY_ONPLANE ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                                 ChildList[3].push_back( CurrentPoly );

        } // End if in-front or on-plane

    } // Next Triangle
```

We can see above that ChildList[2] is the list compiled for the quadrant that is in front of the XY plane and behind the YZ plane (the back left quadrant) and ChildList[3] is for polygons that are in front of both planes (the back right quadrant).

At this point we have four polygon lists (one for each quadrant) and we now need to do the same thing with the node detail areas. Notice that the following code is identical to that we saw above with the exception that we are using our new CCollision::AABBClassifyPlane method to calculate the classification between the AABB and each plane.

```
    // Classify the areas and sort them into the child lists.
    for ( AreaIterator = AreaList.begin();
          AreaIterator != AreaList.end(); ++AreaIterator )
    {
        // Store current area
        TreeDetailArea * pDetailArea = *AreaIterator;
        if ( !pDetailArea ) continue;

        // Classify the area against the planes
        Location[0] = CCollision::AABBClassifyPlane( pDetailArea->BoundsMin,
                                                     pDetailArea->BoundsMax,
                                                     (D3DXVECTOR3&)Planes[0],
                                                     Planes[0].d );

        Location[1] = CCollision::AABBClassifyPlane( pDetailArea->BoundsMin,
                                                     pDetailArea->BoundsMax,
                                                     (D3DXVECTOR3&)Planes[1],
                                                     Planes[1].d );
```

Once again, the same logic is used to determine in which quadrant the AABB is contained and to which list it should be added.

```
        // Position relative to XY plane
        if ( Location[0] == CCollision::CLASSIFY_BEHIND ||
             Location[0] == CCollision::CLASSIFY_SPANNING )
        {
            // Position relative to ZY plane
            if ( Location[1] == CCollision::CLASSIFY_BEHIND ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                            ChildAreaList[0].push_back( pDetailArea );

            if ( Location[1] == CCollision::CLASSIFY_INFRONT ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                            ChildAreaList[1].push_back( pDetailArea );

        } // End if behind or spanning
        if ( Location[0] == CCollision::CLASSIFY_INFRONT ||
             Location[0] == CCollision::CLASSIFY_SPANNING )
        {
            // Position relative to ZY plane
            if ( Location[1] == CCollision::CLASSIFY_BEHIND ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                            ChildAreaList[2].push_back( pDetailArea );
```

```
            if ( Location[1] == CCollision::CLASSIFY_INFRONT ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                                ChildAreaList[3].push_back( pDetailArea );

        } // End if in-front or on-plane

    } // Next Detail Area
```

We are very nearly done. We have four lists of polygons that describe the polygons that fit in each quadrant of the node, and we have four lists of detail objects that also are contained (or partially contained) in each quadrant. We know at this point that we want each quadrant in this node to be represented by four new child nodes. As the BuildTree function will be called for each of these nodes and expects to be passed the node's bounding volume, we will have to create the AABB for each child node in this function.

In the next and final section of code, we set up a loop that will iterate for each child. Depending on which iteration of the loop we are on we will calculate the bounding box for that node and store it in temporary vectors NewBoundsMin and NewBoundsMax. The box computation is simple since the mid-point of the parent node will describe the location where all child volumes meet in the center of the node. We can see for example that in the first iteration of the loop we are building the volume for the BehindLeft child. Its minimum extents vector is simply the minimum extents vector of the parent node and its maximum extents vector is in the center of the parent node along the x and z axes. All quad-tree nodes inherit their height from the root node, so we can see that all nodes will always have a maximum y extents component of BoundsMax.y and will always have a minimum y extents component of BoundsMin.y. Once we have the bounding box for the current node we are processing, we allocate a new CQuadTreeNode structure and store its pointer in the parent node's child pointer list. The function then calls itself recursively passing in the new child node, the bounding box of that node that we have just calculated, and the polygon and detail area lists we compiled for its quadrant.

```
    // Build each of the children here
    for( i = 0; i < 4; ++i )
    {
        // Calculate child bounding box values
        D3DXVECTOR3 NewBoundsMin,
                    NewBoundsMax,
                    MidPoint = (BoundsMin + BoundsMax) / 2.0f;
        switch( i )
        {
            case 0: // Behind Left
                NewBoundsMin = BoundsMin;
                NewBoundsMax = D3DXVECTOR3( MidPoint.x, BoundsMax.y, MidPoint.z);
                break;

            case 1: // Behind Right
                NewBoundsMin = D3DXVECTOR3( MidPoint.x, BoundsMin.y, BoundsMin.z );
                NewBoundsMax = D3DXVECTOR3( BoundsMax.x, BoundsMax.y, MidPoint.z);
                break;

            case 2: // Infront Left
                NewBoundsMin = D3DXVECTOR3( BoundsMin.x, BoundsMin.y, MidPoint.z );
                NewBoundsMax = D3DXVECTOR3( MidPoint.x, BoundsMax.y, BoundsMax.z );
                break;
```

```
            case 3: // Infront Right
                NewBoundsMin = D3DXVECTOR3( MidPoint.x, BoundsMin.y, MidPoint.z );
                NewBoundsMax = BoundsMax;
                break;

        } // End Child Type Switch

        // Allocate child node
        pNode->Children[i] = new CQuadTreeNode;
        if ( !pNode->Children[i] ) return false;

        // Recurs into this new node
        BuildTree( pNode->Children[i],
                   ChildList[i],
                   ChildAreaList[i],
                   NewBoundsMin,
                   NewBoundsMax );

        // Clean up
        ChildList[i].clear();
        ChildAreaList[i].clear();

    } // Next Child

    // Success!
    return true;
}
```

In each iteration of the node generation loop above, the BuildTree function is passed a child node. As this function will perform all the same steps on the child node, and so on down the tree, until a leaf is located, we can imagine that once this function returned for the first child node, the entire branch of the tree that starts at that node will have been created. We then process the remaining three nodes in the loop and our job is done. Notice at the bottom of the node loop that once the BuildTree method returns for a given child, the polygon list and detail area list we compiled for it earlier in the function are no longer needed, so we release them. When this loop exits, every node and leaf under the current node being processed will have been built, so we can return. If we are in the instance of the BuildTree method that was called for the root node for example, the tree will have been completely built and program flow will pass back to the Build method which we saw previously.

You have just written a quad-tree compiler and implemented all the steps involved in the build process. The really nice thing about this is that the build functions for our oct-tree and kD-tree are almost identical. The only difference is that they split the node with a different number of planes and create a different number of child nodes. This means that we will be able to examine the build methods of the other tree with very little explanation.

Although we have covered all the code involved in the build process, there are still several query methods we must implement in the derived class to allow the application (or any user) to collect leaves based on intersections. We will examine these queries next before moving on to the other tree types.

14.17.3 The Quad-Tree Query Methods

The query functions for any spatial tree are what make the tree useful. The CollectLeavesAABB method for example is used by the application to link dynamic objects to leaves. The application can simply pass the bounding volume of the dynamic object into the CollectLeavesAABB method and have a list filled with pointers to all the leaves the volume intersected. This is obviously very handy for tasks like visibility processing since the dynamic object only has to be rendered if the IsVisible method of one of these leaves returns true.

The CollectLeavesAABB method is not just used by the application. Recall that CBaseTree demands that it is implemented in the derived class because it is called to speed up the T-junction repair process. For each polygon currently being repaired, it was used to return a list of leaves whose volumes intersect the AABB of the polygon. Only the polygons contained in these leaves would need to be tested against each other at the edge/vertex level.

For each of our tree classes we will implement two query functions which allow us to collect leaves from the tree using different primitives. The CollectLeavesAABB method sends an AABB down the tree and adds the pointer of any leaf it intersects to the passed list. The CollectLeavesRay method passes a ray down the tree and adds the pointers to any leaves the ray intersects to the passed leaf list. Fortunately, both functions are quite small due to the fact that they use the collision routines we added to CCollision earlier in this lesson. You should feel free to add query routines of your own for different primitive types (spheres would be another good choice) and extend the ISpatialTree interface as needed.

CollectLeavesAABB – CQuadTree

The CollectLeavesAABB method is a wrapper around the first call to the CollectAABBRecurse method (the recursive method that steps through the tree and adds any leaves it encounters to the passed leaf list). The CollectLeavesAABB method just starts the recursive process at the root node of the quad-tree. Here is the code.

```
bool CQuadTree::CollectLeavesAABB( LeafList & List,
                                   const D3DXVECTOR3 & Min,
                                   const D3DXVECTOR3 & Max )
{
    // Trigger Recursion
    return CollectAABBRecurse( m_pRootNode, List, Min, Max );
}
```

The method is passed three parameters. The first should be of type LeafList, which you will recall is a type definition for an STL linked list that contains ILeaf pointers. The list is passed by reference and is assumed to be empty, since it will be the job of the CollectAABBRecurse method to fill it with leaves. The second and third parameters are the extents of the AABB we would like to query the tree with (e.g., the AABB of a dynamic object).

When the CollectAABBRecurse method returns, the leaf list will contain all the pointers to leaves that were intersected by the passed AABB. Of course, the core of the query process is found inside the CollectAABBRecurse method, which we will examine next.

CollectAABBRecurse - CQuadTree

This function is passed a pointer to the node it is currently visiting, which will be a pointer to the root node the first time it is called by CollectLeavesAABB. It is also passed a leaf list which it should fill with any leaves found to be intersecting the query volume described by parameters Min and Max. The function also accepts a final boolean parameter (set to false by default) called bAutoCollect. Because this parameter is optional, and is not passed by the previous function, this will always be set to zero when it is first called for the root node. This boolean will be tracked as the tree is traversed and will be set to true once we find a node that is completely contained in the query volume.

You will recall from earlier in the lesson that we wrote a CCollision::AABBIntersectAABB method which took a boolean reference as its first parameter. The function returns true if the two boxes intersect but the boolean passed in the first parameter will also be set to true if the second box is fully contained in the first. We use this to optimize our leaf collection process because, if we find at any node in the tree that has its box fully contained inside the query volume, there is no point in performing the same AABBIntersectAABB test as we visit each of its children. Since all the children will be contained in the parent node's box, which is itself fully contained in the query volume, we know that all nodes and leaves under that node must be contained in the query volume as well. Therefore, as soon as the boolean is set to true, any further AABB tests on the children of that node will be abandoned; we will simply traverse down that branch of the tree and add leaves to the list as we find them.

The function uses the CCollision::AABBIntersectAABB method we wrote earlier in this lesson to test if the passed AABB intersects the AABB of the node currently being visited. If it does not, then this node and all of its child cannot possibly intersect the query volume, so we can return false immediately and stop traversing down this branch of the tree. Again, we only do the AABB intersection test if the bAutoCollect parameter is not set to true. If it is, then we can just proceed to collect leaves without further testing.

```
bool CQuadTree::CollectAABBRecurse( CQuadTreeNode * pNode,
                                    LeafList & List,
                                    const D3DXVECTOR3 & Min,
                                    const D3DXVECTOR3 & Max,
                                    bool  bAutoCollect /*=false*/ )
{
    bool  bResult = false;
    ULONG i;

    // Validate parameters
    if ( !pNode ) return false;

    // Does the specified box intersect this node?
    if ( !bAutoCollect && !CCollision::AABBIntersectAABB( bAutoCollect,
                                                          Min,
```

```
                                                        Max,
                                                        pNode->BoundsMin,
                                                        pNode->BoundsMax,
                                                        false,
                                                        true,
                                                        false ) ) return false;
```

Notice that we pass our boolean variable as the first parameter to the AABB intersection method so that the function can set its value to true in the event of box 2 being completely contained in box 1. As this boolean will be passed into the child node traversals this will allow us to avoid needlessly performing AABB tests at those child nodes. The extents vectors of the query volume are passed as the next two parameters followed by the extents of the node's bounding box in the second pair of parameters. Remember that the three boolean parameters at the end of this method's parameter list indicate whether we would like to ignore any axes during the test. For a quad-tree, where every node has the same height, we pass true as the bIgnoreY parameter so that the AABB intersection test is performed only on the XZ plane. It assumes that the quad-tree nodes are infinitely tall since there is no vertical partitioning in a vanilla quad-tree.

If the above collision code did not force an early return from the function, it means the query volume does intersect the node's volume. If the node's Leaf member is not set to NULL then this node is a leaf node and we add its leaf pointer to the passed list. As a leaf is a terminal node, it has no children for us to traverse and as such, our job is done and we can return.

```
    // Is there a leaf here, add it to the list
    if ( pNode->Leaf ) { List.push_back( pNode->Leaf ); return true; }
```

If the above condition was not true then it means the node intersects the query volume but the node is not a leaf node. In this case, we want to traverse into each of its four children. The function recursively calls itself for each child, making sure that it passes the original list and query volume extents down to the children. Notice in the following code how we pass the bAutoCollect boolean value into the child nodes so that if it is set to true, the AABB tests will not be performed on the child nodes (they are assumed to be inside the query volume). The remainder of the function is shown below.

```
    // Traverse down to children
    for ( i = 0; i < 4; ++i )
    {
        if ( CollectAABBRecurse( pNode->Children[i], List, Min, Max, bAutoCollect))
        bResult = true;

    } // Next Child

    // Return the 'was anything added' result.
    return bResult;
}
```

It is hard to believe that such a small function could be so powerful and useful. But thanks to spatial partitioning this is indeed the case. The function to query a ray against the tree is equally as simple, as we will see next.

CollectLeavesRay – CQuadTree

The CollectLeavesRay method can be called by the application to fill a list of all the leaves intersected by the passed ray. The method is a wrapper around the call to the CollectRayRecurse method for the root node. It is the CollectRayRecurse method which performs the traversal and collision logic.

```
bool CQuadTree::CollectLeavesRay( LeafList & List,
                                  const D3DXVECTOR3 & RayOrigin,
                                  const D3DXVECTOR3 & Velocity )
{
    return CollectRayRecurse( m_pRootNode, List, RayOrigin, Velocity );
}
```

The method is passed three parameters, the leaf list that we would like to have filled with leaves which intersect the ray, the ray origin, and the ray delta vector.

CollectRayRecurse – CQuadTree

This method is almost identical to the CollectLeavesRecurse method discussed above. It recursively calls itself visiting each node. At the current node being visited it performs a ray/box intersection test between the passed ray and the node's AABB. We use our new CCollision::RayIntersectAABB method for this and once again pass in a boolean parameter to indicate that we would like to ignore the y dimensions in the test and assume the box to be infinitely high. Although the RayIntersectAABB method returns the *t* value of intersection in its fourth parameter, we are only interested in a true or false result in this case and as such, the *t* value is ignored.

```
bool CQuadTree::CollectRayRecurse(  CQuadTreeNode * pNode,
                                    LeafList & List,
                                    const D3DXVECTOR3 & RayOrigin,
                                    const D3DXVECTOR3 & Velocity )
{
    bool  bResult = false;
    ULONG i;
    float t;

    // Validate parameters
    if ( !pNode ) return false;

    // Does the ray intersect this node?
    if ( !CCollision::RayIntersectAABB( RayOrigin, Velocity,
                                        pNode->BoundsMin,
                                        pNode->BoundsMax,
                                        t,
                                        false,
                                        true,
                                        false ) ) return false;

    // Is there a leaf here, add it to the list
```

```
    if ( pNode->Leaf ) { List.push_back( pNode->Leaf ); return true; }

    // Traverse down to children
    for ( i = 0; i < 4; ++i )
    {
        if ( CollectRayRecurse( pNode->Children[i],
                                List,
                                RayOrigin,
                                Velocity ) ) bResult = true;

    } // Next Child

    // Return the 'was anything added' result.
    return bResult;
}
```

As you can see, if the ray does not intersect the box, then it also means it cannot possibly intersect any children of the node, so we can return false are reject the rest of this branch of the tree. If the ray does intersect the box and the node is a leaf, we add its pointer to the leaf list and return. Finally, if the node is intersected by the ray but it is not a leaf node, we traverse into each of the node's children.

14.17.4 The Quad-Tree DebugDraw Routines

As discussed earlier, we have implemented some deliberately simple debug drawing routines that allow an application to request that the bounding boxes of the leaf nodes be rendered. These routines are far from optimal and are not designed to ship in commercial code. They are written help you solve any problems or choose a nice leaf size for your tree. These functions are small since we included the code that renders a box in a CBaseTree method so that all derived classes can easily implement their debug routines. We also implemented a screen tint function in CBaseTree which is called to tint the screen red when the camera enters a leaf that contains polygon or detail area data.

DebugDraw - CQuadTree

The only debug routine the application has to call is the DebugDraw routine. It should be called only after the entire scene has been rendered. It is passed the camera the application is currently using, which it passes along to the recursive function, DebugDrawRecurse. It is this function which walks the tree and renders the bounding boxes. The code to the CQuadTree::DebugDraw method is shown below.

```
void CQuadTree::DebugDraw( CCamera & Camera )
{
    // Simply start the recursive process
    DebugDrawRecurse( m_pRootNode, Camera, false );

    if ( DebugDrawRecurse( m_pRootNode, Camera, true ) )
         DrawScreenTint( 0x33FF0000 );
}
```

Notice that the DebugDrawRecurse method is called twice since we wish to render the boxes in two passes through the hierarchy. In the first pass, we want to render all the leaf nodes the camera is not currently contained in, which is why we pass false as the final parameter. These leaf nodes will be rendered blue, with Z testing enabled. This means the rendered boxes will be obscured by any geometry that is closer to the camera, just like normal scene rendering. The second time the method is called we pass true as this final parameter, which means we are only interested in rendering the leaf the camera is currently contained in. For these leaves, Z testing will be disabled so that the lines of the box overwrite anything already in the frame buffer, even if that geometry is closer to the camera. This allows us to always see all the lines of the bounding box of the leaf in which you are currently contained. If the current camera leaf has no geometry or detail areas assigned to it (it is an empty leaf) the box is rendered in green and the function return false. If it does have geometry or detail area data, the box lines are rendered in red and the function returns true. We can see in the above code that when this is the case, we also call the CBaseTree::DrawScreenTint function (covered earlier in the lesson) to tint the screen red (alpha value of 0x33).

DebugDrawRecurse - CQuadTree

This method visits each node in the tree and determines whether its box should be rendered and if so, in what color. If the boolean parameter is set to false, the function will render a leaf box when the camera position is not contained in it. If the boolean parameter is set to true, the method will traverse the tree searching only for the camera leaf node and render that box in a different manner than the other boxes. The method will also return true if the boolean parameter is set to true and the camera is contained in a leaf that has either polygon data or detail area assigned to it.

As this method is only interested in rendering leaf nodes, it first tests to see if the node it is currently visiting is a leaf node. If it is, then it uses our new CCollision::PointInAABB test to see if the camera position is contained inside the AABB of the leaf. We once again pass true for the bIgnoreY parameter in the quad-tree case so that the test is essentially performed using only the x and z components of the box and the point. We store the result of this test in the bInLeaf local variable. It will be set true only if the node this function is currently visiting is a leaf and the camera position is within its AABB.

```
bool CQuadTree::DebugDrawRecurse( CQuadTreeNode * pNode,
                                  CCamera & Camera,
                                  bool bRenderInLeaf )
{
    ULONG i;
    bool  bDrawTint = false;

    // Render the leaf
    if ( pNode->Leaf )
    {
        ILeaf * pLeaf = pNode->Leaf;
        bool bInLeaf = CCollision::PointInAABB( Camera.GetPosition(),
                                                pNode->BoundsMin,
                                                pNode->BoundsMax,
                                                false, true, false );
```

At this point, if bInLeaf is set to true and the bRenderInLeaf parameter was also set to true, it means this method is in the mode that renders only the leaf the camera is in. As bInLeaf is true, we have found that leaf so we must render it. We first fetch the polygon count and the detail area count from the leaf. If both are set to zero then it means the camera is in an empty leaf and we set its color to green. Otherwise, we set the color of the box lines to red. If the leaf is not empty, we also set the bDrawTint value to true. This is the value that will be returned from the function. It is set to false at the start of the function by default, so this function will only ever return true if the camera is in a non-empty leaf node and if the function is in the mode that renders only the camera leaf. We then call the CBaseTree::DrawBoundingBox method to render the lines of the leaf's box.

```
        if ( bRenderInLeaf && bInLeaf )
        {
            ULONG Color = 0xFFFF0000; // Red by default

            // Is there really anything in this?
            if ( pLeaf->GetPolygonCount() == 0
                 && pLeaf->GetDetailAreaCount() == 0 )
                Color = 0xFF00FF00;
            else
                bDrawTint = true;

            // Draw the bounding box
            DrawBoundingBox( pNode->BoundsMin, pNode->BoundsMax, Color, false );

        } // End if we should draw a red (inside) box here
```

Notice in the above call to DrawBoundingBox that we pass in the extents of the node's bounding box and the color we calculated based on the leaf's empty status. We also pass in false as the final parameter which instructs the method to render this box without Z testing enabled. This means all the visible lines of the box (those in the frustum) will always be rendered over the top of anything contained in the frame buffer. This will make it much easier to see the extents of the box the camera is currently in without worrying about the lines of the box being obscured by nearby geometry.

We have handled the case for when the function is in 'draw camera leaf only' mode. The next section of code is executed for the 'draw everything except the camera leaf' mode and the current node is not a node the camera is contained in. It uses the CBaseTree::DrawBoundingBox method to draw a blue box, only this time we pass true as the final parameter so that the depth buffer is enabled and the box is rendered in the normal way.

```
        // Draw blue box?
        if ( !bRenderInLeaf && !bInLeaf )
        {
            DrawBoundingBox( pNode->BoundsMin, pNode->BoundsMax, 0xFF0000FF,true );

        } // End if we should draw a blue box (outside) here
```

Finally, as detail areas are not something we can usually see, we will also render a box around any detail areas that might be contained in the current leaf node. As you can see, we simply set up a loop to extract each detail area assigned to the current leaf and render a blue box using the detail area's bounding box. For detail areas, we render with depth testing disabled so that they are not obscured by nearby geometry.

```
        for ( i = 0; i < pLeaf->GetDetailAreaCount(); ++i )
        {
            TreeDetailArea * pDetailArea = pLeaf->GetDetailArea( i );
            if ( !pDetailArea ) continue;

            // Now let's render the detail area
            DrawBoundingBox( pDetailArea->BoundsMin,
                             pDetailArea->BoundsMax,
                             0xFF00FF00,
                             false );

        } // Next Detail Area

    } // End if not a leaf
```

We have now seen all the code that is executed if the current node is a leaf node. If it is not, then this is a non-terminal node that will have four children, so we better visit those too.

```
    // Step down to children.
    for ( i = 0; i < 4; ++i )
    {
        if ( pNode->Children[i] )
        {
            if ( DebugDrawRecurse( pNode->Children[i], Camera, bRenderInLeaf ) )
                 bDrawTint = true;

        } // End if child exists

    } // Next child

    // Return whether we should draw the tint
    return bDrawTint;

}
```

If this function returns true, it means the camera is in a leaf that contains geometry or detail areas and the parent function (DebugDraw) tints the screen slightly red when this is the case.

14.17.5 Quad-Tree Conclusion

We have now covered all the code to build and query the quad-tree for collision and spatial queries. In the next lesson we will add code to CBaseTree (and one or two small functions to the derived classes) that will exist to implement an efficient hardware rendering system. The focus of this lesson however has been on using the tree for spatial queries and we have now successfully created a quad-tree. We will now move on to discuss the implementation of the other tree types, which should be quite easy now that we have covered the quad-tree code and the concepts are all very similar.

14.18 The Y-Variant Quad-Tree

An alternative approach to working with quad-trees is to factor in the Y component at each node such that the bounding box has a better fit around the geometry set (i.e., it is not assumed to be infinitely tall). Figure 14.79 reminds us what a Y-variant quad-tree node might look like with each of its children not filling the entire volume of the parent node.

Figure 14.79

Because the bounding boxes are now built to the fit the size of the geometry contained at each node along the vertical extent, we get nodes with smaller boxes that provide more accurate querying versus the vanilla quad-tree case.

We can imagine a situation for example where a spacecraft might be hovering in the skies above a cityscape. In the vanilla quad-tree case, the leaf in which the cityscape is contained would be infinitely tall (or as tall as the tallest thing in the scene) and as such, the spacecraft would be considered to be in the same leaf node as the cityscape even though it was far above it. This would lead to the cityscape being rendered even if the plane was so far above it that that the geometry of the cityscape was well below the frustum of the camera mounted on that craft. In the Y-variant quad-tree case, the leaf in which the cityscape is contained would only be as tall as the tallest building in that city, which would mean the spacecraft would be outside that leaf and it would not be rendered. Of course, the savings are a lot less obvious when we are compiling indoor scenes.

While an oct-tree is one obvious way to solve this problem, we can make a modification to the quad-tree implementation and derive a new class called CQuadTreeYV that will be built slightly differently. At each node, the bounding box's Y extents are not inherited from the root node, but are calculated based on the polygon data in that node. This will allow us to more effectively frustum cull leaves that might not be culled in the vanilla quad-tree implementation.

Although it might seem that the Y-variant quad-tree would also introduce similar savings in collision queries (which is technically true), we will not be able to do this with our implementation. You will recall that the CollectLeavesAABB used by our collision system is implemented in the vanilla quad-tree case to assume infinitely tall leaves by way of ignoring the Y component of the node's box during AABB/AABB intersection tests (the CollectLeavesRay method does the same). Although we could easily re-implement these in our Y-variant version of the quad-tree, this design does not cooperate well with our dynamic object system.

Looking at Figure 14.79 we can see that at any given node, if the child volumes do not totally consume the parent volume, we have a situation where locations within the quad-tree do not fall within any leaf

node. In the circular inset we can see some children have a very small Y extent while the Y extent of the parent node would be equal to the green child. What happens if we feed an AABB into the tree which happens to fall in the space just above the blue child node? It would clearly be contained inside the parent node's volume, but it would not fall into any of its children. Thus, it would essentially be in no-man's land and the function would simply return and no leaf would be added to the leaf collection list.

Now, if this was a collision query being performed, we would really benefit from the Y-variant tree's smaller boxes. If we passed the swept sphere's AABB down the tree and it ended up in an area that is not bounded by a leaf, the returned list would be empty and we would know that the swept sphere does not intersect any geometry. However, the same CollectLeavesAABB method is also used by our application to determine which leaves a dynamic object is in. The object is only rendered if at least one of its leaves is visible. However, in the Y-variant case we might find that when we feed in the dynamic object's bounding volume, it exists in no leaves. What do we do?

We would have no choice in such situations other than to always render those dynamic objects. That is, if a dynamic object is not currently in a leaf, we do not know whether or not it is visible, so we should render it to be safe. We could end up rendering many objects which are nowhere near the camera and not even close to being visible, and this would certain hinder performance in many cases. Of course, there are ways around such problems; we could store dynamic object pointers at nodes as well as leaves and when traversing the tree, render any objects that are contained at that node before moving on. However, that really does not fit our design very well, where we make a clear distinction between nodes and leaves. So we have made the design decision to ignore the y extents of a node's box during the leaf collection functions. This means that, just as in the case of the vanilla quad-tree, during the leaf collection process the node volumes are assumed to have infinite Y extents. The savings we get from implementing the YV quad-tree will be purely during the frustum culling pass of the tree for static objects.

Note that this tree will behave almost exactly like the vanilla quad-tree -- even the CollectLeavesAABB method will be the same since we are choosing to ignore the Y components. In fact, the only difference (frustum culling aside, as this will be discussed in the next lesson) between the quad-tree and the YV quad-tree will be a small section of code in the recursive BuildTree function that fits the bounding box of the node to the polygon set along the Y extents, instead of inheriting it from the root node's volume. As the BuildTree method of CQuadTree is virtual, we can simply derive CQuadTreeYV from CQuadTree and just override it.

Below we show the class declaration for CQuadTreeYV which is contained in CQuadTreeYV.h.

```
class CQuadTreeYV : public CQuadTree
{
public:

    // Constructors & Destructors for This Class.
    CQuadTreeYV( LPDIRECT3DDEVICE9 pDevice,
                 bool bHardwareTnL,
                 float fMinLeafSize = 300.0f,
                 ULONG nMinPolyCount = 600,
                 ULONG nMinAreaCount = 0 ) : CQuadTree( pDevice,
                                                        bHardwareTnL,
                                                        fMinLeafSize,
```

```
                                                    nMinPolyCount,
                                                    nMinAreaCount ) {};

protected:
    // Protected virtual Functions for This Class

    virtual bool BuildTree ( CQuadTreeNode * pNode,
                             PolygonList PolyList,
                             DetailAreaList AreaList,
                             const D3DXVECTOR3 & BoundsMin,
                             const D3DXVECTOR3 & BoundsMax );
};
```

As you can see, with the exception of the constructor which is empty and simply passes the data on to the base class (CQuadTree), we have to implement just one function. The BuildTree method is a method we are now very familiar with. We will override it in this class due to the fact that we need to calculate the bounding box of each node a little differently. We will now cover the BuildTree method and highlight the small differences in the YV version.

BuildTree – CQuadTreeYV

Although we will see the complete function code listing below, most of it is unchanged from the CQuadTree::BuildTree method. Recall that this is the method that is called from the Build method and passed the root node and its polygon and detail area data along with the bounding box of the root node. This function will then recursively build the entire tree.

Because this code has already been thoroughly discussed, we will move quickly and only stop to examine the changes from the function that it overrides.

```
bool CQuadTreeYV::BuildTree( CQuadTreeNode * pNode,
                             PolygonList PolyList,
                             DetailAreaList AreaList,
                             const D3DXVECTOR3 & BoundsMin,
                             const D3DXVECTOR3 & BoundsMax )
{
    D3DXVECTOR3                 Normal;
    PolygonList::iterator       PolyIterator;
    DetailAreaList::iterator    AreaIterator;
    CPolygon                  * CurrentPoly, * FrontSplit, * BackSplit;
    PolygonList                 ChildList[4];
    DetailAreaList              ChildAreaList[4];
    CCollision::CLASSIFYTYPE    Location[2];
    D3DXPLANE                   Planes[2];
    unsigned long               i;
    bool                        bStopCode;

    // Store the bounding box properties in the node
    pNode->BoundsMin = BoundsMin;
    pNode->BoundsMax = BoundsMax;
```

```
    // Calculate 'Stop' code
    D3DXVECTOR3 vecLeafSize = D3DXVECTOR3( BoundsMax.x - BoundsMin.x,
                                           0,
                                           BoundsMax.z - BoundsMin.z );

    bStopCode  = (AreaList.size() == 0 && PolyList.size() == 0) ||
                 (AreaList.size() <= m_nMinAreaCount &&
                  PolyList.size() <= m_nMinPolyCount) ||
                  D3DXVec3Length( &vecLeafSize ) <= m_fMinLeafSize;
```

The first section code stored the passed bounding box in the passed node and calculated the 2D size of the node (vecLeafSize). Although this is a YV quad-tree we still do not want the y extents of the node to play any part in whether or not we subdivide. Unlike the oct-tree where we intend to subdivide space vertically, the YV quad-tree does not have leaves stacked on top of each other. So a leaf must still contain the entire vertical range of geometry that exists in the XZ space. The only difference is that when we do create a node/leaf bounding box, we will calculate the extents of the actual geometry that made it into that node. After we have calculated the leaf size, we compute the bStopCode boolean. This code is all unchanged.

As before, if the stop code is set to true then we have found a node that should become a leaf so we allocate a new CBaseLeaf object. We then loop through each polygon in the passed list (the polygons that made it into this node) and add their pointers to the leaf. Remember that if this is a clipped tree, we also add the polygons to the tree's polygon list.

```
    // If we reached our stop limit, build a leaf here
    if ( bStopCode )
    {
        // Build a leaf
        CBaseLeaf * pLeaf = new CBaseLeaf( this );
        if ( !pLeaf ) return false;

        // Store the polygons
        for ( PolyIterator = PolyList.begin();
              PolyIterator != PolyList.end();
              ++PolyIterator )
        {
            // Retrieve poly
            CurrentPoly = *PolyIterator;
            if ( !CurrentPoly ) continue;

            // Add to the polygon list ONLY if splitting was allowed
            if ( m_bAllowSplits ) AddPolygon( CurrentPoly );

            // Also add a reference to the leaf's list
            pLeaf->AddPolygon( CurrentPoly );

        } // Next Polygon
```

Of course, we do the same for any detail area that made it into this leaf.

```
        // Store the area lists
        for ( AreaIterator = AreaList.begin();
```

```
              AreaIterator != AreaList.end(); ++AreaIterator )
        {
            // Retrieve detail area item
            TreeDetailArea * pDetailArea = *AreaIterator;
            if ( !pDetailArea ) continue;

            // Add a reference to the leaf's list
            pLeaf->AddDetailArea( pDetailArea );

        } // Next Polygon
```

We then assign the node's leaf pointer to point at the newly populated CBaseLeaf and set the leaf object's bounding box to that of the node it represents. We then add the leaf pointer to the tree's leaf array and return. That takes care of the leaf case.

```
        // Store pointer to leaf in the node and the bounds
        pNode->Leaf = pLeaf;

        // Store the bounding box in the leaf
        pLeaf->SetBoundingBox( pNode->BoundsMin, pNode->BoundsMax );

        // Store the leaf in the leaf list
        AddLeaf( pLeaf );

        // We have reached a leaf
        return true;

    } // End if reached stop code
```

The next piece of code is new for the Y-variant quad-tree. Remember that we only reach this part of the function if the current node is not a leaf. Although we already know the X and Z extents of the node's bounding box because they were passed into the function, the y extents will currently represent the y extents of the parent node's volume. We want to set the height of this node's volume so that it matches the y range of vertices it stores. Therefore, we first set the y extents of the node's AABB to impossibly small (inside out) values. We then loop through every polygon in the passed list (the polygons contained in this node) and test the y extents of each of its vertices against the y extents of the node's box. Whenever we find a vertex that has a y component that is outside the box, we grow the box extents to contain it. At the end of the following section of code, the current node's bounding box will be an exact fit (vertically) around the polygon data passed into this node.

```
    // Update the Y coordinate of the bounding box for the 'Y Variant'
    // quad-tree information

    pNode->BoundsMin.y = FLT_MAX; pNode->BoundsMax.y = -FLT_MAX;

    for ( PolyIterator = PolyList.begin();
          PolyIterator != PolyList.end(); ++PolyIterator )
    {
        // Store current poly
        CurrentPoly = *PolyIterator;
        if ( !CurrentPoly ) continue;
```

```
        // Loop through each vertex
        for ( i = 0; i < CurrentPoly->m_nVertexCount; ++i )
        {
            CVertex * pVertex = &CurrentPoly->m_pVertex[i];
            if ( pVertex->y < pNode->BoundsMin.y ) pNode->BoundsMin.y = pVertex->y;
            if ( pVertex->y > pNode->BoundsMax.y ) pNode->BoundsMax.y = pVertex->y;

        } // Next Vertex

    } // Next Polygon
```

Of course, we must make sure that the box is also large enough to contain any detail areas that made it into this node. In the next section of code we loop through each detail area in this node and grow the y extents of the node's AABB if any detail area is found to not be fully contained.

```
    for ( AreaIterator = AreaList.begin();
          AreaIterator != AreaList.end(); ++AreaIterator )
    {
        // Store current detail area
        TreeDetailArea * pDetailArea = *AreaIterator;

        if ( pDetailArea->BoundsMin.x < pNode->BoundsMin.x )
             pNode->BoundsMin.x = pDetailArea->BoundsMin.x;

        if ( pDetailArea->BoundsMin.y < pNode->BoundsMin.y )
             pNode->BoundsMin.y = pDetailArea->BoundsMin.y;

        if ( pDetailArea->BoundsMin.z < pNode->BoundsMin.z )
             pNode->BoundsMin.z = pDetailArea->BoundsMin.z;

        if ( pDetailArea->BoundsMax.x > pNode->BoundsMax.x )
             pNode->BoundsMax.x = pDetailArea->BoundsMax.x;

        if ( pDetailArea->BoundsMax.y > pNode->BoundsMax.y )
             pNode->BoundsMax.y = pDetailArea->BoundsMax.y;

        if ( pDetailArea->BoundsMax.z > pNode->BoundsMax.z )
             pNode->BoundsMax.z = pDetailArea->BoundsMax.z;

    } // Next Detail Area
```

With the node's bounding volume now a tight fit around its data, we create the two split planes as before.

```
    // Generate the two split planes
    D3DXPlaneFromPointNormal( &Planes[0],
                              &((pNode->BoundsMin + pNode->BoundsMax) / 2.0f),
                              &D3DXVECTOR3( 0.0f, 0.0f, 1.0f ) );

    D3DXPlaneFromPointNormal( &Planes[1],
                              &((pNode->BoundsMin + pNode->BoundsMax) / 2.0f),
                              &D3DXVECTOR3( 1.0f, 0.0f, 0.0f ) );
```

If we are building a clipped tree then we will first need to split all the polygons in this node's list to the planes so that we end up with a list of polygons that will each fit into exactly one child.

```
    // Split all polygons against both planes if required
    if ( m_bAllowSplits )
    {
        for ( i = 0; i < 2; ++i )
        {
            for ( PolyIterator = PolyList.begin();
                  PolyIterator != PolyList.end(); ++PolyIterator )
            {
                // Store current poly
                CurrentPoly = *PolyIterator;
                if ( !CurrentPoly ) continue;

        // Classify the poly against the first plane
        Location[0] = CCollision::PolyClassifyPlane( CurrentPoly->m_pVertex,
                                                     CurrentPoly->m_nVertexCount,
                                                     sizeof(CVertex),
                                                     (D3DXVECTOR3&)Planes[i],
                                                     Planes[i].d );

                if ( Location[0] == CCollision::CLASSIFY_SPANNING )
                {
                    // Split the current poly against the plane
                    CurrentPoly->Split( Planes[i], &FrontSplit, &BackSplit );
                    delete CurrentPoly;
                    *PolyIterator = NULL;

                    // Add these to the end of the current poly list
                    PolyList.push_back( FrontSplit );
                    PolyList.push_back( BackSplit );

                } // End if Spanning

            } // Next Polygon

        } // Next Plane

    } // End if allow splits
```

As before, the next section of code adds each polygon to the appropriate child list. It is unchanged from the normal quad-tree case.

```
    // Classify the polygons and sort them into the four child lists.
    for ( PolyIterator = PolyList.begin();
          PolyIterator != PolyList.end(); ++PolyIterator )
    {
        // Store current poly
        CurrentPoly = *PolyIterator;
        if ( !CurrentPoly ) continue;

        // Classify the poly against the planes
        Location[0] = CCollision::PolyClassifyPlane( CurrentPoly->m_pVertex,
                                                     CurrentPoly->m_nVertexCount,
```

```
                                                    sizeof(CVertex),
                                                    (D3DXVECTOR3&)Planes[0],
                                                    Planes[0].d );

        Location[1] = CCollision::PolyClassifyPlane( CurrentPoly->m_pVertex,
                                                    CurrentPoly->m_nVertexCount,
                                                    sizeof(CVertex),
                                                    (D3DXVECTOR3&)Planes[1],
                                                    Planes[1].d );

        // Position relative to XY plane
        if ( Location[0] == CCollision::CLASSIFY_BEHIND ||
             Location[0] == CCollision::CLASSIFY_SPANNING )
        {
            // Position relative to ZY plane
            if ( Location[1] == CCollision::CLASSIFY_BEHIND ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                            ChildList[0].push_back( CurrentPoly );

            if ( Location[1] == CCollision::CLASSIFY_INFRONT ||
                 Location[1] == CCollision::CLASSIFY_ONPLANE ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                             ChildList[1].push_back( CurrentPoly );

        } // End if behind or spanning

        if ( Location[0] == CCollision::CLASSIFY_INFRONT ||
             Location[0] == CCollision::CLASSIFY_ONPLANE ||
             Location[0] == CCollision::CLASSIFY_SPANNING )
        {
            // Position relative to ZY plane
            if ( Location[1] == CCollision::CLASSIFY_BEHIND ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                            ChildList[2].push_back( CurrentPoly );

            if ( Location[1] == CCollision::CLASSIFY_INFRONT ||
                 Location[1] == CCollision::CLASSIFY_ONPLANE ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                            ChildList[3].push_back( CurrentPoly );

        } // End if in-front or on-plane

    } // Next Triangle
```

At this point, the polygon data at this node has been sorted into four lists (one per quadrant). We now have to sort the detail areas into four lists also so that we know which children they should be assigned to. This code is also unchanged from the normal quad-tree code.

```
    // Classify the areas and sort them into the child lists.
    for ( AreaIterator = AreaList.begin();
          AreaIterator != AreaList.end(); ++AreaIterator )
    {
        // Store current area
        TreeDetailArea * pDetailArea = *AreaIterator;
        if ( !pDetailArea ) continue;
```

```
        // Classify the poly against the planes
        Location[0] = CCollision::AABBClassifyPlane( pDetailArea->BoundsMin,
                                                     pDetailArea->BoundsMax,
                                                     (D3DXVECTOR3&)Planes[0],
                                                     Planes[0].d );

        Location[1] = CCollision::AABBClassifyPlane( pDetailArea->BoundsMin,
                                                     pDetailArea->BoundsMax,
                                                     (D3DXVECTOR3&)Planes[1],
                                                     Planes[1].d );

        // Position relative to XY plane
        if ( Location[0] == CCollision::CLASSIFY_BEHIND ||
             Location[0] == CCollision::CLASSIFY_SPANNING )
        {
            // Position relative to ZY plane
            if ( Location[1] == CCollision::CLASSIFY_BEHIND ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                                ChildAreaList[0].push_back( pDetailArea );

            if ( Location[1] == CCollision::CLASSIFY_INFRONT ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                                ChildAreaList[1].push_back( pDetailArea );

        } // End if behind or spanning

        if ( Location[0] == CCollision::CLASSIFY_INFRONT ||
             Location[0] == CCollision::CLASSIFY_SPANNING )
        {
            // Position relative to ZY plane
            if ( Location[1] == CCollision::CLASSIFY_BEHIND ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                                ChildAreaList[2].push_back( pDetailArea );

            if ( Location[1] == CCollision::CLASSIFY_INFRONT ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
                                ChildAreaList[3].push_back( pDetailArea );

        } // End if in-front or on-plane

    } // Next Detail Area
```

We now have four lists of polygons and four lists of detail objects, so we create the four child nodes to which they belong and calculate the bounding box of each child. As before, we set up a loop where a single child node is created with each iteration. In each of the four iterations, we allocate a new quad-tree node and store its pointer in the parent node's child list and then calculate the bounding volume of that node by assigning the associated quadrant of the parent node's bounding volume. We then step into the child node by issuing the recursive call.

```
    // Build each of the children here
    for( i = 0; i < 4; ++i )
    {
        // Calculate child bounding box values
        D3DXVECTOR3 NewBoundsMin, NewBoundsMax,
```

```
                MidPoint = (pNode->BoundsMin + pNode->BoundsMax) / 2.0f;

        switch( i )
        {
        case 0: // Behind Left
            NewBoundsMin = pNode->BoundsMin;
            NewBoundsMax = D3DXVECTOR3( MidPoint.x,
                                        pNode->BoundsMax.y,
                                        MidPoint.z);
            break;

        case 1: // Behind Right
            NewBoundsMin = D3DXVECTOR3( MidPoint.x,
                                        pNode->BoundsMin.y,
                                        pNode->BoundsMin.z );

            NewBoundsMax = D3DXVECTOR3( pNode->BoundsMax.x,
                                        pNode->BoundsMax.y,
                                        MidPoint.z);
            break;

        case 2: // InFront Left
            NewBoundsMin = D3DXVECTOR3( pNode->BoundsMin.x,
                                        pNode->BoundsMin.y,
                                        MidPoint.z );

            NewBoundsMax = D3DXVECTOR3( MidPoint.x,
                                        pNode->BoundsMax.y,
                                        pNode->BoundsMax.z );
            break;

        case 3: // InFront Right
            NewBoundsMin = D3DXVECTOR3( MidPoint.x,
                                        pNode->BoundsMin.y,
                                        MidPoint.z );

            NewBoundsMax = pNode->BoundsMax;
            break;

        } // End Child Type Switch

        // Allocate child node
        pNode->Children[i] = new CQuadTreeNode;
        if ( !pNode->Children[i] ) return false;

        // Recurse into this new node
        BuildTree( pNode->Children[i],
                   ChildList[i],
                   ChildAreaList[i],
                   NewBoundsMin,
                   NewBoundsMax );

        // Clean up
        ChildList[i].clear();
        ChildAreaList[i].clear();
```

```
    } // Next Child

    // Success!
    return true;
}
```

Note how quickly we were able to create new tree behavior. In the case of the Y-variant quad-tree, it meant overriding a single method. That is all the code we need to cover for the YV Quad-tree.

14.19 Oct-Tree Implementation

The source files COctTree.cpp and COctTree.h contain the code for our oct-tree implementation. This tree is derived from CBaseTree and as such, we must implement the same methods from ISpatialTree that are not implemented in CBaseTree. Just as with the quad-tree, we will only need to implement the Build, CollectLeavesAABB, CollectLeavesRay and a few others in order to create our oct-tree because CBaseTree provides all the housekeeping tasks.

The oct-tree implementation will be so similar to that of the quad-tree that examining its code will be trivial for the most part. The only real difference in each version of the method implemented for the oct-tree is that each node has eight children to visit/create instead of four. In the Build function we will now have three planes to clip and classify against instead of two. These three planes will divide the node's volume in octants (instead of quadrants) as shown in Figure 14.80.

Octree Node Partitioning

Figure 14.80

Although CBaseTree provides the leaf structure that all our trees will use, the node structure is dependant on the tree being built. For example, in the quad-tree case we implemented the CQuadTreeNode object to represent a single node in the tree. This node has four child pointers as we would expect. The Y-variant quad-tree also shared this same node structure. The oct-tree will need its own node structure that is capable or storing pointers to eight child nodes instead of four. That is really the only difference between the node objects used by all of our tree types; the varying number of children.

14.19.1 COctTreeNode – The Source Code

Each node in our oct-tree will be represented by an object of type COctTreeNode which is declared and implemented in COctTree.h and COctTree.cpp. It contains the same SetVisible member function as its quad-tree counterpart and also stores the same members. It stores a pointer to a CBaseLeaf object that will be used only by terminal nodes and contains two vectors describing the extents of the node's bounding volume. It also contains the same LastFrustumPlane member which we will discuss in the following lesson as it is used to speed up visibility processing. Finally, you will notice that the only difference (except the name) between this object and the CQuadTreeNode object is that each node stores an array of 8 COctTreeNode pointers instead of an array of 4 CQuadTreeNode pointers.

```
class COctTreeNode
{
public:

    // Constructors & Destructors for This Class.
     COctTreeNode( );
    ~COctTreeNode( );

    // Public Functions for This Class
    void SetVisible( bool bVisible );

    // Public Variables for This Class
    COctTreeNode  * Children[8];        // The eight child nodes
    CBaseLeaf     * Leaf;               // If this is a leaf, store here.
    D3DXVECTOR3     BoundsMin;          // Minimum bounding box extents
    D3DXVECTOR3     BoundsMax;          // Maximum bounding box extents
    signed char     LastFrustumPlane;   // 'last plane' index.
};
```

SetVisible – COctTreeNode

Each of our node types supports the SetVisible method which is used by the tree to set the visibility status of all leaves below the node for which it is called. It works in exactly the same way as its quad-tree node counterpart. How this function is used will become clearer in the following lesson when we implement the rendering and visibility code for our trees.

The method is passed a boolean parameter indicating whether the node is considered visible or not. If the node is a leaf then the attached leaf object has its visibility status set to true. If this is not a leaf we simply traverse into the eight children performing the same test. As a node has no member to store its visibility status, what we are actually doing here is just traversing down to find any leaf nodes and setting their status to the parameter passed to the top level instance of the function.

```
void COctTreeNode::SetVisible( bool bVisible )
{
    unsigned long i;

    // Set leaf property
    if ( Leaf  ) { Leaf->SetVisible( bVisible ); return; }

    // Recurse down if applicable
    for ( i = 0; i < 8; ++i )
    {
        if ( Children[i] ) Children[i]->SetVisible(bVisible);

    } // Next Child
}
```

Notice that the only difference between this code and the quad-tree node's method is that we now have a loop that visits eight children instead of four.

14.19.2 COctTree – The Source Code

The COctTree class is derived from CBaseTree and therefore must implement oct-tree versions of the methods we implemented in CQuadTree. The class declaration is contained in COctTree.h and is shown below. Notice that it implements the exact same set of methods we had to implement for our quad-tree class.

```
class COctTree : public CBaseTree
{
public:

       // Constructors & Destructors for This Class.
       virtual ~COctTree( );
       COctTree( LPDIRECT3DDEVICE9 pDevice,
                 bool bHardwareTnL,
                 float fMinLeafSize = 300.0f,
                 ULONG nMinPolyCount = 600,
                 ULONG nMinAreaCount = 0 );

    // Public Virtual Functions for This Class (from base).
    virtual bool Build                  ( bool bAllowSplits = true );
    virtual void ProcessVisibility      ( CCamera & Camera );
    virtual bool CollectLeavesAABB      ( LeafList & List,
                                          const D3DXVECTOR3 & Min,
                                          const D3DXVECTOR3 & Max );
    virtual bool CollectLeavesRay       ( LeafList & List,
                                          const D3DXVECTOR3 & RayOrigin,
                                          const D3DXVECTOR3 & Velocity );

    virtual void DebugDraw              ( CCamera & Camera );
    virtual bool GetSceneBounds         ( D3DXVECTOR3 & Min, D3DXVECTOR3 & Max );
```

```
protected:

    // Protected virtual Functions for This Class
    virtual bool BuildTree              ( COctTreeNode * pNode,
                                          PolygonList PolyList,
                                          DetailAreaList AreaList,
                                          const D3DXVECTOR3 & BoundsMin,
                                          const D3DXVECTOR3 & BoundsMax );

    // Protected Functions for This Class
    void         UpdateTreeVisibility   ( COctTreeNode * pNode,
                                          CCamera & Camera,
                                          UCHAR FrustumBits = 0x0 );

    bool         DebugDrawRecurse       ( COctTreeNode * pNode,
                                          CCamera & Camera, bool bRenderInLeaf );

    bool         CollectAABBRecurse     ( COctTreeNode * pNode,
                                          LeafList & List,
                                          const D3DXVECTOR3 & Min,
                                          const D3DXVECTOR3 & Max,
                                          bool bAutoCollect = false );

    bool         CollectRayRecurse      ( COctTreeNode * pNode,
                                          LeafList & List,
                                          const D3DXVECTOR3 & RayOrigin,
                                          const D3DXVECTOR3 & Velocity );

    // Protected Variables for This Class
    COctTreeNode * m_pRootNode;         // The root node of the tree
    bool           m_bAllowSplits;      // Is splitting allowed?
    float          m_fMinLeafSize;      // Min leaf size stop code
    ULONG          m_nMinPolyCount;     // Min polygon count stop code
    ULONG          m_nMinAreaCount;     // Min detail area count stop code

};
```

The member variables are exactly the same in both name and purpose to those we discussed when implementing the quad-tree. The only slight difference in member variables is that the root node pointer stored by the tree is now of type COctTreeNode instead of CQuadTreeNode. The methods are also exactly the same as their quad-tree counterparts with the exception that the recursive methods that accept node parameters now accept nodes of type COctTreeNode.

Let us now cover the methods of COctTree and discuss how they differ from their quad-tree counterparts.

Build - COctTree

As we know, the Build method is the method called by the application to build the tree. It is called after all geometry and detail areas have been registered. It is not the recursive function that builds the tree but

is instead a convenient wrapper around the top level call to the recursive BuildTree method. Because the code is almost unchanged from its quad-tree counter part we will progress through it quickly.

The first bit of the function initializes the vectors that will be used to record the size of the root node's bounding box to impossibly small values before allocating a new COctTreeNode object that will become the root node of the tree. We also store the value of the boolean parameter in the m_bAllowSplits member variable so that we know during the recursive build process whether we should be clipping the polygon data at each node.

```
bool COctTree::Build( bool bAllowSplits /* = false */ )
{
    PolygonList::iterator       PolyIterator = m_Polygons.begin();
    DetailAreaList::iterator    AreaIterator = m_DetailAreas.begin();
    PolygonList                 PolyList;
    DetailAreaList              AreaList;
    unsigned long               i;

    // Reset our tree info values.
    D3DXVECTOR3 vecBoundsMin( FLT_MAX, FLT_MAX, FLT_MAX );
    D3DXVECTOR3 vecBoundsMax( -FLT_MAX, -FLT_MAX, -FLT_MAX );

    // Allocate a new root node
    m_pRootNode = new COctTreeNode;
    if ( !m_pRootNode ) return false;

    // Store the allow splits value for later retrieval.
    m_bAllowSplits = bAllowSplits;
```

Now we need to calculate the size of the root nodes bounding volume by looping through every polygon in the tree's polygon list and testing each of its vertices against the current box extents. If we find any vertex is outside these extents, we grow the box. At the end of the loop we will have a bounding box that contains all the vertices of all the polygons.

```
    // Loop through all of the initial polygons
    for ( ; PolyIterator != m_Polygons.end(); ++PolyIterator )
    {
        // Retrieve the polygon
        CPolygon * pPoly = *PolyIterator;
        if ( !pPoly ) continue;

        // Calculate total scene bounding box.
        for ( i = 0; i < pPoly->m_nVertexCount; ++i )
        {
            // Store info
            CVertex * pVertex = &pPoly->m_pVertex[i];
            if ( pVertex->x < vecBoundsMin.x ) vecBoundsMin.x = pVertex->x;
            if ( pVertex->y < vecBoundsMin.y ) vecBoundsMin.y = pVertex->y;
            if ( pVertex->z < vecBoundsMin.z ) vecBoundsMin.z = pVertex->z;
            if ( pVertex->x > vecBoundsMax.x ) vecBoundsMax.x = pVertex->x;
            if ( pVertex->y > vecBoundsMax.y ) vecBoundsMax.y = pVertex->y;
            if ( pVertex->z > vecBoundsMax.z ) vecBoundsMax.z = pVertex->z;

        } // Next Vertex
```

```
        // Store this polygon in the top polygon list
        PolyList.push_back( pPoly );

    } // Next Polygon

    // Clear the initial polygon list if we are going to split the polygons
    // as this will eventually become storage for whatever gets built
    if ( bAllowSplits ) m_Polygons.clear();
```

Just as before, at the bottom of the outer loop, as we test each polygon, we add it to the temporary PolyList. It is this list that will be passed into the recursive process. As we are currently at the root node, PolyList will contain a complete copy of all the pointers that were registered with the tree and stored in the m_Polygons list. Outside the loop you can see that just as before, if we are going to build a clipped tree, we clear the tree's polygon list since we will need to rebuild it from scratch with the clipped polygon data that makes it into each leaf node.

Our root node's bounding box is currently large enough to contain all the polygon data but we need to make sure it is large enough to contain any detail areas that may have been registered with the tree as well. In the next section of code we loop through each detail area and extend the bounding box extents if any detail area is found not to be fully contained inside it. Notice also that as we process each detail area, we also add its pointer to the temporary detail area list. This is the detail area list we will send into the recursive build process.

```
    // Loop through all of the detail areas
    for ( ; AreaIterator != m_DetailAreas.end(); ++AreaIterator )
    {
        // Retrieve the detail area
        TreeDetailArea * pDetailArea = *AreaIterator;
        if ( !pDetailArea ) continue;

        // Calculate total scene bounding box.
        D3DXVECTOR3 & Min = pDetailArea->BoundsMin;
        D3DXVECTOR3 & Max = pDetailArea->BoundsMax;
        if ( Min.x < vecBoundsMin.x ) vecBoundsMin.x = Min.x;
        if ( Min.y < vecBoundsMin.y ) vecBoundsMin.y = Min.y;
        if ( Min.z < vecBoundsMin.z ) vecBoundsMin.z = Min.z;
        if ( Max.x > vecBoundsMax.x ) vecBoundsMax.x = Max.x;
        if ( Max.y > vecBoundsMax.y ) vecBoundsMax.y = Max.y;
        if ( Max.z > vecBoundsMax.z ) vecBoundsMax.z = Max.z;

        // Store this in the top detail area list
        AreaList.push_back( pDetailArea );

    } // Next Polygon
```

Finally, with the root node's bounding volume calculated and with PolyList and AreaList containing copies of all the polygon and detail area pointers, we can now step into the recursive BuildTree method starting at the root node and let it build the entire tree from the root node down.

```
    // Build the tree itself
    if (!BuildTree( m_pRootNode, PolyList, AreaList, vecBoundsMin, vecBoundsMax ))
```

```
        return false;
```

At this point the tree will be completely built so we call the CBaseTree::PostBuild method and let it do any final preparation on the tree data. We will see in the next lesson how this method not only calculates and stores the bounding boxes for each polygon stored in the tree (as we have already shown) but also initializes CBaseTree's render system.

```
    // Allow our base class to finish any remaining processing
    return CBaseTree::PostBuild( );
}
```

BuildTree - COctTree

The BuildTree method has the task of dividing the current node's polygon and detail area lists into eight children instead of four and creating eight child nodes. However, with the exception that we must now carve the node into octants using three split planes and creating eight child lists of both polygon and detail area data, the function is essentially the same as the quad-tree version.

Notice in this first section of code how we now instantiate local arrays of eight polygon lists and eight detail area lists and also allocate an array to hold three split planes instead of two.

```
bool COctTree::BuildTree( COctTreeNode * pNode,
                          PolygonList PolyList,
                          DetailAreaList AreaList,
                          const D3DXVECTOR3 & BoundsMin,
                          const D3DXVECTOR3 & BoundsMax )
{
    D3DXVECTOR3                 Normal;
    PolygonList::iterator       PolyIterator;
    DetailAreaList::iterator    AreaIterator;
    CPolygon                  * CurrentPoly, * FrontSplit, * BackSplit;
    PolygonList                 ChildList[8];
    DetailAreaList              ChildAreaList[8];
    CCollision::CLASSIFYTYPE    Location[3];
    D3DXPLANE                   Planes[3];
    unsigned long               i;
    bool                        bStopCode;

    // Store the bounding box properties in the node
    pNode->BoundsMin = BoundsMin;
    pNode->BoundsMax = BoundsMax;

    // Calculate 'Stop' code
    D3DXVECTOR3 vecLeafSize = BoundsMax - BoundsMin;

    bStopCode  = (AreaList.size() == 0 && PolyList.size() == 0) ||
                 (AreaList.size() <= m_nMinAreaCount &&
                  PolyList.size() <= m_nMinPolyCount ) ||
                  D3DXVec3Length( &vecLeafSize ) <= m_fMinLeafSize;
```

Just as before we store the passed bounding box extents in the node and then calculate the leaf size. Notice that this time when calculating the leaf size variable; we also take the y extents into account. Remember, in the quad-tree case we only subtracted the x and z extents of the bounding box to get the diagonal node length. This was because in a quad-tree, we do not partition space vertically. However, in the case of the oct-tree, we take the full diagonal length of the box into account so that the height of a node's bounding box is also a factor in whether or not it becomes a terminal node. As you can see, by simply subtracting the minimum box extents from the maximum box extents, we get a vector whose length describes the minimum size a node can be before it automatically becomes a leaf.

If the stop code variable is true, it means there are two few polygons or detail areas in this node or that the node is too small. Either way, we no longer wish to further partition the space of this node and instead wish to make it a leaf. The following conditional code that makes the node a leaf is completely unchanged from the quad-tree case. It creates a new CBaseLeaf and loops through every polygon and detail area in the node's list and adds them to the leaf. If clipping is being used it is at this point that the pointer of each potentially clipped polygon is also added back to the tree's main polygon list. The node's leaf pointer is then assigned to point at this new leaf and the leaf's bounding box is set to be the same as the node. At this point the node has been successfully turned into a leaf and we return.

```
    // If we reached our stop limit, build a leaf here
    if ( bStopCode )
    {
        // Build a leaf
        CBaseLeaf * pLeaf = new CBaseLeaf( this );
        if ( !pLeaf ) return false;

        // Store the polygons
        for ( PolyIterator = PolyList.begin();
              PolyIterator != PolyList.end(); ++PolyIterator )
        {
            // Retrieve poly
            CurrentPoly = *PolyIterator;
            if ( !CurrentPoly ) continue;

            // Add to full tree polygon list ONLY if splitting was allowed
            if ( m_bAllowSplits ) AddPolygon( CurrentPoly );

            // Also add a reference to the leaf's list
            pLeaf->AddPolygon( CurrentPoly );

        } // Next Polygon

        // Store the area lists
        for ( AreaIterator = AreaList.begin();
              AreaIterator != AreaList.end(); ++AreaIterator )
        {
            // Retrieve detail area item
            TreeDetailArea * pDetailArea = *AreaIterator;
            if ( !pDetailArea ) continue;

            // Add a reference to the leaf's list
            pLeaf->AddDetailArea( pDetailArea );

        } // Next Polygon
```

```
        // Store pointer to leaf in the node and the bounds
        pNode->Leaf = pLeaf;

        // Store the bounding box in the leaf
        pLeaf->SetBoundingBox( pNode->BoundsMin, pNode->BoundsMax );

        // Store the leaf in the leaf list
        AddLeaf( pLeaf );

        // We have reached a leaf
        return true;

    } // End if reached stop code
```

If we make it this far in the function then it means the node is not a leaf and we will further divide its space and its data into eight children. To divide an oct-tree node, we create three planes with which to split and assign the polygon and detail area data to each child list. The first two planes are identical to the planes of the quad-tree node (a plane facing down the positive Z axis and a plane facing down the positive X axis). Now we add a third plane whose normal faces along the positive Y axis and splits space vertically. All three planes intersect at the center of the node and therefore the point on plane used to create each plane is simply the center point of the box.

```
    // Generate the three split planes
    D3DXPlaneFromPointNormal( &Planes[0],
                              &((BoundsMin + BoundsMax) / 2.0f),
                              &D3DXVECTOR3( 0.0f, 0.0f, 1.0f ) );

    D3DXPlaneFromPointNormal( &Planes[1],
                              &((BoundsMin + BoundsMax) / 2.0f),
                              &D3DXVECTOR3( 1.0f, 0.0f, 0.0f ) );

    D3DXPlaneFromPointNormal( &Planes[2],
                              &((BoundsMin + BoundsMax) / 2.0f),
                              &D3DXVECTOR3( 0.0f, 1.0f, 0.0f ) );
```

If we are building a clipped tree then we will need to loop through each of these three planes, and for each plane we will need to classify every polygon in the node's list against it. If we find any polygon spanning a plane, it is split by the plane, the original polygon is deleted from the list, and the two new split polygons are added. This code is exactly the same as the previous versions of the function we have seen with the exception that the outer loop now iterates through three planes instead of two.

```
    // Split all polygons against all three planes if required
    if ( m_bAllowSplits )
    {
        for ( i = 0; i < 3; ++i )
        {
            for ( PolyIterator = PolyList.begin();
                  PolyIterator != PolyList.end(); ++PolyIterator )
            {
                // Store current poly
                CurrentPoly = *PolyIterator;
                if ( !CurrentPoly ) continue;
```

```
        // Classify the poly against the first plane
        Location[0] = CCollision::PolyClassifyPlane(CurrentPoly->m_pVertex,
                                                    CurrentPoly->m_nVertexCount,
                                                    sizeof(CVertex),
                                                    (D3DXVECTOR3&)Planes[i],
                                                    Planes[i].d );

             if ( Location[0] == CCollision::CLASSIFY_SPANNING )
             {
                 // Split the current poly against the plane
                 CurrentPoly->Split( Planes[i], &FrontSplit, &BackSplit );

                 delete CurrentPoly;
                 *PolyIterator = NULL;

                 // Add these to the end of the current poly list
                 PolyList.push_back( FrontSplit );
                 PolyList.push_back( BackSplit );

             } // End if Spanning

         } // Next Polygon

     } // Next Plane

 } // End if allow splits
```

At this point if clipping was desired all the polygons in the node's list will have been clipped and will fit neatly into one of the octants of the node. Our task is to loop through every polygon in the list and find out in which octant it is contained. This is done by classifying the polygon against the three planes and analyzing the result. For example, we know that if it is behind the first plane it must lay in the back halfspace of the node. If it is in front of the second plane we know that it is somewhere in the back right area of the node. Finally, if it is in front of the third plane we know that it is contained in the upper back right octant of the node. The strategy in this code is exactly the same as in the quad-tree version except now we have an extra plane to classify each polygon against, adding a few more conditionals.

```
 // Classify the polygons and sort them into the child lists.
 for ( PolyIterator = PolyList.begin();
       PolyIterator != PolyList.end(); ++PolyIterator )
 {
     // Store current poly
     CurrentPoly = *PolyIterator;
     if ( !CurrentPoly ) continue;

     // Classify the poly against the planes
     Location[0] = CCollision::PolyClassifyPlane( CurrentPoly->m_pVertex,
                                                  CurrentPoly->m_nVertexCount,
                                                  sizeof(CVertex),
                                                  (D3DXVECTOR3&)Planes[0],
                                                  Planes[0].d );

     Location[1] = CCollision::PolyClassifyPlane( CurrentPoly->m_pVertex,
                                                  CurrentPoly->m_nVertexCount,
```

```
                                                    sizeof(CVertex),
                                                    (D3DXVECTOR3&)Planes[1],
                                                    Planes[1].d );

        Location[2] = CCollision::PolyClassifyPlane( CurrentPoly->m_pVertex,
                                                    CurrentPoly->m_nVertexCount,
                                                    sizeof(CVertex),
                                                    (D3DXVECTOR3&)Planes[2],
                                                    Planes[2].d );
```

With the classification results for the current polygon stored in the three element Location array, let us now analyze the three results and work out in which octants the polygon is contained and to which child lists the polygon's pointers should be added.

```
        // Position relative to XY plane
        if ( Location[0] == CCollision::CLASSIFY_BEHIND ||
             Location[0] == CCollision::CLASSIFY_SPANNING )
        {
            // Position relative to ZY plane
            if ( Location[1] == CCollision::CLASSIFY_BEHIND ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
            {
                // Position relative to XZ plane
                if ( Location[2] == CCollision::CLASSIFY_BEHIND ||
                     Location[2] == CCollision::CLASSIFY_SPANNING)
                                    ChildList[0].push_back( CurrentPoly );

                if ( Location[2] == CCollision::CLASSIFY_INFRONT ||
                     Location[2] == CCollision::CLASSIFY_ONPLANE ||
                     Location[2] == CCollision::CLASSIFY_SPANNING)
                                     ChildList[4].push_back( CurrentPoly );

            } // End if behind

            if ( Location[1] == CCollision::CLASSIFY_INFRONT ||
                 Location[1] == CCollision::CLASSIFY_ONPLANE ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
            {
                // Position relative to XZ plane
                if ( Location[2] == CCollision::CLASSIFY_BEHIND ||
                     Location[2] == CCollision::CLASSIFY_SPANNING)
                                    ChildList[1].push_back( CurrentPoly );

                if ( Location[2] == CCollision::CLASSIFY_INFRONT ||
                     Location[2] == CCollision::CLASSIFY_ONPLANE ||
                     Location[2] == CCollision::CLASSIFY_SPANNING)
                                    ChildList[5].push_back( CurrentPoly );

            } // End if in-front or on-plane

        } // End if behind

        if ( Location[0] == CCollision::CLASSIFY_INFRONT ||
             Location[0] == CCollision::CLASSIFY_ONPLANE ||
             Location[0] == CCollision::CLASSIFY_SPANNING )
```

```
        {
            // Position relative to ZY plane
            if ( Location[1] == CCollision::CLASSIFY_BEHIND ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
            {
                // Position relative to XZ plane
                if ( Location[2] == CCollision::CLASSIFY_BEHIND ||
                     Location[2] == CCollision::CLASSIFY_SPANNING)
                                    ChildList[2].push_back( CurrentPoly );

                if ( Location[2] == CCollision::CLASSIFY_INFRONT ||
                     Location[2] == CCollision::CLASSIFY_ONPLANE ||
                     Location[2] == CCollision::CLASSIFY_SPANNING)
                                    ChildList[6].push_back( CurrentPoly );

            } // End if behind

            if ( Location[1] == CCollision::CLASSIFY_INFRONT ||
                 Location[1] == CCollision::CLASSIFY_ONPLANE ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
            {
                // Position relative to XZ plane
                if ( Location[2] == CCollision::CLASSIFY_BEHIND ||
                     Location[2] == CCollision::CLASSIFY_SPANNING)
                                    ChildList[3].push_back( CurrentPoly );

                if ( Location[2] == CCollision::CLASSIFY_INFRONT ||
                     Location[2] == CCollision::CLASSIFY_ONPLANE ||
                     Location[2] == CCollision::CLASSIFY_SPANNING)
                                    ChildList[7].push_back( CurrentPoly );

            } // End if in-front or on-plane

        } // End if in-front or on-plane

    } // Next Triangle
```

At this point we have added all the polygon pointers for this node to the child lists so we must also do the same for the detail areas. The next section of code classifies the detail areas of this node against the three node planes to find out which child lists the detail areas should be added to. The code is almost the same as the quad-tree version with the exception that we now have an extra plane to classify against and more results to analyze.

```
    // Classify the areas and sort them into the child lists.
    for ( AreaIterator = AreaList.begin();
          AreaIterator != AreaList.end(); ++AreaIterator )
    {
        // Store current area
        TreeDetailArea * pDetailArea = *AreaIterator;
        if ( !pDetailArea ) continue;

        // Classify the area against the planes
        Location[0] = CCollision::AABBClassifyPlane( pDetailArea->BoundsMin,
                                                     pDetailArea->BoundsMax,
                                                     (D3DXVECTOR3&)Planes[0],
```

```
                                                Planes[0].d );

        Location[1] = CCollision::AABBClassifyPlane( pDetailArea->BoundsMin,
                                                     pDetailArea->BoundsMax,
                                                     (D3DXVECTOR3&)Planes[1],
                                                     Planes[1].d );

        Location[2] = CCollision::AABBClassifyPlane( pDetailArea->BoundsMin,
                                                     pDetailArea->BoundsMax,
                                                     (D3DXVECTOR3&)Planes[2],
                                                     Planes[2].d );

        // Position relative to XY plane
        if ( Location[0] == CCollision::CLASSIFY_BEHIND ||
             Location[0] == CCollision::CLASSIFY_SPANNING )
        {
            // Position relative to ZY plane
            if ( Location[1] == CCollision::CLASSIFY_BEHIND ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
            {
                // Position relative to XZ plane
                if ( Location[2] == CCollision::CLASSIFY_BEHIND ||
                     Location[2] == CCollision::CLASSIFY_SPANNING)
                                    ChildAreaList[0].push_back( pDetailArea );

                if ( Location[2] == CCollision::CLASSIFY_INFRONT ||
                     Location[2] == CCollision::CLASSIFY_SPANNING)
                                    ChildAreaList[4].push_back( pDetailArea );

            } // End if behind

            if ( Location[1] == CCollision::CLASSIFY_INFRONT ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
            {
                // Position relative to XZ plane
                if ( Location[2] == CCollision::CLASSIFY_BEHIND ||
                     Location[2] == CCollision::CLASSIFY_SPANNING)
                                    ChildAreaList[1].push_back( pDetailArea );

                if ( Location[2] == CCollision::CLASSIFY_INFRONT ||
                     Location[2] == CCollision::CLASSIFY_SPANNING)
                                    ChildAreaList[5].push_back( pDetailArea );

            } // End if in-front or on-plane

        } // End if behind

        if ( Location[0] == CCollision::CLASSIFY_INFRONT ||
             Location[0] == CCollision::CLASSIFY_SPANNING )
        {
            // Position relative to ZY plane
            if ( Location[1] == CCollision::CLASSIFY_BEHIND ||
                 Location[1] == CCollision::CLASSIFY_SPANNING )
            {
                // Position relative to XZ plane
                if ( Location[2] == CCollision::CLASSIFY_BEHIND ||
```

```
                    Location[2] == CCollision::CLASSIFY_SPANNING)
                                   ChildAreaList[2].push_back( pDetailArea );

               if ( Location[2] == CCollision::CLASSIFY_INFRONT ||
                    Location[2] == CCollision::CLASSIFY_SPANNING)
                                   ChildAreaList[6].push_back( pDetailArea );

           } // End if behind

           if ( Location[1] == CCollision::CLASSIFY_INFRONT ||
                Location[1] == CCollision::CLASSIFY_SPANNING )
           {
               // Position relative to XZ plane
               if ( Location[2] == CCollision::CLASSIFY_BEHIND ||
                    Location[2] == CCollision::CLASSIFY_SPANNING)
                                   ChildAreaList[3].push_back( pDetailArea );

               if ( Location[2] == CCollision::CLASSIFY_INFRONT ||
                    Location[2] == CCollision::CLASSIFY_SPANNING)
                                   ChildAreaList[7].push_back( pDetailArea );

           } // End if in-front or on-plane

       } // End if in-front or on-plane

   } // Next Detail Area
```

At this point we have the eight polygon lists and the eight detail area lists, so it is time to create each child node, compute its bounding box, and store a pointer to each child node in the parent node's child list.

```
   // Build each of the children here
   for( i = 0; i < 8; ++i )
   {
       // Calculate child bounding box values
       D3DXVECTOR3 NewBoundsMin, NewBoundsMax,
                   MidPoint = (BoundsMin + BoundsMax) / 2.0f;
       switch( i )
       {
           case 0: // Bottom Behind Left
               NewBoundsMin = BoundsMin;
               NewBoundsMax = D3DXVECTOR3( MidPoint.x, MidPoint.y, MidPoint.z);
               break;

           case 1: // Bottom Behind Right
               NewBoundsMin = D3DXVECTOR3( MidPoint.x, BoundsMin.y, BoundsMin.z );
               NewBoundsMax = D3DXVECTOR3( BoundsMax.x, MidPoint.y, MidPoint.z);
               break;

           case 2: // Bottom InFront Left
               NewBoundsMin = D3DXVECTOR3( BoundsMin.x, BoundsMin.y, MidPoint.z );
               NewBoundsMax = D3DXVECTOR3( MidPoint.x, MidPoint.y, BoundsMax.z );
               break;

           case 3: // Bottom InFront Right
```

```
                NewBoundsMin = D3DXVECTOR3( MidPoint.x, BoundsMin.y, MidPoint.z );
                NewBoundsMax = D3DXVECTOR3( BoundsMax.x, MidPoint.y, BoundsMax.z );
                break;

            case 4: // Top Behind Left
                NewBoundsMin = D3DXVECTOR3( BoundsMin.x, MidPoint.y, BoundsMin.z );
                NewBoundsMax = D3DXVECTOR3( MidPoint.x, BoundsMax.y, MidPoint.z);
                break;

            case 5: // Top Behind Right
                NewBoundsMin = D3DXVECTOR3( MidPoint.x, MidPoint.y, BoundsMin.z );
                NewBoundsMax = D3DXVECTOR3( BoundsMax.x, BoundsMax.y, MidPoint.z);
                break;

            case 6: // Top InFront Left
                NewBoundsMin = D3DXVECTOR3( BoundsMin.x, MidPoint.y, MidPoint.z );
                NewBoundsMax = D3DXVECTOR3( MidPoint.x, BoundsMax.y, BoundsMax.z );
                break;

            case 7: // Top InFront Right
                NewBoundsMin = D3DXVECTOR3( MidPoint.x, MidPoint.y, MidPoint.z );
                NewBoundsMax = BoundsMax;
                break;

        } // End Child Type Switch

        // Allocate child node
        pNode->Children[i] = new COctTreeNode;
        if ( !pNode->Children[i] ) return false;

        // Recurse into this new node
        BuildTree( pNode->Children[i],
                   ChildList[i],
                   ChildAreaList[i],
                   NewBoundsMin,
                   NewBoundsMax );

        // Clean up
        ChildList[i].clear();
        ChildAreaList[i].clear();

    } // Next Child

    // Success!
    return true;
}
```

At the end of the child creation loop, once the node has been attached to the parent, we traverse into that node by passing its pointer, its polygon and detail area lists, and its bounding box into another recursion of the BuildTree method.

We have now covered all the code to build an oct-tree. It should be clear to you that having the class hierarchy and the housekeeping methods tucked away in CBaseTree and CBaseLeaf, makes creating new tree types simple and requires very little code.

14.19.3 The Oct-Tree Query Methods

The methods to query the oct-tree are almost identical to their quad-tree counterparts, so we will cover them only briefly. Each function works in exactly the same way with the exception that eight children will need to be tested and traversed into instead of four.

CollectLeavesAABB - COctTree

The CollectLeavesAABB method is actually identical to its quad-tree counterpart. It is passed an empty leaf list and a bounding box describing the query volume. The function simply wraps a call to the CollectAABBRecurse method for the root node.

```
bool COctTree::CollectLeavesAABB( LeafList & List,
                                  const D3DXVECTOR3 & Min,
                                  const D3DXVECTOR3 & Max )
{
    // Trigger Recursion
    return CollectAABBRecurse( m_pRootNode, List, Min, Max );
}
```

CollectAABBRecurse – COctTree

This recursive method steps through every leaf in the tree that is contained or partially contained in the passed query volume. For a leaf found inside the query volume, its pointer is added to the passed leaf list so it can be returned to the application. If it is determined at any node that its volume does not intersect the query volume we can refrain from further traversing that branch of the tree. Otherwise, we must traverse into any child nodes that do intersect the query volume. As soon as a leaf is found, its pointer is added to the passed leaf list. If at any point the query volume is found to completely contain the node volume, we know that all the children of that node must also be contained. In such a situation the bAutoCollect boolean is set to true and for every child node under the contained node, we no longer perform AABB tests and automatically step into each of its children until the leaf nodes are encountered.

```
bool COctTree::CollectAABBRecurse( COctTreeNode * pNode,
                                   LeafList & List,
                                   const D3DXVECTOR3 & Min,
                                   const D3DXVECTOR3 & Max,
                                   bool bAutoCollect /* = false */ )
{
    bool  bResult = false;
    ULONG i;

    // Validate parameters
    if ( !pNode ) return false;

    // Does the specified box intersect this node?
```

```
    if ( !bAutoCollect && !CCollision::AABBIntersectAABB( bAutoCollect,
                                                          Min,
                                                          Max,
                                                          pNode->BoundsMin,
                                                          pNode->BoundsMax ) )
                                                          return false;

    // Is there a leaf here, add it to the list
    if ( pNode->Leaf ) { List.push_back( pNode->Leaf ); return true; }

    // Traverse down to children
    for ( i = 0; i < 8; ++i )
    {
        if ( CollectAABBRecurse( pNode->Children[i],
                                 List,
                                 Min,
                                 Max,
                                 bAutoCollect ) ) bResult = true;

    } // Next Child

    // Return the 'was anything added' result.
    return bResult;
}
```

So the only difference between this method and its quad-tree counterpart is the fact that it loops through eight children instead of four. You should be able to see a pattern forming here that will allow you to create any tree type you desire by implementing only a few core functions.

CollectLeavesRay - COctTree

The CollectLeavesRay method is called by the application to query the oct-tree for any leaves that intersect the passed ray. This method is simply a wrapper around a call to the CollectRayRecurse method for the root node. It is unchanged from its quad-tree counterpart.

```
bool COctTree::CollectLeavesRay( LeafList & List,
                                 const D3DXVECTOR3 & RayOrigin,
                                 const D3DXVECTOR3 & Velocity )
{
    return CollectRayRecurse( m_pRootNode, List, RayOrigin, Velocity );
}
```

CollectRayRecurse - COctTree

This method is almost unchanged from its quad-tree counterpart with the exception that it steps into eight children at each non-terminal node instead of four.

```
bool COctTree::CollectRayRecurse( COctTreeNode * pNode,
                                  LeafList & List,
                                  const D3DXVECTOR3 & RayOrigin,
                                  const D3DXVECTOR3 & Velocity )
{
    bool  bResult = false;
    ULONG i;
    float t;

    // Validate parameters
    if ( !pNode ) return false;

    // Does the ray intersect this node?
    if ( !CCollision::RayIntersectAABB( RayOrigin,
                                        Velocity,
                                        pNode->BoundsMin,
                                        pNode->BoundsMax,
                                        t ) ) return false;

    // Is there a leaf here, add it to the list
    if ( pNode->Leaf ) { List.push_back( pNode->Leaf ); return true; }

    // Traverse down to children
    for ( i = 0; i < 8; ++i )
    {
        if ( CollectRayRecurse( pNode->Children[i],
                                List,
                                RayOrigin,
                                Velocity ) ) bResult = true;

    } // Next Child

    // Return the 'was anything added' result.
    return bResult;
}
```

And there we have it. We have implemented the query methods for the oct-tree with only a few changes to the code for the quad-tree.

14.19.4 The Oct-Tree Debug Draw Routine

As you have seen, most of the oct-tree functions were essentially the same as their quad-tree counterparts with the exception that eight children have to be processed at each node instead of four.

Because of this, we will not spend time showing the code to the COctTree::DebugDraw method even though it has been implemented in the source code. If you examine the code you will see that it is almost identical to its quad-tree counterpart with the exception that it steps into eight children.

This concludes our discussion and implementation of oct-trees for this lesson. We now have three tree types (quad-tree, YV quad-tree, oct-tree) to choose from for use as a spatial manager in our future applications. We have just one more tree type to create in this lesson: the kD-tree.

14.20 kD-Tree Implementation

The kD-tree is really the simplest tree to implement due to the fact that we only have a single plane used to partition space at each node. Implementing the kD-tree will once again involve deriving a class from CBaseTree and implementing the core functions to build and query the tree. The kD-tree class declaration and implementation can be found in the project source files CKDTree.h and CKDTree.cpp. As with all tree types, we will implement a node type specific to the tree type.

Although the kD-tree object's query function could be implemented in exactly the same way as the quad-tree and oct-tree versions (only with two children instead of one) we will use the CKDTree::CollectLeavesRay method to implement a traversal strategy closer to what we will see when we introduce the BSP tree. You will recall that while, technically speaking, a kD-tree is a BSP tree because it partitions space into two halfspaces at each node, the kD-tree carves the world into axis aligned bounding boxes that fit neatly into each leaf node. Therefore, with a kD-tree, just like an oct-tree and a quad-tree, the query methods that traverse the tree can locate the leaves that a ray intersects by performing ray/box intersection tests if desired. However, there is an alternative that we will explore that does not use box testing.

A BSP tree (see Chapters 16 and 17) is a binary tree that partitions space into two halfspaces at each node just like the kD-tree. However, the split planes of a BSP tree do not have to be axis aligned; in fact they are usually based on the polygon data being compiled. While this will all make a lot more sense later in the course (and beyond, when we really get into using BSP trees), just know for now that the leaves of a BSP tree will not all be box shaped. The leaves can be arbitrarily shaped convex hulls which cannot be neatly represented with an AABB. Therefore, we cannot actually traverse a BSP tree in quite the same way when we want to find the leaves. The CollectLeavesRay method of the kD-tree will be a more BSP-centric version that traverses the tree performing a series of ray/plane tests instead of ray/box tests. This will give us some early insight into the BSP traversals we will be performing in later chapters. However, it is worth noting that in the case of the kD-tree, where the leaves are all box shaped, you could replace our CollectLeavesRay method with a version that is almost identical to the ones we have seen for other tree types.

14.20.1 CKDTreeNode – The Source Code

Each node in our KD-tree will be an object of type CKDTreeNode which is implemented in the project source files CKDTree.h and CKDTree.cpp. Just like the other node types we have seen it stores a bounding box and a pointer to a CBaseLeaf object which will be used only by terminal nodes. Because a kD-tree only has two children, we will not store the child pointers in an array but will instead simply have two pointers called Front and Back. The names of these children obviously describe its position relative to the parent node's single split plane. Like all other node types, we implement the recursive SetVisible method so that the tree can inform a node to start a recursive process that will flag all child leaves of the node as either visible or invisible. Finally, notice in the following class declaration that unlike the quad-tree and oct-tree implementations, where the node split planes were created temporarily and then discarded, in the case of the kD-tree, we have decided to store the single split plane used to partition the node's space during the build process.

```
class CKDTreeNode
{
public:

    // Constructors & Destructors for This Class.
     CKDTreeNode( );
    ~CKDTreeNode( );

    // Public Functions for This Class
    void SetVisible( bool bVisible );

    // Public Variables for This Class
    D3DXPLANE       Plane;              // Splitting plane for this node
    CKDTreeNode *   Front;              // Node in front of the plane
    CKDTreeNode *   Back;               // Node behind the plane
    CBaseLeaf   *   Leaf;               // If this is a leaf, store here.
    D3DXVECTOR3     BoundsMin;          // Minimum bounding box extents
    D3DXVECTOR3     BoundsMax;          // Maximum bounding box extents
    signed char     LastFrustumPlane;   // The 'last plane' index.
};
```

The reason we have decided to store the node plane in the kD-tree case is because this is more in keeping with the traditional BSP approach. In a BSP tree, each node stores a single split plane and pointers to two children that represent the halfspaces of that plane. By storing the plane in the kD-tree node, we enable our kD-tree to have the ability to work more like a traditional BSP tree if we so desire (again, in many respects they are basically the same type of tree, so this works quite well).

For example, in the CollectLeavesAABB method we will implement it using the same style as the quad-tree and oct-tree. The tree will be traversed with a query volume that will be tested for intersection against the bounding box of each child. However, in the CollectLeavesRay method we will implement the method just as we would for a BSP tree. We will assume that we have no AABB stored at each node; only a split plane. This method will send the ray down the tree and at each node test to see if the ray is spanning the node. If it is, the ray is split in two and each half of the ray is sent into the respective child for the halfspace the ray segment is contained within. Eventually, all of our split ray fragments will pop out in leaf nodes. At that point, the leaves are added to the collection list (more on this later). In order for

such a method to be implemented we need to have a tree where each node represents a split plane, just like a BSP tree. By storing the split plane in the kD-tree node and implementing our ray query method as a BSP method, we draw attention to the similarities between the kD-tree and the BSP tree. This should prove to be helpful when we move on to examine BSP trees.

SetVisible - CKDTreeNode

The SetVisible method of the kD-tree's node object is the simplest we have seen so far. If the current node being visited points to a leaf object, then this is a terminal node and we set the visibility status of the attached leaf and return. Otherwise, we are in a normal kD-tree node and we must traverse into both children.

```
void CKDTreeNode::SetVisible( bool bVisible )
{
    // Set leaf property
    if ( Leaf  ) { Leaf->SetVisible( bVisible ); return; }

    // Recurse down front / back if applicable
    if ( Front ) Front->SetVisible( bVisible );
    if ( Back  ) Back->SetVisible( bVisible );
}
```

This function is simpler than the oct-tree and quad-tree case because we have only two children to process and no need to loop.

14.20.2 The CKDTree Source Code

The CKDTree class looks almost identical to the quad-tree and oct-tree class declarations due to the fact that it is derived from CBaseTree and has to implement all the same building and querying methods.

```
class CKDTree : public CBaseTree
{
public:

    // Constructors & Destructors for This Class.
    virtual ~CKDTree();
             CKDTree( LPDIRECT3DDEVICE9 pDevice,
                      bool  bHardwareTnL,
                      float fMinLeafSize = 300.0f,
                      ULONG nMinPolyCount = 600,
                      ULONG nMinAreaCount = 0 );

    // Public Virtual Functions for This Class (from base).
    virtual bool Build                 ( bool bAllowSplits = true );

    virtual void ProcessVisibility     ( CCamera & Camera );
```

```
    virtual bool CollectLeavesAABB      ( LeafList & List,
                                          const D3DXVECTOR3 & Min,
                                          const D3DXVECTOR3 & Max );

    virtual bool CollectLeavesRay       ( LeafList & List,
                                          const D3DXVECTOR3 & RayOrigin,
                                          const D3DXVECTOR3 & Velocity );

    virtual void DebugDraw              ( CCamera & Camera );

    virtual bool GetSceneBounds         ( D3DXVECTOR3 & Min, D3DXVECTOR3 & Max );

protected:

    // Protected virtual Functions for This Class
    virtual bool BuildTree              ( CKDTreeNode * pNode,
                                          PolygonList PolyList,
                                          DetailAreaList AreaList,
                                          const D3DXVECTOR3 & BoundsMin,
                                          const D3DXVECTOR3 & BoundsMax,
                                          ULONG PlaneType = 0 );

    // Protected Functions for This Class
    void         UpdateTreeVisibility   ( CKDTreeNode * pNode,
                                          CCamera & Camera,
                                          UCHAR FrustumBits = 0x0 );

    bool         DebugDrawRecurse       ( CKDTreeNode * pNode,
                                          CCamera & Camera,
                                          bool bRenderInLeaf );

    bool         CollectAABBRecurse     ( CKDTreeNode * pNode,
                                          LeafList & List,
                                          const D3DXVECTOR3 & Min,
                                          const D3DXVECTOR3 & Max,
                                          bool bAutoCollect = false );

    bool         CollectRayRecurse      ( CKDTreeNode * pNode,
                                          LeafList & List,
                                          const D3DXVECTOR3 & RayOrigin,
                                          const D3DXVECTOR3 & Velocity );

    // Protected Variables for This Class

    CKDTreeNode * m_pRootNode;          // The root node of the tree
    bool          m_bAllowSplits;       // Is splitting allowed?
    float         m_fMinLeafSize;       // Min leaf size stop code
    ULONG         m_nMinPolyCount;      // Min polygon count stop code
    ULONG         m_nMinAreaCount;      // Min detail area count stop code

};
```

As you can see, the only difference in the member variable list is that it now stores a root node pointer of type CKDTreeNode.

Build - CKDTree

We now know that the Build function of our derived classes is responsible for allocating the root node and calculating its bounding box. It then begins the recursive building process, starting at the root, with a call to the BuildTree method.

The Build method of the kD-tree is almost identical to the others we have seen, so we will cover it only briefly here.

The function first allocates a new CKDTreeNode object and assigns the tree's root node pointer to point at it. We then store that passed boolean parameter so that we know during the building process whether or not we are creating a clipped tree.

```
bool CKDTree::Build( bool bAllowSplits /* = true */ )
{
    PolygonList::iterator       PolyIterator = m_Polygons.begin();
    DetailAreaList::iterator    AreaIterator = m_DetailAreas.begin();
    PolygonList                 PolyList;
    DetailAreaList              AreaList;
    unsigned long               i;

    // Reset our tree info values.
    D3DXVECTOR3 vecBoundsMin( FLT_MAX, FLT_MAX, FLT_MAX );
    D3DXVECTOR3 vecBoundsMax( -FLT_MAX, -FLT_MAX, -FLT_MAX );

    // Allocate a new root node
    m_pRootNode = new CKDTreeNode;
    if ( !m_pRootNode ) return false;

    // Store the allow splits value for later retrieval.
    m_bAllowSplits = bAllowSplits;
```

We now need to calculate the bounding box for the root node so we loop through every vertex of every polygon registered with the tree and expand the box to fit all vertices. As we process each polygon, its pointer is also copied into the local polygon list (PolyList). After we have resized the box for every polygon and made a copy of the original tree's polygon list, we test to see if a clipped tree is being built. If so, we empty the tree's polygon list since it will be populated with polygon fragments during clipping.

```
    // Loop through all of the initial polygons
    for ( ; PolyIterator != m_Polygons.end(); ++PolyIterator )
    {
        // Retrieve the polygon
        CPolygon * pPoly = *PolyIterator;
        if ( !pPoly ) continue;

        // Calculate total scene bounding box.
        for ( i = 0; i < pPoly->m_nVertexCount; ++i )
        {
            // Store info
            CVertex * pVertex = &pPoly->m_pVertex[i];
            if ( pVertex->x < vecBoundsMin.x ) vecBoundsMin.x = pVertex->x;
```

```
            if ( pVertex->y < vecBoundsMin.y ) vecBoundsMin.y = pVertex->y;
            if ( pVertex->z < vecBoundsMin.z ) vecBoundsMin.z = pVertex->z;
            if ( pVertex->x > vecBoundsMax.x ) vecBoundsMax.x = pVertex->x;
            if ( pVertex->y > vecBoundsMax.y ) vecBoundsMax.y = pVertex->y;
            if ( pVertex->z > vecBoundsMax.z ) vecBoundsMax.z = pVertex->z;
        }

        // Store this polygon in the top polygon list
        PolyList.push_back( pPoly );

    } // Next Polygon

    // Clear the initial polygon list if we are going to split the polygons
    // as this will eventually become storage for whatever gets built
    if ( bAllowSplits ) m_Polygons.clear();
```

The bounding box is large enough to contain all registered polygons, but we also need to factor in any registered detail areas.

```
    // Loop through all of the detail areas
    for ( ; AreaIterator != m_DetailAreas.end(); ++AreaIterator )
    {
        // Retrieve the detail area
        TreeDetailArea * pDetailArea = *AreaIterator;
        if ( !pDetailArea ) continue;

        // Calculate total scene bounding box.
        D3DXVECTOR3 & Min = pDetailArea->BoundsMin;
        D3DXVECTOR3 & Max = pDetailArea->BoundsMax;
        if ( Min.x < vecBoundsMin.x ) vecBoundsMin.x = Min.x;
        if ( Min.y < vecBoundsMin.y ) vecBoundsMin.y = Min.y;
        if ( Min.z < vecBoundsMin.z ) vecBoundsMin.z = Min.z;
        if ( Max.x > vecBoundsMax.x ) vecBoundsMax.x = Max.x;
        if ( Max.y > vecBoundsMax.y ) vecBoundsMax.y = Max.y;
        if ( Max.z > vecBoundsMax.z ) vecBoundsMax.z = Max.z;

        // Store this in the top detail area list
        AreaList.push_back( pDetailArea );

    } // Next Polygon
```

At this point we call the BuildTree method to start the tree building process from the root node. The function is passed the root node pointer and a list of polygons and detail areas that are contained in the root node's bounding box. The final two parameters represent the AABB that bounds all data contained in the root node.

```
    // Build the tree itself
    if ( !BuildTree( m_pRootNode, PolyList, AreaList, vecBoundsMin,vecBoundsMax))
         return false;

    // Allow our base class to finish any remaining processing
    return CBaseTree::PostBuild( );
}
```

When the BuildTree method returns and the entire tree has been compiled, we remember to call the CBaseTree::PostBuild method to give the base class a chance to initialize the rendering system and calculate the AABBs for each polygon in the tree.

BuildTree - CKDTree

This function is a little different from the others we have seen so far. Not only does it split the node using a single plane and compile two lists of polygon and detail area data (one for each child), the plane used to split the node is actually switched between iterations. That is, at the first node we split the node using a plane whose normal faces down the world Z axis. When we step into each of the children, we flip the plane so that it is now aligned with the world X axis. For each of its children the plane is flipped again so that its normal is facing along the world Y axis. Therefore, although at each node we are partitioning space into only two children, the scene is carved up in a very similar way to an oct-tree. As we step through the levels of the kD-tree, the plane is continuously alternated between the three world axis aligned planes, wrapping around to the first plane used after every three levels of depth.

> **Note:** You can also use a kD-tree to partition 2D space. Simply transition between the two planes you are interested in rather than three planes.

The Build function is actually a bit simpler than the others we have seen, although at first glance it may not appear so because it is a little larger. The only reason why this is the case is because we are not generating the child nodes in a loop since there are only two children.

The kD-tree BuildTree method accepts an additional plane flag parameter which defaults to zero the first time it is called for the root node. Every time this method calls itself recursively, this parameter will be set in the range [0, 2] describing which of the three world aligned planes should be used to partition the node. The first time it is called from the Build method no value is passed, which means it is set to zero for the root node. This tells the function that the root node should be divided using the first of the three split planes; the split plane whose normal is pointing down the world z axis. Every time this method calls itself to traverse into children, it will increment this value (wrapping around to zero once it is greater than 2) such that the next world aligned plane will be used for its children. For example, the root node will use plane 0 which is the plane aligned with the world Z axis. Its children will be passed a plane value of 1 describing that they should be partitioned using the plane aligned with the world X axis, and so on.

The first section of the code stores the passed bounding box in the passed node and calculates the size of the node's bounding box. It then uses this box and the number of polygons and detail areas passed into the node to determine if this node should become a leaf.

```
bool CKDTree::BuildTree(      CKDTreeNode * pNode,
                              PolygonList PolyList,
                              DetailAreaList AreaList,
                              const D3DXVECTOR3 & BoundsMin,
                              const D3DXVECTOR3 & BoundsMax,
                              ULONG PlaneType /* = 0 */ )
{
```

```
    D3DXVECTOR3                 Normal;
    PolygonList::iterator       PolyIterator;
    DetailAreaList::iterator    AreaIterator;
    CPolygon                  * CurrentPoly, * FrontSplit, * BackSplit;
    PolygonList                 FrontList, BackList;
    DetailAreaList              FrontAreaList, BackAreaList;
    bool                        bStopCode;

    // Store the bounding box properties in the node
    pNode->BoundsMin = BoundsMin;
    pNode->BoundsMax = BoundsMax;

    // Calculate 'Stop' code
    D3DXVECTOR3 vecLeafSize = BoundsMax - BoundsMin;
    bStopCode  = (AreaList.size() == 0 && PolyList.size() == 0) ||
                 (AreaList.size() <= m_nMinAreaCount &&
                  PolyList.size() <= m_nMinPolyCount) ||
                 D3DXVec3Length( &vecLeafSize ) <= m_fMinLeafSize;
```

As with all other tree types, if the stop code boolean gets set to true, we know we have reached a terminal node. The code for creating the leaf is exactly the same as all other tree types. We create a new CBaseLeaf object and then add every polygon and detail area that made it into this node to the leaf. If a clipped tree is being built, then we also re-add the polygon data that made it into this node to the tree's main polygon list. We then attach the leaf to the node, store the node's bounding box in the leaf, and add the leaf to the tree's leaf list before returning.

```
    // If we reached our stop limit, build a leaf here
    if ( bStopCode )
    {
        // Build a leaf
        CBaseLeaf * pLeaf = new CBaseLeaf( this );
        if ( !pLeaf ) return false;

        // Store the polygons
        for (     PolyIterator = PolyList.begin();
                  PolyIterator != PolyList.end(); ++PolyIterator )
        {
            // Retrieve poly
            CurrentPoly = *PolyIterator;
            if ( !CurrentPoly ) continue;

            // Add to full tree polygon list ONLY if splitting was allowed
            if ( m_bAllowSplits ) AddPolygon( CurrentPoly );

            // Also add a reference to the leaf's list
            pLeaf->AddPolygon( CurrentPoly );

        } // Next Polygon

        // Store the area lists
        for ( AreaIterator = AreaList.begin();
              AreaIterator != AreaList.end(); ++AreaIterator )
        {
            // Retrieve detail area item
            TreeDetailArea * pDetailArea = *AreaIterator;
```

```
            if ( !pDetailArea ) continue;

            // Add a reference to the leaf's list
            pLeaf->AddDetailArea( pDetailArea );

        } // Next Polygon

        // Store pointer to leaf in the node and the bounds
        pNode->Leaf = pLeaf;

        // Store the bounding box in the leaf
        pLeaf->SetBoundingBox( pNode->BoundsMin, pNode->BoundsMax );

        // Store the leaf in the leaf list
        AddLeaf( pLeaf );

        // We have reached a leaf
        return true;

    } // End if reached stop code
```

If we reach this point in the function, we know we are not at a leaf node and we will have to further partition this node into two halfspaces using the split plane. Which of the three axis aligned split planes we use to create the split plane is determined by the PlaneType parameter passed in. Notice in the next code block that this time we actually store the split plane in the node's Plane member.

```
    // Otherwise we must continue to refine. Choose a plane.
    if ( PlaneType == 0 )
        Normal = D3DXVECTOR3( 0.0f, 0.0f, 1.0f );
    else if ( PlaneType == 1 )
        Normal = D3DXVECTOR3( 1.0f, 0.0f, 0.0f );
    else if ( PlaneType == 2 )
        Normal = D3DXVECTOR3( 0.0f, 1.0f, 0.0f );

    // Generate the actual plane
    D3DXPlaneFromPointNormal( &pNode->Plane,
                              &((BoundsMin + BoundsMax) / 2.0f),
                              &Normal );
```

Now that we have determined which split plane to use at this node, we will loop through every polygon in the node's polygon list and classify it against the plane. If it is in front of the plane we will add it to the front polygon list (the list that will be passed to the front child) and if it is behind the plane we will add it to the back list. In the case where the polygon is on the plane, it does not really matter which child we assign it to (we will add it to the front list).

```
    // Classify all polygons
    for (   PolyIterator = PolyList.begin();
            PolyIterator != PolyList.end(); ++PolyIterator )
    {
        // Store current poly
        CurrentPoly = *PolyIterator;

        // Classify the poly against the plane
```

```
        CCollision::CLASSIFYTYPE Location = CCollision::PolyClassifyPlane
                                                    (CurrentPoly->m_pVertex,
                                                     CurrentPoly->m_nVertexCount,
                                                     sizeof(CVertex),
                                                     (D3DXVECTOR3&)pNode->Plane,
                                                     pNode->Plane.d );

        // Decide what to do
        switch ( Location )
        {
            case CCollision::CLASSIFY_BEHIND:

                // Add straight to the back list
                BackList.push_back( CurrentPoly );
                break;

            case CCollision::CLASSIFY_ONPLANE:
            case CCollision::CLASSIFY_INFRONT:

                // Add straight to the front list
                FrontList.push_back( CurrentPoly );
                break;
```

If the polygon is spanning the plane and we are building a clipped tree, we will split the polygon into two new child polygons and delete the original polygon. We will then add the front split polygon to the front list and the back split polygon to the back list. If the polygon is spanning but we are not building a clipped tree, we will simply assign the polygon to the front and back lists to that it gets assigned to both child nodes in which it is partially contained.

```
            case CCollision::CLASSIFY_SPANNING:

                // Is splitting allowed?
                if ( m_bAllowSplits )
                {
                    // Split the current poly against the plane and delete it
                    CurrentPoly->Split( pNode->Plane, &FrontSplit, &BackSplit );
                    delete CurrentPoly;

                    // Add the fragments (if any survived) to the appropriate lists
                    if ( BackSplit  ) BackList.push_back( BackSplit );
                    if ( FrontSplit ) FrontList.push_back( FrontSplit );
                }
                else
                {
                    // Add to both lists!
                    FrontList.push_back( CurrentPoly );
                    BackList.push_back( CurrentPoly );
                }
                break;
        }
    }
```

With the polygon lists compiled for both children, we will classify the detail areas against the plane and add them to either the front or back list (or both). If the detail area is behind the plane it is added to the

back list of detail objects and if it is in front of the plane it is added to the front detail list. If the detail area's AABB is spanning the plane, it is added to the detail area list of both children.

```
    // Classify all detail areas
    for ( AreaIterator = AreaList.begin();
          AreaIterator != AreaList.end();
        ++AreaIterator )
    {
        // Store current area
        TreeDetailArea * pDetailArea = *AreaIterator;

        // Classify the area against the plane
        CCollision::CLASSIFYTYPE Location = CCollision::AABBClassifyPlane
                                                       (pDetailArea->BoundsMin,
                                                        pDetailArea->BoundsMax,
                                                        (D3DXVECTOR3&)pNode->Plane,
                                                        pNode->Plane.d );

        // Decide what to do
        switch ( Location )
        {
            case CCollision::CLASSIFY_BEHIND:

                // Add straight to the back list
                BackAreaList.push_back( pDetailArea );
                break;

            case CCollision::CLASSIFY_INFRONT:

                // Add straight to the front list
                FrontAreaList.push_back( pDetailArea );
                break;

            case CCollision::CLASSIFY_SPANNING:

                // Add to both the front and back lists
                BackAreaList.push_back( pDetailArea );
                FrontAreaList.push_back( pDetailArea );
                break;

        } // End Switch

    } // Next Detail Area
```

At this point we have the polygon lists and the detail area lists compiled for each child node that we are about to create. Unlike the same method from previous tree types, we will not perform child creation in a loop (we will unroll that loop). This next section of code builds the front child first. It calculates its bounding volume based on the split plane being used by the parent node and then allocates a new CKDTreeNode object which is assigned to the front child pointer of the parent node. We then recur into that node by calling the BuildTree function again for the front child.

```
    D3DXVECTOR3 NewBoundsMin, NewBoundsMax, MidPoint;

    // Calculate box midpoint
```

```
    MidPoint = (BoundsMin + BoundsMax) / 2.0f;

    // Calculate child bounding box values
    NewBoundsMax = BoundsMax;

    if ( PlaneType == 0 ) // XY Plane
        NewBoundsMin = D3DXVECTOR3( BoundsMin.x, BoundsMin.y, MidPoint.z);
    else if ( PlaneType == 1 ) // XZ Plane
        NewBoundsMin = D3DXVECTOR3( MidPoint.x, BoundsMin.y, BoundsMin.z);
    else if ( PlaneType == 2 ) // YZ Plane
        NewBoundsMin = D3DXVECTOR3( BoundsMin.x, MidPoint.y, BoundsMin.z);

    // Allocate child node
    pNode->Front = new CKDTreeNode;
    if ( !pNode->Front ) return false;

    // Recurse into this new node
    BuildTree( pNode->Front,
               FrontList,
               FrontAreaList,
               NewBoundsMin,
               NewBoundsMax,
              (PlaneType + 1) % 3 );

    // Clean up
    FrontList.clear();
    FrontAreaList.clear();
```

As you can see, the above code is calculating the bounding box for the child that is in the front half space of the node. This basically means the child node's bounding volume will be one half of the parent node's volume. If the parent node split its space using the XY plane, the minimum extent of the bounding box will be minx, miny and minz as this describes the minimum extents of a box that starts halfway along the parent node's Z axis (see Figure 14.81). In the case of the YZ plane, the front child's bounding box will be the right half of the parent node, where the minimum X extent will be in the center of the box. In each case, because of the way the normals of the planes are facing, the maximum extents of the front child will always be the maximum extents of the parent node (see Figures 14.81 through 14.83). Figure 14.83 similarly shows how the minimum and maximum extents of the front child's AABB would be calculated using the parent node's bounding box if the parent node partitioned space using the XZ plane.

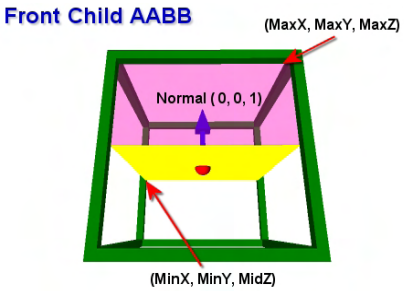

Figure 14.81
Front child of the XY plane.

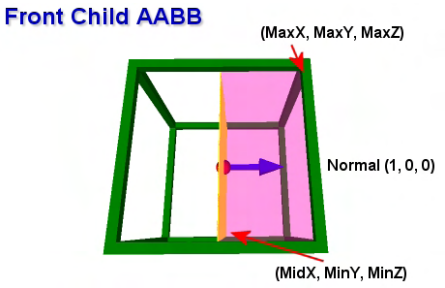

Figure 14.82
Front child of the YZ plane.

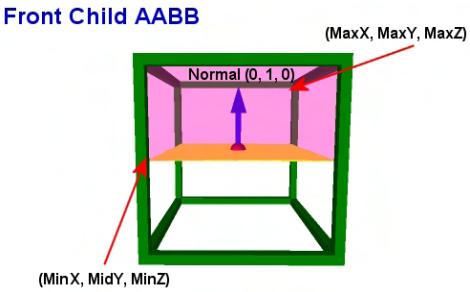

Figure 14.83
Front Child of the XZ Plane.

After we determine which plane was used in the above code we calculate the bounding box for the front child and allocate the new node. The node is then attached to the parent node's front pointer. The BuildTree function then calls itself to step into the front child node and continue the build process down that branch of the tree. Notice that when we call the BuildTree function, we increment the current value of the PlaneType parameter so that the child node will use the next plane in the list of three to partition its space. Also note that we mod this with the number 3 so that as soon as we increment PlaneCount beyond a value of 2, it wraps around to 0 again to start the plane selection process from the beginning. That is, in the child node, the XY plane will be chosen as the split plane.

When the BuildTree method returns above, the front child and all its child nodes and leaves will have been created. Now it is time to build the back child (i.e., the child that is positioned in the back halfspace of the parent node's split plane).

The first thing we do is calculate the bounding box extents of the back child based on the plane that was used as a splitter for the parent node. Because this child is on the back of the parent node's split plane, the bounding box extents of the child will range from min to midpoint on the axis aligned with the plane. The minimum extents of the back child will always be equal to the minimum extents of the parent node's volume for all components, regardless of the split plane being used.

```
    // Calculate child bounding box values
    NewBoundsMin = BoundsMin;

    if ( PlaneType == 0 ) // XY Plane
        NewBoundsMax = D3DXVECTOR3( BoundsMax.x, BoundsMax.y, MidPoint.z);
    else if ( PlaneType == 1 ) // XZ Plane
        NewBoundsMax = D3DXVECTOR3( MidPoint.x, BoundsMax.y, BoundsMax.z);
    else if ( PlaneType == 2 ) // YZ Plane
        NewBoundsMax = D3DXVECTOR3( BoundsMax.x, MidPoint.y, BoundsMax.z);
```

If you are having trouble picturing what we are doing then take a look at Figures 14.84 through 14.86. The figures depict how the bounding box of the back child is calculated using the components of the parent node's volume based on chosen split plane.

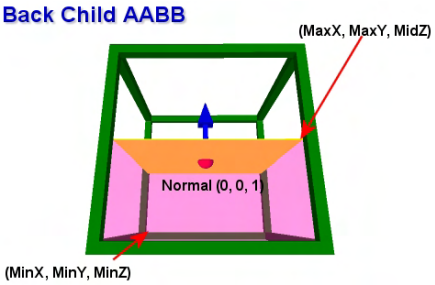

Figure 14.84
Back child of the XY plane.

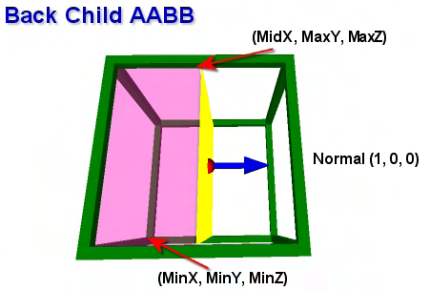

Figure 14.85
Back child of the YZ plane.

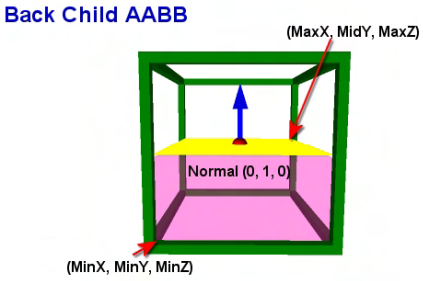

Figure 14.86
Back child of the XZ plane

With the bounding box calculated for the back child we allocate a new CKDTreeNode and attach it to the parent node's Back child pointer. We then call the BuildTree method and recur into the back child passing in the polygon and detail area lists for that node along with its bounding volume. Once again, we increment the PlaneType value that was passed into this instance of the function so that in the next level of the tree we use the next split plane. The modulus is performed so that we wrap this value around to 0 should it exceed 2.

```
    // Allocate child node
    pNode->Back = new CKDTreeNode;
    if ( !pNode->Back ) return false;

    // Recurse into this new node
    BuildTree( pNode->Back,
               BackList,
               BackAreaList,
               NewBoundsMin,
               NewBoundsMax,
               (PlaneType + 1) % 3 );

    // Clean up
    BackList.clear();
    BackAreaList.clear();

    // Success!
    return true;
}
```

This completes the build code for the kD-tree, the last tree type we will have to compile in this lesson. We have now learned how to build quad-trees, oct-trees and kD-trees. These trees should turn out to be very useful throughout your game making career. Indeed, we will be using such trees in virtually all of our lab projects moving forward.

14.20.3 The kD-Tree Query Methods

Querying the kD-tree can be done in a nearly identical manner to quad-trees and oct-trees, with the exception that only two children will need to be tested and traversed during leaf collection. However, although CollectLeavesAABB (and its recursive helper function) will be implemented in an almost

identical manner to the previous versions we have covered for other trees, we have chosen to implement the CollectLeavesRay method (and its recursive helper function) to test using the node split plane instead of the bounding box. This need not be done this way because the box could be used instead, but it does give us an opportunity to introduce a strategy that will be used by its BSP counterpart (BSP trees are generally traversed using the node planes). This will help prepare you for the querying operations we will perform on BSP trees, where the leaves do not fit neatly into axis aligned bounding boxes as we have seen with the trees in this lesson.

CollectLeavesAABB - CKDTree

This method is identical to those implemented in all other tree classes. It simply wraps the call to the recursive CollectAABBRecurse method for the root node. It is called by the application to start the traversal at the root node, finding and collecting all leaves that intersect the query volume.

```
bool CKDTree::CollectLeavesAABB( LeafList & List,
                                 const D3DXVECTOR3 & Min,
                                 const D3DXVECTOR3 & Max )
{
    // Trigger Recursion
    return CollectAABBRecurse( m_pRootNode, List, Min, Max );
}
```

CollectAABBRecurse – CKDTree

This method is called by the previous method to visit the nodes of the tree and step into any children that are inside (or partially inside) the query volume. It is implemented in an identical manner to the other versions of this method for the other tree types with the exception that when a node is not a leaf, we step into only two children.

```
bool CKDTree::CollectAABBRecurse( CKDTreeNode * pNode,
                                  LeafList & List,
                                  const D3DXVECTOR3 & Min,
                                  const D3DXVECTOR3 & Max,
                                  bool bAutoCollect /* = false */ )
{
    bool bResult = false;

    // Validate parameters
    if ( !pNode ) return false;

    // Does the specified box intersect this node?
    if ( !bAutoCollect && !CCollision::AABBIntersectAABB( bAutoCollect,
                                                          Min,
                                                          Max,
                                                          pNode->BoundsMin,
                                                          pNode->BoundsMax ))
           return false;
```

```
    // Is there a leaf here, add it to the list
    if ( pNode->Leaf ) { List.push_back( pNode->Leaf ); return true; }

    // Traverse down to children
    if ( CollectAABBRecurse( pNode->Front, List, Min, Max, bAutoCollect ))
         bResult = true;

    if ( CollectAABBRecurse( pNode->Back , List, Min, Max, bAutoCollect ))
         bResult = true;

    // Return the 'was anything added' result.
    return bResult;
}
```

Once again we use the bAutoCollect boolean to initiate immediate collection of children without further AABB testing.

CollectLeavesRay - CKDTree

The CollectLeavesRay method is also identical to previous versions. It wraps the call to the CollectRayRecurse method for the root node. The function is passed an empty leaf list and a ray origin and delta vector. On function return the passed leaf list will contain a list of all the leaves intersected by the ray.

```
bool CKDTree::CollectLeavesRay( LeafList & List,
                                const D3DXVECTOR3 & RayOrigin,
                                const D3DXVECTOR3 & Velocity )
{
    return CollectRayRecurse( m_pRootNode, List, RayOrigin, Velocity );
}
```

CollectRayRecurse - CKDTree

Unlike prior versions, we will implement this query using the split plane stored at each node instead of the bounding box. These are the types of queries we will be implementing when we start relying on BSP trees in the later lessons of this course. It also tends to be more efficient to perform a single ray plane test rather than a ray box test.

The basic process is to send a ray into a node and perform a ray/plane intersection with the split plane stored there. If the ray is contained completely in the front space of the plane, the function calls itself recursively passing the ray into the front child. If the ray is contained in the back space of the node we send the ray into the back child. However, if the ray is spanning the node we do *not* simply pass it down both the front and back children since this would certainly return leaves that the ray is not intersecting. Instead we will split the ray on the plane and send each ray fragment into its respective child node. Of course, the ray may get split into many fragments during its journey through the tree, but eventually

these ray fragments will pop out in leaf nodes for all leaves that were intersected by the original ray. Figure 14.87 depicts the basic ray splitting concept.

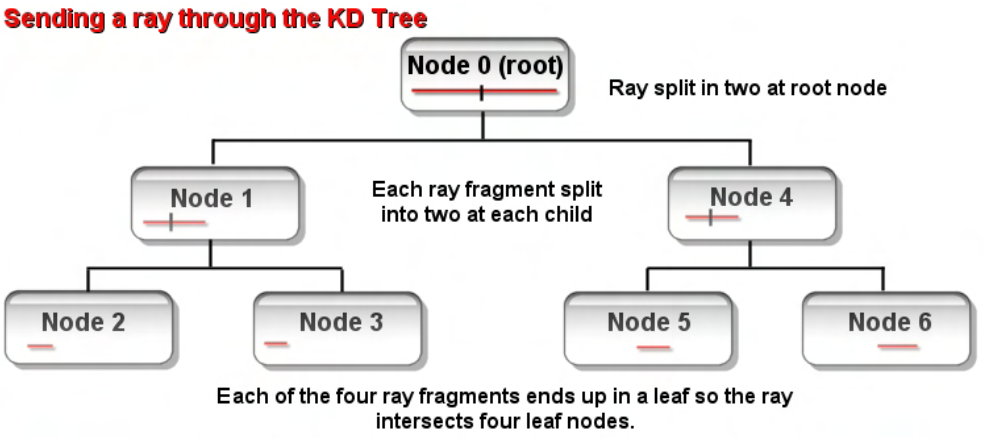

Figure 14.87

In this simple example, the kD-tree consists of seven nodes in total, with four of them being leaf nodes. The ray is assumed to intersect all leaf nodes in this example. Let us step through what is happening.

At the root node, the ray is classified against the plane and is found to be spanning that plane. The ray is split into two segments by this split plane creating two new rays, one in the plane's back space and the other in the front space. The ray fragment in the root node's front space is passed down into the front node (node 1). The ray fragment in node 1 is also found to be spanning its plane, so is further split into two new fragments. One fragment is passed to its front child (node 2) and the other is passed into its back child (node 3). When we reach node 2 and node 3, we find that the ray fragment has been passed into leaf nodes, so the original ray must intersect these leaves. The leaves for both nodes would thus be added to the leaf collection list. At this point the function would return and the recursive process will unroll back up the root node's traversal into its front child. Now the root node has to pass the other ray fragment (the back space fragment) into its back child (node 5). The ray fragment passed into node 5 is also spanning node 5's plane, so it is further split into two ray fragments which end up being passed into leaf nodes 6 and 7 for the front and back fragment, respectively. These are leaves are also added to the leaf collection list.

The above example had the ray was spanning the plane at every node to get across the idea of the recursive splitting process. However, if at any node the ray is found to be in *either* the front or back space, the ray is not split; it is simply passed into the respective child unaltered. In the end, we are essentially just sending the ray down the tree and collecting any leaves that contain any portion/fragment of the ray.

Clipping a ray that spans a plane into two fragments is very easy to do using the CCollision::RayIntersectPlane method we added to our collision library in the previous chapter. This function returns a *t* value of intersection that can be multiplied with the ray delta vector and added to the origin to calculate the actual point of intersection. Once we have the ray start and end points and the ray intersection point, it is easy to see which points define each ray fragment (see Figure 14.88).

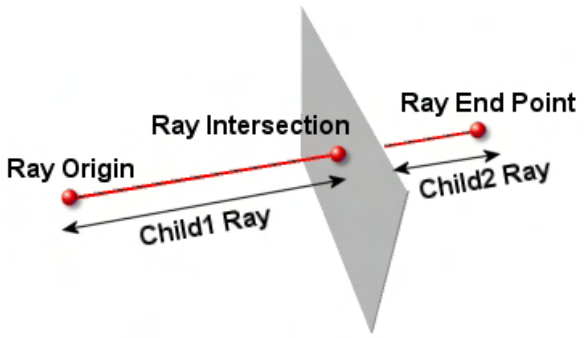

Figure 14.88

In this example we see a plane that intersects a ray. Once the intersection point with the plane is calculated, the ray in the left halfspace in this image is formed by the ray origin and the intersection point, and the ray fragment in the right halfspace is formed by the ray intersection point and the ray end point. That is, the ray intersection point forms the end of one fragment and the beginning of another. These two ray fragments would then be passed into the child nodes.

While splitting the ray and sending the fragments down the tree is pretty simple to implement, what might not be so obvious is why we need to split the ray at all. One might imagine that if the ray spans the plane we could simply send it in its entirety into both children. However, this will actually return incorrect leaves as shown in Figure 14.89.

Figure 14.89 shows a very simple kD-tree consisting of four leaf nodes and a ray that intersects three of those four leaves. In this example, we can assume that the split plane stored at the root node is labeled 'A'. During the building process it was determined that the child node attached to the front of the root (plane A) no longer needed to be subdivided, so the node was made a leaf. This leaf is labeled Leaf 1. When the building process processed the back child of the root (the space down the back of plane A) it was decided that this space should be further subdivided and as such a non-terminal node was created whose split plane is labeled 'B'. Down the front of B it was decided that we no longer needed to partition space, so Leaf 2 was created there. Down the back of B, another non-terminal node was created with the split plane labeled 'C', which further partitioned the top right quadrant of the tree into Leaf 3 and Leaf 4.

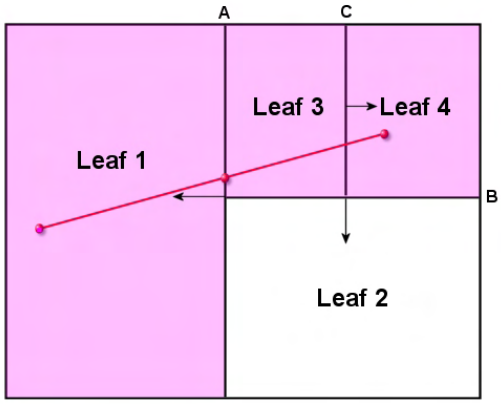

Figure 14.89

We can clearly see that the ray is contained in only three of the four leaf nodes (1, 3, and 4). However, let us see what would happen if we did not split the ray in the spanning case and just sent it through the tree unaltered. What we will learn is that Leaf 2 will be added to the collection list even though the ray does not intersect it. If Leaf 2 contains tens of thousands of polygons, that is a lot of polygons we would need to send to a narrow phase unnecessarily. Let us see why this is the case.

First we send the ray into the root node where it is classified against plane A. We find that it is spanning plane A (remember, we are not splitting in this example to demonstrate the flaw in that approach) so we send the ray into the front and back child of A. Down the front of A the ray ends up in Leaf 1 and it gets added to the list. So far, so good. Down the back of A we find we are at node B and once again classify the ray against plane B. Remembering that planes are infinite, we can see that the ray is actually spanning plane B (imagine B extending infinitely to the left and right). Because it is spanning B, we need to pass it into both children of B. Unfortunately, the front child of B is Leaf 2. Thus, we have just

allowed the ray to fall into Leaf 2 even though it does not intersect this leaf. We need go no further; already we can see that our approach is flawed.

Let us now see what happens if we split the ray at every spanning plane.

Looking again at Figure 14.89 we can see that when the ray is first passed into the root node, it is found to be spanning node plane A. We calculate the intersection point with the plane and create two child rays. The first ray is in the plane's front space and has the original ray's origin as its origin and the intersection point as its end point. The second ray is the ray contained in the plane's back space and has the intersection point as its origin and the original ray end point as its end point. We can see this relationship in Figure 14.90.

Figure 14.90 shows the intersection point between the ray and plane A. We create two new rays at this node. The ray fragment in the plane's front half space is fed into Leaf 1 and Leaf 1 is added to the list. The ray in the plane's back space is created from the ray intersection point with plane A and the original ray end point at the top right of the ray. When we feed this ray fragment into the back space of plane A, we find ourselves at the non-terminal node containing plane B. The important point here is that when we test the ray fed into node B, whose origin is the intersection point between the original ray and plane A, we see that the ray is completely behind plane B and therefore, we never traverse into the front space of B. Therefore, the ray never reaches Leaf 2 and Leaf 2 is never added to the collection list.

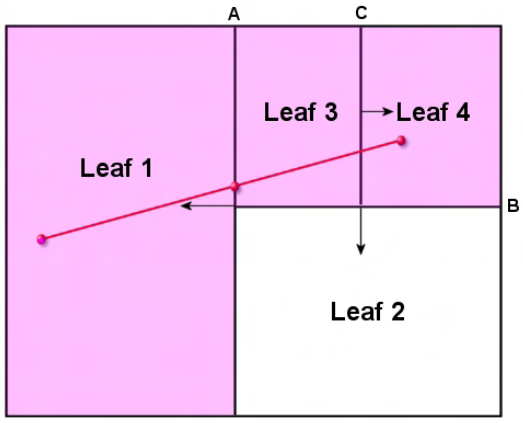

Figure 14.90

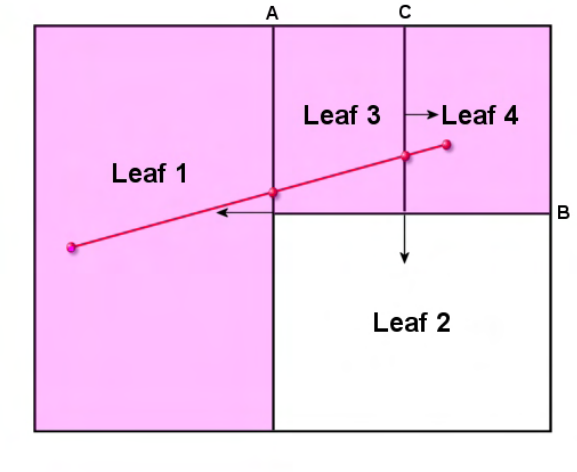

Figure 14.91

In Figure 14.90 the ray fragment was found to be completely behind plane B so it is passed into its child where it enters the non-terminal node containing node C. At node C, the ray spans its plane so the fragment is further clipped into two more ray fragments (see Figure 14.91).

The ray fragment in the back space of C is constructed from the original intersection point between the ray and node A and the intersection of the current fragment with node C. This is passed into the back node of C where it enters Leaf 3 and is added to the leaf collection list. The ray fragment in the front space of C is created from the intersection point of the ray fragment with the split plane of node C and the end point of the ray fragment passed into that function (the original ray end point).

So we have seen why the ray must be split at each node plane. This is a practice that we will see used again when working with BSP trees. Let us now look at the recursive function called by the CKDTree::CollectLeavesRay method to perform this ray splitting traversal through the tree.

Just like the ray traversal method for the other tree types, the parameters are the current node being visited, the leaf list for collection, and the ray origin and delta vectors.

```
bool CKDTree::CollectRayRecurse( CKDTreeNode * pNode,
                                 LeafList & List,
                                 const D3DXVECTOR3 & RayOrigin,
                                 const D3DXVECTOR3 & Velocity )
{
    CCollision::CLASSIFYTYPE PointA, PointB;
    D3DXVECTOR3 RayEnd, Intersection;
    bool        bResult;
    D3DXPLANE   Plane;
    float       t;

    // No operation if the node was null
    if ( !pNode ) return false;

    // If this node stores a leaf, just add it to the list and return
    if ( pNode->Leaf )
    {
        // Add the leaf to the list
        List.push_back( pNode->Leaf );

        // We collected a leaf
        return true;

    } // End if stores a leaf
```

The section of code above shows what happens when the node being visited is a leaf node. This can only happen if a fragment of the original ray has made it into a leaf. When this is the case the node's leaf pointer is simply added to the leaf collection list and the function returns true so that the caller knows that at least part of the ray was found to exist in at least one leaf.

The remainder of the code is executed only when a non-terminal node is entered. The first thing we do is add the ray delta vector to the ray origin to calculate the ray end position. We also use a local variable to point to the node plane for ease of access. We then classify the ray origin and ray end points against the split plane and store the classification results in the PointA and PointB local variables.

```
    // Calculate the end point of the ray
    RayEnd = RayOrigin + Velocity;

    // Retrieve the plane, and classify the ray points against it
    Plane  = pNode->Plane;

    PointA = CCollision::PointClassifyPlane( RayOrigin,
                                             (D3DXVECTOR3&)Plane,
                                             Plane.d );
```

```
    PointB = CCollision::PointClassifyPlane( RayEnd   ,
                                             (D3DXVECTOR3&)Plane,
                                             Plane.d );
```

If both points of the ray lay on the plane then the ray lies exactly on that plane. In this case, we will pass the ray into the front and back children. If a ray is on the plane, it is on the boundary of both nodes, so we should pass it into both nodes. Notice that we initially set the result boolean to false and set it true if any of the front and back recursions return true. We then return this boolean from the function so that the intersection status is returned back up to the root.

```
    // Test for the combination of ray point positions
    if ( PointA == CCollision::CLASSIFY_ONPLANE &&
         PointB == CCollision::CLASSIFY_ONPLANE )
    {
        // Traverse down the front and back
        bResult = false;
        if ( CollectRayRecurse( pNode->Front,
                                List,
                                RayOrigin,
                                Velocity ) ) bResult = true;

        if ( CollectRayRecurse( pNode->Back,
                                List,
                                RayOrigin,
                                Velocity ) ) bResult = true;
        return bResult;

    } // End If both points on plane
```

If the ray origin is in front of the plane and the ray end point is behind the plane (i.e., we have a spanning case), we perform a ray/plane intersection to calculate the *t* value from the ray origin. Once we have the *t* value we calculate the intersection point by scaling the ray delta vector by *t* and adding the result to the ray origin. Once we have the intersection point we recurs into the front child with the sub-ray constructed from the ray origin and the intersection point and recurs into the back child using the sub-ray constructed from the ray intersection point and the ray end point. If either function returns true, we set the boolean result to true and return.

```
    else

    if ( PointA == CCollision::CLASSIFY_INFRONT &&
         PointB == CCollision::CLASSIFY_BEHIND )
    {
        // The ray is spanning the plane, with the origin in front.
        CCollision::RayIntersectPlane( RayOrigin,
                                       Velocity,
                                       (D3DXVECTOR3&)Plane,
                                       Plane.d,
                                       t,
                                       true );

        Intersection = RayOrigin + (Velocity * t);

        // Traverse down both sides passing the relevant segments of the ray
```

```
        bResult = false;

        if ( CollectRayRecurse( pNode->Front,
                                List,
                                RayOrigin,
                                Intersection - RayOrigin ) ) bResult = true;

        if ( CollectRayRecurse( pNode->Back,
                                List,
                                Intersection,
                                RayEnd - Intersection ) ) bResult = true;
        return bResult;

    } // End If Spanning with origin in front
```

The next case is almost identical to the previous spanning case but is executed if the ray origin is behind the plane and the ray end point is in front of the plane. The same basic steps are taken, but the sub-ray fed into each halfspace is constructed differently due the different orientation of the plane with respect to the ray. This time, the sub-ray that we feed into the front node starts at the original ray end point and has the intersection point as its end. The ray we feed into the back child starts at the intersection point and has the original ray origin as its end point.

```
    else

    if ( PointA == CCollision::CLASSIFY_BEHIND &&
         PointB == CCollision::CLASSIFY_INFRONT )
    {
        // The ray is spanning the plane, with the origin in front.
        CCollision::RayIntersectPlane( RayOrigin,
                                       Velocity,
                                       (D3DXVECTOR3&)Plane,
                                       Plane.d,
                                       t,
                                       true );

        Intersection = RayOrigin + (Velocity * t);

        // Traverse down both sides passing the relevant segments of the ray
        bResult = false;

        if ( CollectRayRecurse( pNode->Front,
                                List,
                                Intersection,
                                RayEnd - Intersection ) ) bResult = true;

        if ( CollectRayRecurse( pNode->Back,
                                List,
                                RayOrigin,
                                Intersection - RayOrigin ) ) bResult = true;
        return bResult;

    } // End If Spanning with origin in front
```

The next cases are easier. If both points are in front of the plane, then the ray is totally contained in the plane's front space and we just pass the ray down the front child. Notice that we are actually saying that if Point A or Point B is in front of the plane, we send the entire ray down the front. Remember though, we only get here if the ray is *not* spanning the plane, so this tells us that if Point A or Point B is in the front space then the other must be in the front space too or on the plane (which also counts as the ray being fully contained in the front space).

```
    else

    if ( PointA == CCollision::CLASSIFY_INFRONT ||
         PointB == CCollision::CLASSIFY_INFRONT )
    {

        // Either of the points are in front (but not spanning), pass down front
        return CollectRayRecurse( pNode->Front, List, RayOrigin, Velocity );

    } // End if either point in front
```

Finally, the last code block only gets executed if the ray is behind the plane. That is, if one of the points is definitely behind the plane and the other is either behind the plane or situated on it. When this is the case we pass the entire ray down to the back child.

```
    else
    {
        // Either of the points are behind (but not spanning), pass down  back
        return CollectRayRecurse( pNode->Back, List, RayOrigin, Velocity );

    } // End if either point behind
}
```

Although the coverage of that function might have seemed more laborious than the simple box test, it was good practice to work with a recursive ray splitting procedure like this. We will see such ideas again when working with BSP trees in the coming lessons, so it was worth reviewing. Of course, functions like this can be hard to follow along with in your head (or even on paper) once the tree gets more than a few levels deep, but just remember that all we are doing here is a ray/plane test and creating two rays using the three points at our disposal (the ray origin, the ray intersection point, and the ray end point). We then pass these rays down to the children and eventually all fragments will pop out in the leaves in which they belong. Whenever a fragment enters a leaf, we add the leaf to the list and thus, track and return all leaves that are intersected by the ray.

14.20.4 The kD-Tree Debug Draw Routine

We will not spend time showing the code to the CKDTree::DebugDraw method even though it has been implemented in the source code. If you study the code you will see that it is basically identical to its quad-tree and oct-tree counterparts with the exception that it steps into two children rather than of four or eight.

This concludes our discussion and implementation of spatial trees for this lesson. We now have four tree types (quad-tree, YV quad-tree, oct-tree, and kD-tree) to choose from for use as a spatial manager in future applications. The remainder of this lesson will discuss the addition of a broad phase to our collision system using any of the ISpatialTree derived classes we introduced. As far the collision system (and our application) is concerned, these trees are all the same (they are ISpatialTrees) and thus can be used interchangeably without the user needing to understand the underlying data types.

14.21 Adding Spatial Trees to Lab Project 14.1

Lab Project 14.1 will include the core source code for this lesson and the next. Thus, much of the code in this project associated with the rendering system will be explained in the following lesson. In this lesson, we will focus our attention on how the spatial tree is populated with polygon data and how the collision system uses it to perform very efficient collision queries. Before we discuss the changes to the collision system, we will look at some functionality that has been added to other modules to support the introduction of spatial trees to our existing framework.

14.21.1 The CGameApp Class

Earlier in this lesson we discussed how our collision system will need to make sure that it does not send the same polygon into the expensive narrow phase multiple times. It avoids this by storing a value in each polygon as and when it processes it. As the value it stores is different every time a new query is issued, the collision system knows that if a polygon it is about to test has the same value stored in its structure, it must be one that has been processed already in this frame (perhaps it exists in a leaf that has been previously tested).

Although the system used will be fleshed out in much more detail when we discuss the change to the collision code, we have decided that this functionality might be useful for other modules as well. Therefore, we will store this value in CGameApp and expose two functions that return and increment this counter.

Excerpt from CGameApp.h

```
ULONG               GetAppCounter       () const { return m_nAppCounter; }
void                IncrementAppCounter ()       { m_nAppCounter++; }
```

The application counter is a simple ULONG that can be retrieved and incremented via the two methods shown above. Below we see that the current value of the application counter is stored in a new CGameApp member variable called m_nAppCounter.

Excerpt from CGameApp.h

```
ULONG               m_nAppCounter;      // Simple Application counter
```

Later you will see why it is useful to have an application global value that can be incremented and retrieved in this way.

14.21.2 The CScene Class

The CScene class has now had an ISpatialTree pointer added to its list of members. It is called m_pSpatialTree and will contain the pointer to the derived tree class we are currently using in our application. Because this is a pointer to a base class, we can make this point at any of our derived tree classes (CQuadTree, COctTree, etc.). Thus, we can easily plug in any of our tree classes without changing any code.

Excerpt from CScene.h

```
ISpatialTree       *m_pSpatialTree;                 // Spatial partitioning tree.
```

This pointer is set to NULL in CScene's constructor, as shown below.

Excerpt from CScene::CScene

```
m_pSpatialTree     = NULL;
```

LoadSceneFromIWF – CScene

The LoadSceneFromIWF function is the parent function that loads and processes the data loaded stored in an IWF file. We will not show all the code again here, so you may want to open the source file to check it out for yourself. What we will look at below is a shortened layout of this function just so you can see how the spatial tree is allocated, built, and registered with the collision system.

Excerpt from CScene::LoadSceneFromIWF

```
m_pSpatialTree = new COctTree( m_pD3DDevice, m_bHardwareTnL );

…
…
… Call Process Functions
…
…
…

if ( !m_pSpatialTree->Build( ) ) return false;

m_Collision.SetSpatialTree( m_pSpatialTree );
…
…
… Create Sound Manager Here
…
…
```

Near the top of the function we allocate a spatial tree of the type we wish to use. In this example, our COctTree class is selected as the spatial manager, but it could have been any one of our derived tree types.

The next section of the function loads the data and calls a series of processing functions to extract the information from the geometry and material vectors populated by the CFileIWF::Load method. One such function that has been changed slightly is the CScene::ProcessVertices method, which is called from CScene::ProcessMeshes (called from LoadSceneFromIWF) for each face loaded from the IWF file. The ProcessVertices method is passed the polygon (as an iwfSurface object) and stores its vertex data in a way that the application can parse and use. Our implementation of this function will create a new CPolygon and populate it with the vertex data for the face currently being loaded. It will then use the ISpatialTree::AddPolygon method to add that polygon to the spatial tree.

After the processing methods have been called, all static polygon data will have been added to the tree, so we issue a call to the tree's Build method, which as we now know, compiles the tree. After the Build function returns, our tree is ready to be used by the collision system, so we call the collision system's new SetSpatialTree method which stores a pointer to this tree for later use in collision queries. We will discuss how the collision system uses the spatial tree in a moment. The rest of the function is unchanged.

ProcessVertices - CScene

We have made some small changes in this function so that the vertex data for the passed face is stored in a new CPolygon structure and added to the spatial tree. Let us have a look at the code.

In the first section of the function we allocate a new CPolygon structure and set its normal to the normal of the passed face. We also set the attribute ID of the polygon to that passed into the function by ProcessMeshes. If the BackFace boolean is set to true, it means we would like to reverse the winding order of this polygon before we use it, so we negate the normal.

```
bool CScene::ProcessVertices( iwfSurface * pFilePoly,
                              ULONG nAttribID,
                              bool BackFace /* = false */ )
{
    // Validate parameters
    if ( !pFilePoly ) return false;

    long      i, nOffset = 0;
    CVertex * pVertices = NULL;
    float     fScale = 1.00f;

    // Allocate a new empty polygon
    CPolygon * pPolygon = new CPolygon;
    if ( !pPolygon ) return false;

    // Set the polygon's attribute ID
    pPolygon->m_nAttribID = nAttribID;
    pPolygon->m_vecNormal = (D3DXVECTOR3&)pFilePoly->Normal;

    if ( BackFace ) pPolygon->m_vecNormal = -pPolygon->m_vecNormal;
```

We then extract the number of vertices in the passed face and use this to inform the CPolygon to allocate enough space in its vertex array for the correct number of vertices.

```
    // Allocate enough vertices
    if ( pPolygon->AddVertex( pFilePoly->VertexCount ) < 0 ) return false;
    pVertices = pPolygon->m_pVertex;
```

Now we loop through each vertex and copy its data into the CPolygon vertex array.

```
    // If we are adding a back-face, setup the offset
    if ( BackFace ) nOffset = pFilePoly->VertexCount - 1;

    // Loop through each vertex and copy required data.
    for ( i = 0; i < (signed)pFilePoly->VertexCount; i++ )
    {
        // Copy over vertex data
        pVertices[i + nOffset].x      = pFilePoly->Vertices[i].x * fScale;
        pVertices[i + nOffset].y      = pFilePoly->Vertices[i].y * fScale;
        pVertices[i + nOffset].z      = pFilePoly->Vertices[i].z * fScale;

        pVertices[i + nOffset].Normal = D3DXVECTOR3&)pFilePoly->Vertices[i].Normal;

        if ( BackFace ) pVertices[i+nOffset].Normal=-pVertices[i + nOffset].Normal;

        // If we have any texture coordinates, set them
        if ( pFilePoly->TexChannelCount > 0 && pFilePoly->TexCoordSize[0] == 2 )
        {
            pVertices[i + nOffset].tu = pFilePoly->Vertices[i].TexCoords[0][0];
            pVertices[i + nOffset].tv = pFilePoly->Vertices[i].TexCoords[0][1];

        } // End if has tex coordinates

        // If we're adding the backface, decrement the offset
        // Remember, we decrement by two here because 'i' will increment
        if ( BackFace ) nOffset -= 2;

    } // Next Vertex
```

Now that we have a CPolygon representation of the face loaded from the file, we add it to the spatial tree.

```
    // Add this new polygon to the spatial tree
    if ( !m_pSpatialTree->AddPolygon( pPolygon ) ) {delete pPolygon;
                                                    return false; }

    // Success!
    return true;
}
```

These are the only changes to the application framework with respect to populating and building the tree. Next we will discuss the changes to the collision system that need to be made so that we finally have a broad phase in our collision detection code.

14.22 Adding a Broad Phase to CCollision

The collision system will not require significant changes in order to include a broad phase. Most of the changes will involve the addition of new functions to collect tree data. You will recall from the previous chapter that the application calls the CCollision::CollideEllipsoid method to perform a collision query. This method transformed the passed ellipsoid into eSpace and then entered a loop that repeatedly called the EllipsoidIntersectScene method to perform collision detection. If the function returned false, then the ellipsoid could move to the requested position, otherwise a response vector was generated and the collision detection step was called again.

Inside the EllipsoidIntersectScene method is where the detection between the swept sphere and the collision geometry was determined. Detection was performed against three pools of geometry using the EllipsoidIntersectBuffers method for the core intersection determination in all three cases. The first pool we tested was any terrain geometry that may have been registered. We did not store the terrain triangles in the collision system's static geometry array, but instead generated them on the fly using a temporary buffer that was passed to the EllipsoidIntersectBuffers method. After recording any intersections with terrain triangles, we then iterated through the collision system's dynamic object array passing the geometry buffers of each dynamic object into the EllipsoidIntersectBuffers method to record and store any collisions that occurred. Finally, we passed the collision system's static geometry buffers into the EllipsoidIntersectBuffers method so that the static polygon data used by the system was also tested and any collisions recorded.

The EllipsoidIntersectScene method will now be updated in two places. First, there will be a fourth pool of geometry that needs to be checked -- the geometry in the spatial tree that has been assigned to the collision system. As we have seen, the application populates and builds this tree using static scene data and then assigns it to the tree using the CCollision::SetSpatialTree method (which just caches the pointer in a member variable). During the EllipsoidIntersectScene method, we will test the geometry in the tree by sending the AABB of the swept sphere into the spatial tree's CollectLeavesAABB method. Once all intersecting leaves are returned, we will test each polygon in those leaves to see if their bounding boxes intersect the bounding box of the swept sphere (an additional broad phase step). We will only perform narrow phase intersection for polygons that have a good potential for intersect the sphere's AABB. This is essentially our broad phase implementation for static geometry.

One thing might be bothering you at this point. If the static polygon data that we load will now be stored in the tree, what happens to the original static geometry database in the collision system? Well, those vectors will no longer be used because we will always choose to use a spatial tree and connect that to the collision system. We could still add geometry to the collision system's static vectors (using the CCollision::AddIndexedPrimitive method for example) but as we know, every polygon in these vectors will be tested in the narrow phase. Thus, storing static geometry there instead of in our spatial tree would force us to give up our extremely efficient broad phase step. So does that mean that all of the functions that we wrote to store polygons and collide against the static geometry were a waste of time? Absolutely not. Our aim was to create a collision library that can be used in your applications that might rely on other technologies. Although we will favor using a spatial tree to store our static geometry, there may well be users that wish to use the collision system without those trees. Therefore, while it is recommended that you always use a spatial tree to store your static collision data, the collision system

will still do its job even if one is not provided. As we saw in the previous lesson, if somebody just wants to quickly add polygon data to the collision system, we have provided a means to do so.

The other area where the EllipsoidIntersectScene method will change slightly will when testing the swept sphere against dynamic objects. In the previous chapters we saw that we did this by passing the geometry buffers of the dynamic object currently being processed (and its matrix) into the EllipsoidIntersectBuffers method. This essentially performed the narrow phase detection step on every polygon in the dynamic object's buffer. Now, we first test the bounding box of the dynamic object against the AABB of the swept sphere and only call the EllipsoidIntersectBuffers method if the two intersect. Although this may seem like a very crude broad phase for our dynamic objects, AABB/AABB intersection tests are so cheap and our project uses so few dynamic objects there is really no point in using a tree traversal to determine which objects intersect. Therefore, unlike the rendering system that we will cover in the following lesson, our collision system does not use the spatial tree to implement a broad phase for dynamic objects, instead it just loops through each performing an AABB/AABB cull.

> **Note:** It would be easy enough to add some code to take advantage of the tree for your dynamic objects. After all, they are already stored in the tree and you would already have incurred the cost of traversal when you test for static geometry. Thus, there would be only a few extra lines of logic needed to extract the dynamic objects from the leaves you collided with.

In order to implement the AABB/AABB broad phase for the dynamic object testing we will need to extend our collision system's DynamicObject structure to make room for two vectors that will store the minimum and maximum extents of its bounding box. Remembering from the previous lesson that dynamic objects are stored in the collision system as model space geometry with an associated world transformation matrix, the bounding box stored in each dynamic object will also be defined in the model space of the object too. We will see later that when performing the AABB/AABB test between the swept sphere's AABB and the dynamic object, the dynamic object's AABB will be transformed into world space for the test.

Our updated DynamicObject structure is shown below with the two new members highlighted in bold.

Excerpt from CCollision.h

```
struct DynamicObject
{
        CollTriVector  *pCollTriangles;
        CollVertVector *pCollVertices;
        D3DXMATRIX     *pCurrentMatrix;
        D3DXMATRIX      LastMatrix;
        D3DXMATRIX      VelocityMatrix;
        D3DXMATRIX      CollisionMatrix;
        long            ObjectSetIndex;
        bool            IsReference;
        D3DXVECTOR3     BoundsMin;      // Minimum bounding box extents
        D3DXVECTOR3     BoundsMax;      // Maximum bounding box extents
};
```

We just learned that the EllipsoidIntersectScene method will now perform a collision query on the tree. That is, it will use the spatial tree's CollectLeavesAABB method to return a list of all the leaves intersected by the AABB of the swept sphere. Two new members have been added to the CCollision

class for this purpose. The first is a pointer to an ISpatialTree derived object which the application will set using the CCollision::SetSpatialTree. The second is a member of type ISpatialTree::LeafList. Remember, when we run an AABB query on the tree, the CollectLeavesAABB method expects to be passed an empty leaf list that it will fill with leaf pointers. Therefore, the collision object maintains a leaf list of its own which it can empty each time and pass into this function to collect the leaves whenever a query is performed. Thus, once our collision system has called the ISpatialTree::CollectLeavesAABB method, its m_treeLeafList member will contain a list of all the leaves intersected by the swept sphere's AABB. The new members of CCollision are shown below.

New Members to CCollision

```
ISpatialTree           *m_pSpatialTree;
ISpatialTree::LeafList  m_TreeLeafList;
D3DXVECTOR3             m_vecEllipsoidMin;
D3DXVECTOR3             m_vecEllipsoidMax;
```

Notice that we have also added two new 3D vectors as members in the collision object. Because we will need to access the world space bounding box of the ellipsoid during our EllipsoidIntersectScene method, we use these new members to cache the extents. For example, we will need the world space AABB of the ellipsoid in the methods that send the AABB of the ellipsoid down the tree to collect all intersecting leaves. We will also need the world space AABB during the dynamic object tests when we implement a broad phase AABB/AABB test between the world space AABB of the dynamic object and the world space AABB of the ellipsoid. Rather than continually having to calculate this box each time we need it, we will add a function to calculate the ellipsoid bounds. It will generate a bounding box around the ellipsoid and store it in these two variables for the life of the query. This will allow any helper functions that need this information to be able to quickly access it.

SetSpatialTree - CCollision

One of the new methods that we saw being used earlier assigns the collision object's m_pSpatialTree pointer the tree the application would like it to use. This simple function is called once the application has created and populated the tree with the required data.

```
void CCollision::SetSpatialTree( ISpatialTree * pTree )
{
    // Store the tree
    m_pSpatialTree = pTree;
}
```

CalculateEllipsoidBounds – CCollision

This method calculates the bounding box of the query ellipsoid. It tests the x, y, and z components of two points, the ellipsoid center position and the ellipsoid center position plus the velocity vector, to find the minimum and maximum extents for a bounding box that encompasses both points. We will see this method being used in a few of the other collision functions later on.

The function is passed the ellipsoid center position, its radius vector, and its velocity vector. It first examines the radius vector to determine which of its components is the largest. We will use this extent to essentially represent a sphere that bounds the ellipsoid. Notice at the top of the function how we reference the member variables m_vecEllipsoidMin and m_vecEllipsoidMax (which will receive the resulting AABB) with some local variables for ease of access.

```
void CCollision::CalculateEllipsoidBounds( const D3DXVECTOR3& Center,
                                           const D3DXVECTOR3& Radius,
                                           const D3DXVECTOR3& Velocity )
{
    float       fLargestExtent;

    D3DXVECTOR3& vecMin = m_vecEllipsoidMin;
    D3DXVECTOR3& vecMax = m_vecEllipsoidMax;

    // Find largest extent of ellipsoid
    fLargestExtent = Radius.x;
    if ( Radius.y > fLargestExtent ) fLargestExtent = Radius.y;
    if ( Radius.z > fLargestExtent ) fLargestExtent = Radius.z;
```

At this point we have stored the largest component of the ellipsoid's radius vector in fLargestExtent. We will now initialize the bounding box to impossibly small values before performing the tests.

```
    // Reset the bounding box values
    vecMin = D3DXVECTOR3( FLT_MAX, FLT_MAX, FLT_MAX );
    vecMax = D3DXVECTOR3( -FLT_MAX, -FLT_MAX, -FLT_MAX );
```

The first thing we will do is add the largest extent to the ellipsoid center position and test the result to see if it is greater than the value currently stored in the bounding box maximum extent. We do this on a per-component basis. We are essentially growing the box if the sphere that surrounds the ellipsoid pierces the previously discovered maximum extent along any axis. If it does, that component of the maximum extent is updated with the new maximum.

```
    // Calculate the bounding box extents of where the ellipsoid currently
    // is, and the position it will be moving to.

    if ( Center.x + fLargestExtent > vecMax.x )
      vecMax.x = Center.x + fLargestExtent;

    if ( Center.y + fLargestExtent > vecMax.y )
      vecMax.y = Center.y + fLargestExtent;

    if ( Center.z + fLargestExtent > vecMax.z )
      vecMax.z = Center.z + fLargestExtent;
```

We now do exactly the same test for each component to test that the sphere bounding the ellipsoid does not pierce any previously found minimum extent for the box along any world axis. Once again, if it does, that component of the box is updated to the new minimum.

```
    if ( Center.x - fLargestExtent < vecMin.x )
```

```
      vecMin.x = Center.x - fLargestExtent;

    if ( Center.y - fLargestExtent < vecMin.y )
      vecMin.y = Center.y - fLargestExtent;

    if ( Center.z - fLargestExtent < vecMin.z )
      vecMin.z = Center.z - fLargestExtent;
```

Now repeat the same two tests again, only this time we add the velocity vector and the largest radius extent to the center position of the ellipsoid. What we are essentially doing is building a sphere that bounds the ellipsoid at the very end of its velocity vector.

```
    if ( Center.x + Velocity.x + fLargestExtent > vecMax.x )
      vecMax.x = Center.x + Velocity.x + fLargestExtent;

    if ( Center.y + Velocity.y + fLargestExtent > vecMax.y )
      vecMax.y = Center.y + Velocity.y + fLargestExtent;

    if ( Center.z + Velocity.z + fLargestExtent > vecMax.z )
      vecMax.z = Center.z + Velocity.z + fLargestExtent;

    if ( Center.x + Velocity.x - fLargestExtent < vecMin.x )
      vecMin.x = Center.x + Velocity.x - fLargestExtent;

    if ( Center.y + Velocity.y - fLargestExtent < vecMin.y )
      vecMin.y = Center.y + Velocity.y - fLargestExtent;

    if ( Center.z + Velocity.z - fLargestExtent < vecMin.z )
      vecMin.z = Center.z + Velocity.z - fLargestExtent;
```

Finally, just to add a bit of padding to manage limited floating point precision, we extend the box by one unit along each axis in both directions.

```
    // Add Tolerance values
    vecMin -= D3DXVECTOR3( 1.0f, 1.0f, 1.0f );
    vecMax += D3DXVECTOR3( 1.0f, 1.0f, 1.0f );
}
```

We will see this method being used later when discussing the new additions to the collision system.

14.22.1 Dynamic Object Bounding Box Generation

When a dynamic object is registered with the collision system, it will now have to calculate its model space bounding box so that it can be stored in the DynamicObject structure and used during the dynamic object's broad phase test. Adding such a feature involves simply extending the code of the CCollision::AddBufferData method.

You should recall from the previous chapter how the AddBufferData method was a general purpose utility function that was used to add a passed array of vertices and indices to the passed geometry

vectors. This was useful because the same function could be used to add the vertex data for a static polygon to the collision system's static geometry vectors, or it could be used to add the vertex and index data for a dynamic object to the dynamic object's geometry buffers. The AddBufferData method could even be passed an optional matrix pointer parameter that would be used to transform the vertex data prior to storing it in the passed geometry buffers.

To jog your memory, below we see an example of how this method was used by the CCollision::AddIndexedPrimitive method. This method was called in our previous application for every static polygon loaded from the IWF file. As you can see, this method just issues a call to the AddBufferData method, passing as the first two parameters the static geometry buffers of the collision system. When the function returns, the passed vertices and indices will have been added to the collision system's static vectors. We are also reminded that the current transformation matrix for the collision system is also passed in, so that if the application has set this to anything other than an identity matrix (its default state) the geometry will be transformed before it is added to the collision system's static geometry vectors.

```
bool CCollision::AddIndexedPrimitive( LPVOID Vertices,
                                      LPVOID Indices,
                                      ULONG VertexCount,
                                      ULONG TriCount,
                                      ULONG VertexStride,
                                      ULONG IndexStride,
                                      USHORT MaterialIndex )
{
    ULONG i, BaseTriCount;

    // Store the previous triangle count
    BaseTriCount = m_CollTriangles.size();

    // Add to the standard buffer
    if ( !AddBufferData( m_CollVertices,
                         m_CollTriangles,
                         Vertices,
                         Indices,
                         VertexCount,
                         TriCount,
                         VertexStride,
                         IndexStride,
                         m_mtxWorldTransform ) ) return false;

    // Loop through and assign the specified material ID to all triangles
    for ( i = BaseTriCount; i < m_CollTriangles.size(); ++i )
    {
        // Assign to triangle
        m_CollTriangles[i].SurfaceMaterial = MaterialIndex;

    } // Next Triangle

    // Success
    return true;
}
```

The AddBufferData method was also used to add dynamic objects to the system. In this case, the vertex and index data of the object would be passed as the first two parameters, along with the geometry buffers for the dynamic object. The vertex and index data would be copied into the geometry buffers of the collision system's representation of that dynamic object as a result.

Because our dynamic objects will now need to have bounding boxes calculated for them, the AddBufferData member has had two optional parameters added which are only used when the function is being called for dynamic objects. These two parameters are pointers to the dynamic object's bounding box extents. The function will calculate the bounding box extents and store them in the dynamic object before returning.

Below we see the AddDynamicOject method of CCollision which the application can use to register a single dynamic object with the collision system. This code is virtually unchanged from the previous version with the exception that it now passes the addresses of the dynamic object's bounding box extents as the last two parameters to AddBufferData. All of the other code was discussed in detail over the last two lessons, and will not be discussed here.

```
long CCollision::AddDynamicObject( LPVOID Vertices,
                                   LPVOID Indices,
                                   ULONG VertexCount,
                                   ULONG TriCount,
                                   ULONG VertexStride,
                                   ULONG IndexStride,
                                   D3DXMATRIX * pMatrix,
                                   bool bNewObjectSet /* = true */ )
{
    D3DXMATRIX      mtxIdentity;
    DynamicObject * pObject = NULL;

    // Reset identity matrix
    D3DXMatrixIdentity( &mtxIdentity );

    // Ensure that they aren't doing something naughty
    if ( m_nLastObjectSet < 0 ) bNewObjectSet = true;

    // We have used another object set index.
    if ( bNewObjectSet ) m_nLastObjectSet++;

    try
    {
        // Allocate a new dynamic object instance
        pObject = new DynamicObject;
        if ( !pObject ) throw 0;

        // Clear the structure
        ZeroMemory( pObject, sizeof(DynamicObject) );

        // Allocate an empty vector for the buffer data
        pObject->pCollVertices  = new CollVertVector;
        if ( !pObject->pCollVertices ) throw 0;
        pObject->pCollTriangles = new CollTriVector;
        if ( !pObject->pCollTriangles ) throw 0;
```

```
        // Store the matrices we'll need for
        pObject->pCurrentMatrix  = pMatrix;
        pObject->LastMatrix      = *pMatrix;
        pObject->CollisionMatrix = *pMatrix;
        pObject->ObjectSetIndex  = m_nLastObjectSet;
        pObject->IsReference     = false;
        D3DXMatrixIdentity( &pObject->VelocityMatrix );

        // Add to the dynamic object's database
        if ( !AddBufferData( *pObject->pCollVertices,
                            *pObject->pCollTriangles,
                             Vertices,
                             Indices,
                             VertexCount,
                             TriCount,
                             VertexStride,
                              IndexStride,
                              mtxIdentity,
                              &pObject->BoundsMin,
                              &pObject->BoundsMax ) ) throw 0;

        // Store the dynamic object
        m_DynamicObjects.push_back( pObject );

    } // End try block

    catch (...)
    {
        // Release the object if it got created
        if ( pObject )
        {
            if ( pObject->pCollVertices  ) delete pObject->pCollVertices;
            if ( pObject->pCollTriangles ) delete pObject->pCollTriangles;
            delete pObject;

        } // End if object exists

        // Return failure
        return -1;

    } // End Catch Block

    // Return the object index used
    return m_nLastObjectSet;
}
```

When AddBufferData returns, it will have calculated the extents of the model space AABB and will have stored them in the final two parameters.

You will see this slight modification to the AddBufferData call in all of the methods we discussed which register dynamic objects. You will recall for example that when we register an actor with the collision system (using the CCollision::AddActor method) and pass the parameter that states that we would like the actor to be dynamic, the hierarchy is traversed and a dynamic object is created in the collision

system for each mesh container found. However, each dynamic object created from a mesh container is created in exactly the same way as shown above and will now have their bounding boxes computed.

The new version of AddBufferData is shown below with the added code that calculates and stores the model space AABB of the passed geometry.

The first section of the function is the same, it simply makes room in the passed vertex and triangle buffers to add the new data if the buffers are not currently large enough.

```
bool CCollision::AddBufferData( CollVertVector& VertBuffer,
                                CollTriVector& TriBuffer,
                                LPVOID Vertices,
                                LPVOID Indices,
                                ULONG VertexCount,
                                ULONG TriCount,
                                ULONG VertexStride,
                                ULONG IndexStride,
                                const D3DXMATRIX& mtxWorld,
                                D3DXVECTOR3 * pBoundsMin /* = NULL */,
                                D3DXVECTOR3 * pBoundsMax /* = NULL */ )
{
    ULONG        i, Index1, Index2, Index3, BaseVertex;
    UCHAR       *pVertices = (UCHAR*)Vertices;
    UCHAR       *pIndices  = (UCHAR*)Indices;
    CollTriangle Triangle;
    D3DXVECTOR3  Edge1, Edge2;

    // Validate parameters
    if ( !Vertices || !Indices || !VertexCount || !TriCount ||
         !VertexStride || (IndexStride != 2 && IndexStride != 4) ) return false;

    // Catch template exceptions
    try
    {
        // Grow the vertex buffer if required
        while ( VertBuffer.capacity() < VertBuffer.size() + VertexCount )
        {
            // Reserve extra space
            VertBuffer.reserve( VertBuffer.capacity() + m_nVertGrowCount );

        } // Keep growing until we have enough

        // Grow the triangle buffer if required
        while ( TriBuffer.capacity() < TriBuffer.size() + TriCount )
        {
            // Reserve extra space
            TriBuffer.reserve( TriBuffer.capacity() + m_nTriGrowCount );

        } // Keep growing until we have enough
```

Next we store the current number of vertices in the passed vertex vector so that we know where the indices will start indexing (it might not be empty when the function is called, which is certainly the case

when the function is called to add triangles to the static geometry vectors). We also initialize the passed extent vectors to impossible values.

```
        // Store the original vertex count before we copy
        BaseVertex = VertBuffer.size();

        // Reset bounding box values if provided
        if ( pBoundsMin ) *pBoundsMin = D3DXVECTOR3( FLT_MAX, FLT_MAX, FLT_MAX );
        if ( pBoundsMax ) *pBoundsMax = D3DXVECTOR3( -FLT_MAX, -FLT_MAX, -FLT_MAX);
```

Now we loop through each vertex in the passed array and transform it by the passed transformation matrix. We then test the current bounding box extents against the vertex and grow the box if the vertex is found not to be contained in it. We then add the vertex to the passed vertex vector.

```
        // For each vertex passed
        for ( i = 0; i < VertexCount; ++i, pVertices += VertexStride )
        {
            // Transform the vertex
            D3DXVECTOR3 Vertex = *(D3DXVECTOR3*)pVertices;
            D3DXVec3TransformCoord( &Vertex, &Vertex, &mtxWorld );

            // Calculate bounding box extents
            if ( pBoundsMin )
            {
                if ( Vertex.x < pBoundsMin->x ) pBoundsMin->x = Vertex.x;
                if ( Vertex.y < pBoundsMin->y ) pBoundsMin->y = Vertex.y;
                if ( Vertex.z < pBoundsMin->z ) pBoundsMin->z = Vertex.z;

            } // End if minimum extents variable passed

            if ( pBoundsMax )
            {
                if ( Vertex.x > pBoundsMax->x ) pBoundsMax->x = Vertex.x;
                if ( Vertex.y > pBoundsMax->y ) pBoundsMax->y = Vertex.y;
                if ( Vertex.z > pBoundsMax->z ) pBoundsMax->z = Vertex.z;

            } // End if maximum extents variable passed

            // Copy over the vertices
            VertBuffer.push_back( Vertex );

        } // Next Vertex
```

The last section of the function calculates the indices of each triangle and is unchanged.

```
        // Build the triangle data
        for ( i = 0; i < TriCount; ++i )
        {
            // Retrieve the three indices
            Index1 = ( IndexStride == 2 ? (ULONG)*((USHORT*)pIndices) :
                                          *((ULONG*)pIndices) );
            pIndices += IndexStride;

            Index2 = ( IndexStride == 2 ? (ULONG)*((USHORT*)pIndices) :
```

```
                                        *((ULONG*)pIndices) );
            pIndices += IndexStride;

            Index3 = ( IndexStride == 2 ? (ULONG)*((USHORT*)pIndices) :
                       *((ULONG*)pIndices) );
            pIndices += IndexStride;

            // Store the details
            Triangle.SurfaceMaterial = 0;
            Triangle.Indices[0]      = Index1 + BaseVertex;
            Triangle.Indices[1]      = Index2 + BaseVertex;
            Triangle.Indices[2]      = Index3 + BaseVertex;

            // Retrieve the vertices themselves
            D3DXVECTOR3 &v1 = VertBuffer[ Triangle.Indices[0] ];
            D3DXVECTOR3 &v2 = VertBuffer[ Triangle.Indices[1] ];
            D3DXVECTOR3 &v3 = VertBuffer[ Triangle.Indices[2] ];

            // Calculate and store edge values
            D3DXVec3Normalize( &Edge1, &(v2 - v1) );
            D3DXVec3Normalize( &Edge2, &(v3 - v1) );

            // Skip if this is a degenerate triangle, we don't want it in our set
            float fDot = D3DXVec3Dot( &Edge1, &Edge2 );
            if ( fabsf(fDot) >= (1.0f - 1e-5f) ) continue;

            // Generate the triangle normal
            D3DXVec3Cross( &Triangle.Normal, &Edge1, &Edge2 );
            D3DXVec3Normalize( &Triangle.Normal, &Triangle.Normal );

            // Store the triangle in our database
            TriBuffer.push_back( Triangle );

        } // Next Triangle

    } // End Try Block

    catch ( ... )
    {
        // Just fail on any exception.
        return false;

    } // End Catch Block

    // Success!
    return true;
}
```

That covers all of the changes involved in registering geometry with the collision system. They are very small, but the calculation of the bounding boxes of dynamic objects is a significant step that should not be overlooked. We can now move on to discussing the changes to the core collision system.

14.22.2 Changes to the Collision Query Engine

When the application performs a query, it calls the CCollision::CollideEllipsoid method. This method is responsible for transforming the ellipsoid into eSpace and then setting up a loop that will call the detection method (EllipsoidIntersectScene) and generate a slide vector every time the detection function returns true for intersection. Only when the detection phase returns false have we found a new position for the ellipsoid that is free from obstruction.

As we have briefly touched on, we need to make sure during a given detection step that we do not send a polygon to the expensive narrow phase more than once. If we are using a clipped tree, this will never happen since each polygon will be contained in one and only one leaf. However, if a non-clipped tree is being used (often the case) we may have a situation where a single polygon is contained in multiple leaves. Further, when the collision system calls the ISpatialTree::CollectLeavesAABB method, it may get back a list of intersecting leaves that each contains this same polygon. We certainly never want to test the same polygon more than once, so we saw earlier how we implemented an application timer to allow us to efficiently invalidate polygons in the collision system.

The CPolygon structure stores a member called m_AppCounter that can be used to store the current value held in the application counter. Why is this useful?

When our collision system performs a query on the tree, it will get back a list of leaves. Then it will iterate through the polygons in each of those leaves and potentially pass them on to the narrow phase if we have an AABB/AABB intersection between the polygon's box and the swept sphere's box. Once a polygon has been tested and is about to be passed to the narrow phase, we will store the current value of the application counter in its m_nAppCounter member. We will only send polygons to the narrow phase whose m_nAppCounter member is not equal to the current value of the application counter. If the application counter matches, it means this polygon has already been processed since the application counter was last incremented. This would be the case if we were processing a polygon in a leaf that had existed in a previous leaf we had tested. By the end of the collision step, all the polygons in all the returned leaves will have had their m_nAppCounter members set to the same value as the current application counter.

While we could achieve the same end by storing a boolean in each polygon which is set to true once it has been processed, this would leave us with the very unpleasant (and slow) task of looping through every polygon and resetting their booleans prior to performing a new query. Since our CollideEllipsoid method may perform many detection queries during a single update, it would become prohibitively expensive if tens of thousands of polygons had to have their booleans reset dozens of times. Fortunately, with our counting logic, all we have to do before performing another detection query is increment the application's main counter. At this point, the application counter will no longer match the m_nAppCounter member in any polygon, so they will all be tested in the next update.

Of you open up the source code to the CCollision::CollideEllipsoid method you will see that we have added a new function call that increments the application counter with each iteration of the detection loop. We will not show the entire function here since we have only added one new line. However, the

following listing demonstrates where this new line (actually two new lines which are both the same) exists. The new lines are highlighted in bold.

Excerpt from CCollision::CollideEllipsoid

```
bool CCollision::CollideEllipsoid( const D3DXVECTOR3& Center,
                                   const D3DXVECTOR3& Radius,
                                   const D3DXVECTOR3& Velocity,
                                   D3DXVECTOR3& NewCenter,
                                   D3DXVECTOR3& NewIntegrationVelocity,
                                   D3DXVECTOR3& CollExtentsMin,
                                   D3DXVECTOR3& CollExtentsMax )
{
      …
      … Calculate ESpace ellipsoid start, end and radius vectors here
      …
      …
    // Keep testing until we hit our max iteration limit
    for ( i = 0; i < m_nMaxIterations; ++i )
    {

        if ( EllipsoidIntersectScene( eFrom,
                                      Radius,
                                      eVelocity,
                                      m_pIntersections,
                                      IntersectionCount,
                                      true,
                                      true ) )
        {
            …
            … Calculate Response vector and eFrom here
            …
            bHit=true;

        } // End if we got some intersections
        else
        {
            // We found no collisions, so break out of the loop
            break;

        } // End if no collision

        // Increment the app counter so that our polygon testing is reset
        GetGameApp()->IncrementAppCounter();

    } // Next Iteration

    // Did we register any intersection at all?
    if ( bHit )
    {
        // Increment the app counter so that our polygon testing is reset
        GetGameApp()->IncrementAppCounter();

        …
        …
        …  If we ran out of iterations to one collision test here and just
        …  return first intersecting position
```

```
        …

    } // End if intersection found

    // Store the resulting output values
    NewCenter              = vecOutputPos;
    NewIntegrationVelocity = vecOutputVelocity;

    // Return hit code
    return bHit;
}
```

As you can see, the application counter is advanced after each collision detection query so that the next time it is performed, the polygon counters no longer match the application counter and the polygons are considered again in the next test.

EllipsoidIntersectScene - CCollision

The EllipsoidIntersectScene method is called by CollideEllipsoid each time a detection test has to be performed on a velocity vector (or slide vector). Previously this method tested three pools of data; the terrain data, the dynamic objects, and the static geometry vectors. We will now add an additional section that performs a collision test on the static geometry stored in the spatial tree (if one has been assigned to the collision system). In our application, all static data will be stored in the spatial tree and the static geometry vectors of the collision system will be left empty. We also add the AABB/AABB broad phase to the dynamic object test. Although most of the code is unchanged, we will still show the entire function again, but only spend time discussing the additional code in any detail.

The first section of the function transforms the passed ellipsoid centerpoint and velocity vector into eSpace if the caller did not pass these in as eSpace parameters to begin with. It also sets the first collision intersect time (*t*) to 1.0 (i.e., the end of the vector and thus no collision detected).

```
bool CCollision::EllipsoidIntersectScene( const D3DXVECTOR3 &Center,
                                          const D3DXVECTOR3& Radius,
                                          const D3DXVECTOR3& Velocity,
                                          CollIntersect Intersections[],
                                          ULONG & IntersectionCount,
                                          bool bInputEllipsoidSpace /* = false */,
                                          bool bReturnEllipsoidSpace /* = false */)
{
    D3DXVECTOR3 eCenter, eVelocity, eAdjust, vecEndPoint, InvRadius;
    float       eInterval;
    ULONG       i;

    // Vectors for terrain building
    CollVertVector VertBuffer;
    CollTriVector  TriBuffer;

    // Calculate the reciprocal radius to prevent the divides we would need
    InvRadius = D3DXVECTOR3( 1.0f / Radius.x, 1.0f / Radius.y, 1.0f / Radius.z );
```

```
    // Convert the values specified into ellipsoid space if required
    if ( !bInputEllipsoidSpace )
    {
        eCenter   = Vec3VecScale( Center, InvRadius );
        eVelocity = Vec3VecScale( Velocity, InvRadius );

    } // End if the input values were not in ellipsoid space
    else
    {
        eCenter   = Center;
        eVelocity = Velocity;

    } // End if the input values are already in ellipsoid space

    // Reset ellipsoid space interval to maximum
    eInterval = 1.0f;

    // Reset initial intersection count to 0 to save the caller having to do this.
    IntersectionCount = 0;

    // Calculate the bounding box of the ellipsoid
    D3DXVECTOR3 vecCenter   = Vec3VecScale( eCenter, Radius );
    D3DXVECTOR3 vecVelocity = Vec3VecScale( eVelocity, Radius );
    CalculateEllipsoidBounds( vecCenter, Radius, vecVelocity );
```

The new additions to this section are highlighted in bold at the bottom of the code. We transform the ellipsoid center position and velocity vector into world space (by scaling it by the radius vector) and then pass the world space position, velocity, and radius vector of the ellipsoid into the CalculateEllipsoidBounds method (discussed earlier). When this method returns, the CCollision::m_vecEllipsoidMin and CCollision::m_vecEllipsoidMax member variables will store the extents of the current world space bounding box of the ellipsoid. We will see why we need this later in the function.

The next section, which is unchanged from the previous lab project, collects triangles from any terrain object in the immediate vicinity of the swept sphere and runs the intersection test.

```
    // Iterate through our terrain database
    TerrainVector::iterator TerrainIterator = m_TerrainObjects.begin();
    for ( ; TerrainIterator != m_TerrainObjects.end(); ++TerrainIterator )
    {
        const CTerrain * pTerrain = *TerrainIterator;

        // Collect the terrain triangle data
        if ( !CollectTerrainData( *pTerrain,
                                  vecCenter,
                                  Radius,
                                  vecVelocity,
                                  VertBuffer,
                                  TriBuffer ) ) continue;

        // Perform the ellipsoid intersect test against this set of terrain data
        EllipsoidIntersectBuffers( VertBuffer,
                                   TriBuffer,
```

```
                                    eCenter,
                                    Radius,
                                    InvRadius,
                                    eVelocity,
                                    eInterval,
                                    Intersections,
                                    IntersectionCount );

        // Clear buffers for next terrain
        VertBuffer.clear();
        TriBuffer.clear();

    } // Next Terrain
```

The next section is new. It contains the code that performs the intersection test against the geometry stored in the spatial tree (if one has been registered with the collision system). The first thing we do is pass the world space ellipsoid center position and velocity vector to a new method called CCollision::CollectTreeLeaves. This method will simply pass the world space bounding box of the ellipsoid into the ISpatialTree::CollectLeavesAABB method. Earlier we learned that the collision system now includes a member of type LeafList, which is also passed to the CollectLeavesAABB method and used to collect the pointers to the leaves that intersect the ellipsoid AABB. We will look at this method in a moment.

When the CollectTreeLeaves method returns, the CCollision::m_TreeLeafList member will currently contain all the pointers to all leaves that intersect the swept sphere's bounding box. We then call another new method called EllipsoidIntersectTree which performs the narrow phase test on the polygon data stored in those leaves. The EllipsoidIntersectTree method is almost identical to the EllipsoidIntersectBuffers method which performs narrow phase detection on other geometry pools. The reason we had to make a special version of this function is that the CPolygon data stored in the tree uses a different format from what the collision system is used to working with. Rather than incur the costs of copying the data over and converting it into the old format on the fly (which can get very expensive!), we just added a modified version of the prior code to work with CPolygons. We only want to test polygons that have bounding boxes that intersect the ellipsoid's bounding box and that have not already been tested in this update. This is another method we will look at in a moment.

```
    // Collide against tree if available
    if ( m_pSpatialTree )
    {

        // Collect the leaf list if necessary
        CollectTreeLeaves( vecCenter, Radius, vecVelocity );

        EllipsoidIntersectTree( eCenter,
                                Radius,
                                InvRadius,
                                eVelocity,
                                eInterval,
                                Intersections,
                                IntersectionCount );

    } // Next Tree
```

When the EllipsoidIntersectTree method returns, any intersections found between the swept sphere and the polygons stored in the tree will be added to the passed Intersections array and the current intersection count will be increased to reflect the number of intersections found at the closest *t* value. That is the full extent of the changes to EllipsoidIntersectScene with respect to using the spatial tree to query the polygon data as a broad phase.

The next change to the function is performed when testing the dynamic objects against the swept sphere. In our previous implementation we simply looped through every dynamic object and passed its buffers to the EllipsoidIntersectBuffers method. This essentially meant that every polygon in every dynamic object would have been run through the costly narrow phase. Now we will add a simple broad phase early-out test.

For each dynamic object, we transform its model space bounding box into world space using a new math utility function called TransformAABB (see MathUtility.cpp). This is a small function that takes an AABB and a transformation matrix and generates a new AABB that contains the passed AABB in its rotated/transformed form. We will look at the code to this function later.

```
    // Iterate through our triangle database
    DynamicObjectVector::iterator ObjIterator = m_DynamicObjects.begin();
    for ( ; ObjIterator != m_DynamicObjects.end(); ++ObjIterator )
    {
        DynamicObject * pObject = *ObjIterator;

        // Broad Phase AABB test against dynamic objects
        D3DXVECTOR3 Min = pObject->BoundsMin, Max = pObject->BoundsMax;

        MathUtility::TransformAABB( Min, Max, pObject->CollisionMatrix );
```

As we now have the current dynamic object's box in world space and we also stored the ellipsoid's world space bounding box extents in the m_vecEllipsoidMin and m_vecEllipsoidMax member variables at the start of the function, we can perform the AABB/AABB intersection test and skip all the dynamic object collision code that we discussed in the previous lesson. That is, if the boxes do not intersect, we skip to the next iteration of the loop and the next dynamic object to test. The remainder of the function is identical to the prior version.

```
        if ( !AABBIntersectAABB( Min,
                                 Max,
                                 m_vecEllipsoidMin,
                                 m_vecEllipsoidMax ) ) continue;

        // Calculate our adjustment vector in world space. This is for our
        // velocity adjustment for objects so we have to work in the original
        // world space.
        vecEndPoint = (Vec3VecScale( eCenter, Radius ) +
                       Vec3VecScale( eVelocity, Radius ));

        // Transform the end point
        D3DXVec3TransformCoord( &eAdjust, &vecEndPoint, &pObject->VelocityMatrix );

        // Translate back so we have the difference
```

```
        eAdjust -= vecEndPoint;

        // Scale back into ellipsoid space
        eAdjust  = Vec3VecScale( eAdjust, InvRadius );

        // Perform the ellipsoid intersect test against this object
        ULONG StartIntersection =
              EllipsoidIntersectBuffers( *pObject->pCollVertices,
                                        *pObject->pCollTriangles,
                                         eCenter,
                                         Radius,
                                         InvRadius,
                                         eVelocity - eAdjust,
                                         eInterval,
                                         Intersections,
                                         IntersectionCount,
                                         &pObject->CollisionMatrix );

        // Loop through the intersections returned
        for ( i = StartIntersection; i < IntersectionCount; ++i )
        {
            // Move us to the correct point (including the objects velocity)
            // if we were not embedded.
            if ( Intersections[i].Interval > 0 )
            {
                // Translate back
                Intersections[i].NewCenter      += eAdjust;
                Intersections[i].IntersectPoint += eAdjust;

            } // End if not embedded

            // Store object
            Intersections[i].pObject = pObject;

        } // Next Intersection

    } // Next Dynamic Object
```

Once each dynamic object has been tested and the results added to the Intersections array, we call EllipsoidIntersectBuffers one more time to perform the narrow phase tests on any geometry stored in the collision system's static geometry buffers. As discussed, now that we will be storing our static geometry in the spatial tree, these buffers will be empty when the collision system is being used by our applications. However, the logic is still supported for applications that may wish to use the collision library without having the implementation of a spatial tree forced upon them. Every polygon in these static geometry buffers is passed straight to the narrow phase, so there will be no broad phase implementation for geometry stored here. Since we have spatial trees at our disposal now, you will probably not want to store geometry in these buffers in future applications.

```
    // Perform the ellipsoid intersect test against our static scene
    EllipsoidIntersectBuffers( m_CollVertices,
                               m_CollTriangles,
                               eCenter,
                               Radius,
                               InvRadius,
```

```
                                eVelocity,
                                eInterval,
                                Intersections,
                                IntersectionCount );
```

As discussed in the previous lesson, if the caller requested that the intersection information be returned in world space (instead of ellipsoid space), we loop through each intersection that we have collected and transform the new position, collision normal, and intersection point into world space.

```
    // If we were requested to return the values in normal space
    // then we must take the values back out of ellipsoid space here
    if ( !bReturnEllipsoidSpace )
    {
        // For each intersection found
        for ( i = 0; i < IntersectionCount; ++i )
        {
            // Transform the new center position and intersection point
            Intersections[ i ].NewCenter =
                                Vec3VecScale( Intersections[i].NewCenter,
                                              Radius );

            Intersections[ i ].IntersectPoint =
                                Vec3VecScale( Intersections[ i ].IntersectPoint,
                                              Radius );

            // Transform the normal
            D3DXVECTOR3 Normal = Vec3VecScale( Intersections[ i ].IntersectNormal,
                                               InvRadius );

            D3DXVec3Normalize( &Normal, &Normal );

            // Store the transformed normal
            Intersections[ i ].IntersectNormal = Normal;

        } // Next Intersection

    } // End if !bReturnEllipsoidSpace

    // Return hit.
    return (IntersectionCount > 0);
}
```

As you can see, the changes to this core detection step method have been minimal. We will now discuss the new methods used by this function for intersection testing with the spatial tree.

CollectTreeLeaves – CCollision

As we saw in the previous function, if a spatial tree has been registered with the collision system, the CollectTreeLeaves method is called to fill the collision system's leaf array with all the leaves which intersect the world space bounding box of the swept ellipsoid. This function is extremely small. It first makes sure that the leaf list is emptied so that no leaf pointers exist in the leaf from a previous query.

Then this leaf list is passed into the spatial tree's CollectLeavesAABB method along with the world space AABB of the swept ellipsoid.

```
void CCollision::CollectTreeLeaves( )
{
    // Clear the previous leaf list
    m_TreeLeafList.clear();

    // Collect any leaves we're intersecting
    m_pSpatialTree->CollectLeavesAABB( m_TreeLeafList,
                                       m_vecEllipsoidMin,
                                       m_vecEllipsoidMax );
}
```

When this function returns program flow back to the EllipsoidIntersectScene method, the CCollision::m_TreeLeafList member will contain a list of pointers for all leaves that were intersecting the ellipsoid's AABB.

EllipsoidIntersectTree – CCollision

When the CollectTreeLeaves method returns back to EllipsoidIntersectScene, all the leaves have been collected and stored. Next a call is made to the EllipsoidIntersectTree method which iterates through every polygon in those leaves and performs the narrow phase test. Although this function code looks quite large, for the most part it is an exact duplicate of the EllipsoidIntersectBuffers method used to perform the narrow phase test on the other geometry pools. The reason that most of that code has been cut and pasted into this function is that we have to do some additional testing and are working with slightly different source data.

The ellipsoid's eSpace center position and velocity vector are passed in along with the ellipsoid radius and inverse radius vectors. We are also passed a float reference that is used to return the *t* value of intersection back to the caller. The function also requires an array of CollIntersect structures which it will populate when intersections are found that occur at a closer *t* value that the one passed in the eInterval parameter. The final parameter contains the number intersections currently in this array. As you have probably noticed, the parameter list is identical to EllipsoidIntersectBuffers, which we discussed in detail in the previous lesson. That is because this is essentially the same function.

The first thing we do is store the current number of intersections in the passed array in the FirstIndex local variable. This is so we know where we have started adding structures so that we can return this information back to the caller. We then store the current value of the application counter in a local variable so that we can use it to make sure that polygons that exist in multiple leaves do not get tested more than once.

```
ULONG CCollision::EllipsoidIntersectTree( const D3DXVECTOR3& eCenter,
                                          const D3DXVECTOR3& Radius,
                                          const D3DXVECTOR3& InvRadius,
                                          const D3DXVECTOR3& eVelocity,
                                          float& eInterval,
```

```
                                        CollIntersect Intersections[],
                                        ULONG & IntersectionCount )
{
    D3DXVECTOR3 ePoints[3], eNormal;
    D3DXVECTOR3 eIntersectNormal, eNewCenter;
    ULONG       NewIndex, FirstIndex, CurrentCounter;
    long        i, j;
    bool        AddToList;

    // FirstIndex tracks the first item to be added the intersection list.
    FirstIndex = IntersectionCount;

    // Extract the current application counter to ensure duplicate
    // polys are not tested multiple times in the same iteration / frame
    CurrentCounter = GetGameApp()->GetAppCounter();
```

Now we set up a loop to iterate through each collected leaf in the leaf list. For each leaf, we extract its polygon count and set up a loop to iterate though every polygon in that leaf. In this inner loop, we fetch a pointer to the current CPolygon we are going to test in the current leaf we are processing.

```
    // Iterate through our triangle database
    ISpatialTree::LeafList::iterator Iterator = m_TreeLeafList.begin();
    for ( ; Iterator != m_TreeLeafList.end(); ++Iterator )
    {
        ILeaf * pLeaf = *Iterator;
        if ( !pLeaf ) continue;

        // Loop through each polygon
        for ( i = 0; i < (signed)pLeaf->GetPolygonCount(); ++i )
        {
            // Get the polygon
            CPolygon * pPoly = pLeaf->GetPolygon( i );
            if ( !pPoly ) continue;
```

Next we test the polygon's m_nAppCounter member. If we find that it is the same as the current application counter value, it means we have already processed this polygon when visiting an earlier leaf in the list. Therefore, we skip any further testing on this polygon and go to the next polygon in the list.

```
            // Skip if this poly has already been processed on this iteration
            if ( pPoly->m_nAppCounter == CurrentCounter ) continue;
            pPoly->m_nAppCounter = CurrentCounter;
```

If we make it this far in the inner loop, it means we have not yet tested the current polygon. We now perform an additional broad phase step which is an AABB/AABB intersection test between the polygon's bounding box and the bounding box of the swept ellipsoid. If the bounding boxes do not intersect then the swept ellipsoid cannot possibly intersect the polygon, so we skip to the next iteration of the loop. With large leaf sizes, this minimizes the number of polygons passed to the narrow phase test and generates a considerable performance increase.

```
            // Are we roughly intersecting the polygon?
            if ( !AABBIntersectAABB( m_vecEllipsoidMin,
                                     m_vecEllipsoidMax,
                                     pPoly->m_vecBoundsMin,
```

```
                                        pPoly->m_vecBoundsMax ) ) continue;
```

If we make it this far, then we have a polygon that may well intersect the ellipsoid. Thus it will need to be passed on to the narrow phase.

Our next step would usually be to transform the vertices of the triangle into eSpace and then pass this triangle into the SphereIntersectTriangle method. However, our tree does not store triangles; it stores clockwise winding N-gons that describe triangle fans with an arbitrary number of triangles. For example, a polygon might be a clockwise winding of four vertices describing a quad comprised of two triangle primitives. Since our SphereIntersectTriangle method only works with triangles and not N-gons (as its name certainly suggests), we will need to set up an inner loop that will iterate though every triangle in the polygon and send it to the SphereIntersectTriangle method, one at a time. For example, in the case of a quad, we would need to call SphereIntersectTriangle twice, once for its first triangle and once for its second triangle.

To calculate how many triangles comprise a clockwise winding N-gon we simply subtract 2 from the number of vertices. Figure 14.92 demonstrates this relationship by showing a clockwise winding N-gon with 8 vertices and 6 triangles.

As you can see, we can find the vertices for each triangle by stepping around the vertices in a clockwise order. The first triangle will be formed by the first three vertices, and from that point on, we can just advance the last two vertices to form the next triangle. We can see for example that the first vertex V1 forms the first vertex for all triangles. The other two vertices are found for every triangle simply by stepping around the edges. For example, the last two vertices of the first triangle are v2 and v3. The last two vertices of the second triangle are v3 and v4, and so on.

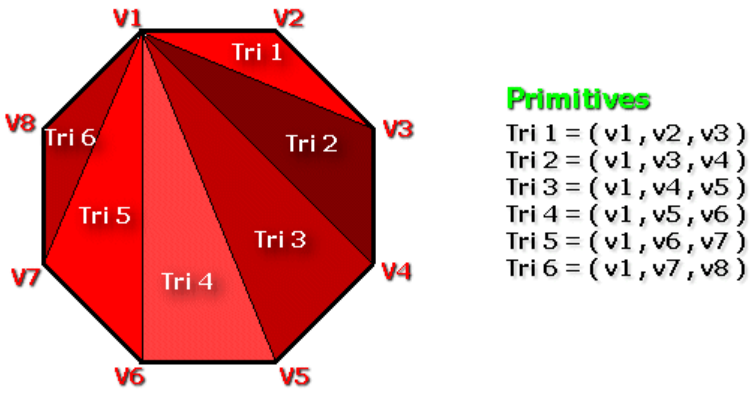

Figure 14.92

In the next section of code we start by transforming the polygon's normal into eSpace. We then set up a loop to iterate through every triangle in the polygon. In each iteration we select the three vertices that form the current triangle we are processing (see Figure 14.92) and transform them into eSpace before sending them into the SphereIntersectTriangle method.

```
            // Transform normal and normalize
            eNormal = Vec3VecScale( pPoly->m_vecNormal, Radius );
            D3DXVec3Normalize( &eNormal, &eNormal );

            // For each triangle
            for ( j = 0; j < pPoly->m_nVertexCount - 2; ++j )
            {
                // Get points and transform into ellipsoid space
                ePoints[0] = Vec3VecScale( (D3DXVECTOR3&)pPoly->m_pVertex[0],
```

```
                                    InvRadius );

            ePoints[1] = Vec3VecScale( (D3DXVECTOR3&)pPoly->m_pVertex[ j + 1 ],
                                    InvRadius );

            ePoints[2] = Vec3VecScale( (D3DXVECTOR3&)pPoly->m_pVertex[ j + 2 ],
                                    InvRadius );

            // Test for intersection with a unit sphere and the
            // ellipsoid space triangle

            if ( SphereIntersectTriangle( eCenter,
                                          1.0f,
                                          eVelocity,
                                          ePoints[0],
                                          ePoints[1],
                                          ePoints[2],
                                          eNormal,
                                          eInterval,
                                          eIntersectNormal ) )
            {
```

Note: The above code could be optimized by pre-transforming the vertices once, storing them in a local buffer, and then subsequently iterating through the triangles.

If the SphereIntersectTriangle method returns true then the sphere does intersect the triangle and eInterval will contain the *t* value of intersection. If eInterval is larger than zero then the intersection happened at some distance along the ray and we can calculate the new non-intersecting position of the sphere by adding the velocity vector scaled by the *t* value to the original centerpoint of the sphere. If eInterval is less than zero, then the sphere is embedded inside the triangle and eInterval describes the distance to move the sphere position along the direction of the plane normal in order to un-embed it.

```
                // Calculate our new sphere center at the point of intersection
                if ( eInterval > 0 )
                    eNewCenter = eCenter + (eVelocity * eInterval);
                else
                    eNewCenter = eCenter - (eIntersectNormal * eInterval);
```

The rest of the function is identical to the EllipsoidIntersectBuffers method. If there are currently no intersections stored in the intersection array, or if the *t* value for this intersection is less than the *t* value for the intersections currently stored in this array, we add the intersection information to the first element in the intersections array and set the intersection count to zero.

```
                // Where in the array should it go?
                AddToList = false;
                if ( IntersectionCount == 0 ||
                     eInterval < Intersections[0].Interval )
                {
                    // We either have nothing in the array yet, or the new
                    // intersection is closer to us
                    AddToList         = true;
                    NewIndex          = 0;
                    IntersectionCount = 1;
```

```
                    // Reset, we've cleared the list
                    FirstIndex        = 0;

                } // End if overwrite existing intersections
```

Alternatively, if eInterval is the same as the *t* value for the intersections stored in the Intersections array, then we add it to the end of the list and increase the intersection count member.

```
            else if ( fabsf( eInterval - Intersections[0].Interval )< 1e-5f )

              {
                    // It has the same interval as those in our list already,
                    // append to
                    // the end unless we've already reached our limit
                    if ( IntersectionCount < m_nMaxIntersections )
                    {
                        AddToList         = true;
                        NewIndex          = IntersectionCount;
                        IntersectionCount++;

                    } // End if we have room to store more

                } // End if the same interval
```

If we get to this point in the inner loop and find that the AddToList boolean has been set to true, it means the current triangle being tested was either closer or at the same distance along the ray as those intersections currently stored in the intersection array. In this case, we fill out the element in the array with the eSpace intersection information for the triangle.

```
                // Add to the list?
                if ( AddToList )
                {
                    Intersections[ NewIndex].Interval     = eInterval;

                    Intersections[ NewIndex].NewCenter    = eNewCenter +
                                                            (eIntersectNormal
                                                            * 1e-3f);

                    Intersections[ NewIndex].IntersectPoint = eNewCenter –
                                                             eIntersectNormal;

                    Intersections[ NewIndex].IntersectNormal= eIntersectNormal;
                    Intersections[ NewIndex].TriangleIndex   = 0;
                    Intersections[ NewIndex].pObject         = NULL;

                } // End if we are inserting in our list

            } // End if collided

        } // Next Triangle

    } // Next Polygon
```

```
    } // Next Leaf

    // Return hit.
    return FirstIndex;
}
```

We have now covered all the changes to the collision system. The end result is a powerful collision query engine that we can use in all future lab projects. The difference in query times with the spatial tree broad phase is quite significant. You can test this for yourself when you experiment with the lab project source code.

14.23 The TransformAABB Math Utility Function

In the EllipsoidIntersectScene method we saw a call being made to the MathUtility::TransformAABB method. This call transformed the AABB of a dynamic object into world space. The method was passed the minimum and maximum extents of a bounding box and a transformation matrix with which to transform the AABB.
Let us be clear about exactly what this function is supposed to do. It does not actually transform the box in the traditional sense, as an AABB by its very nature is always aligned with the world axes. If we were to rotate the box we would in fact have an OBB (oriented bounding box). The OBB would have to be stored in a very different way (position, extents, and orientation of its local axes) and this is not our goal. OBBs are much trickier to work with, and generally more expensive (although tighter fitting), and since our collision system is currently working with AABBs throughout, we will continue to do that.

What this function will do however is calculate a new AABB that contains the passed AABB post-rotation. To understand this concept, take a look at the AABB shown in Figure 14.93. In this example the box is assumed to be centered at the origin of the coordinate system with a maximum extents position vector of (10,10).

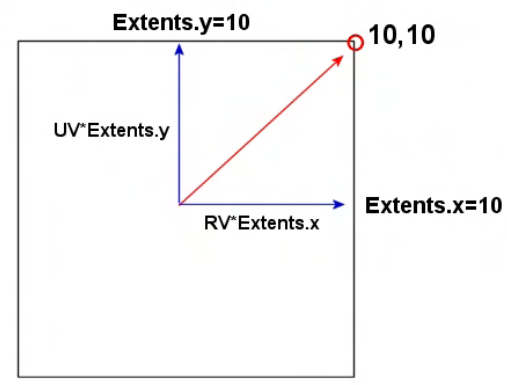

Figure 14.93

We know that an extents vector of <10,10> means the box expands to a maximum of 10 units along the world x axis and a maximum of 10 units along the world y axis. That is, we know that in the case of an AABB, Extents.x describes the position on the world X axis where the right side of the box intersects it and Extents.y describes the position along the world Y axis where the top of the box intersects it. For ease explanation we will deal with a 2D coordinate system, but the same holds true in 3D.

We know that in the case of an axis aligned bounding box, its local right and up vectors are aligned with the world X and Y axes respectively. However, if we perceive the world axes to be the local right and up vectors for the box, we can see that Extents.x describes the amount we would need to scale the box's unit length right vector (RV) to create a vector that when added to the box centerpoint describes a point

on the plane of its right face. Likewise, the unit length up vector for the box (UV), when scaled by the y component of the Extents vector and added to the centerpoint of the box, describes a point on the plane on which its top face lies. We can see that scaling the right vector and the up vector of the AABB by the components of the extents vector essentially just returns the extents vector (just as if we were transforming the extents vector by an identity matrix). However, what we want to do is transform the up and right vectors of the AABB by the passed matrix and calculate a new AABB that encompasses the OBB these new vectors describe.

In Figure 14.94 we show what the box would look like if we were to rotate these vectors 45 degrees to the left, simulating what would happen if the passed transformation matrix contained a 45 degree rotation. We can see that the rotated right and up vectors (which were scaled by the extents vectors components) still describe the location of the right and top planes of the box faces, but they are no longer aligned to the world axes. Essentially, these vectors and the center point describe an OBB now.

We know that if we rotate an AABB 45 degrees to the left or right it will pierce the original extents and a new larger AABB will need to be calculated to contain it. It is this new AABB (the red dashed box in Figure 14.93) that we want this function to efficiently calculate.

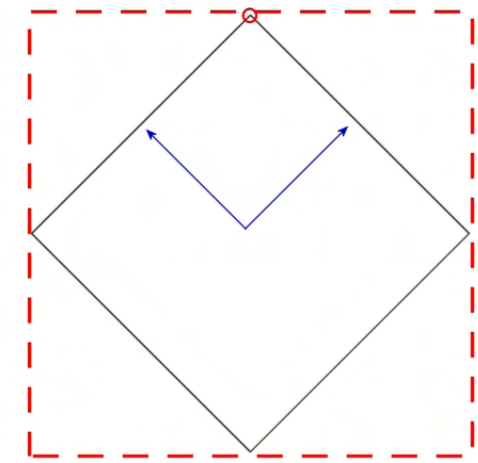

Figure 14.94

The first section of code generates the scaled and rotated right, up, and look vectors (3D) for the box.

First we calculate the center of the box and subtract it from the passed maximum extents vector. This gives us the diagonal half length of the box shown as the red arrow in Figure 14.93. We then make a copy of the passed matrix into a local variable and zero out its translation vector (we will deal with translation separately at the end of the function).

```
void MathUtility::TransformAABB( D3DXVECTOR3 & Min,
                                 D3DXVECTOR3 & Max,
                                 const D3DXMATRIX & mtxTransform )
{
    D3DXVECTOR3 BoundsCentre = (Min + Max) / 2.0f;
    D3DXVECTOR3 Extents = Max - BoundsCentre, Ex, Ey, Ez;
    D3DXMATRIX  mtx = mtxTransform;

    // Clear translation
    mtx._41 = 0; mtx._42 = 0; mtx._43 = 0;
```

Our next step is to transform the centerpoint of the box by the transformation matrix which rotates the centerpoint into the space described by the passed matrix.

```
    // Compute new centre
    D3DXVec3TransformCoord( &BoundsCentre, &BoundsCentre, &mtx );
```

Now we need to compute the scaled and rotated local axes for the box shown as the rotated blue arrows in Figure 14.94. We said that we needed to scale the unit length axes by their matching components in the extents vector so that the local up, right, and look vectors are grown in length such that they describe distances to the planes of the top, right and front faces. However, as the passed transformation matrix already contains the rotated (but unit length) right, up, and look vectors in its 1st, 2nd, and 3rd rows respectively, we can just scale the rotated unit length axes by their matching components in the extents vector to get the rotated axes:

```
    // Compute new extents values
    Ex = D3DXVECTOR3( mtx._11, mtx._12, mtx._13 ) * Extents.x;
    Ey = D3DXVECTOR3( mtx._21, mtx._22, mtx._23 ) * Extents.y;
    Ez = D3DXVECTOR3( mtx._31, mtx._32, mtx._33 ) * Extents.z;
```

Let us plug in some example values to see what has happened so far. We will once again use the 2D case for our diagrams.

Imagine we pass in a transformation matrix that will rotate our original 2D box (with a half diagonal length vector of <10, 10>) 45 degrees to the left. We know in such a case that the first row of the matrix which contains the rotated right vector will store the vector <0.707, 0.707> and the up vector stored in the matrix will be <-0.707, 0.707>. These describe the unit length vectors <1,0,0> and <0,1,0> rotated 45 degrees to the left:

RV = [0.707 , 0.707]
UV = [-0.707, 0.707]

These vectors current describe the directions we would need to travel from the box centerpoint to reach the rotated right and top faces of the box. They do not yet describe the distance over which to travel. However, in the above code we scale the up and right vectors (and the look vector in our 3D code) by their matching components in the Extents vector to generate the up and right vectors shown in Figure 14.95. These describe the direction and distance to the right and top faces of the rotated AABB (OBB).

In Figure 14.95 we see that Ex and Ey contain the results of the scaled RV and UV vectors (scaled by the original extent vector components – which are both 10 units). When added to the center position of the box, they describe points in the center of the right and top faces.

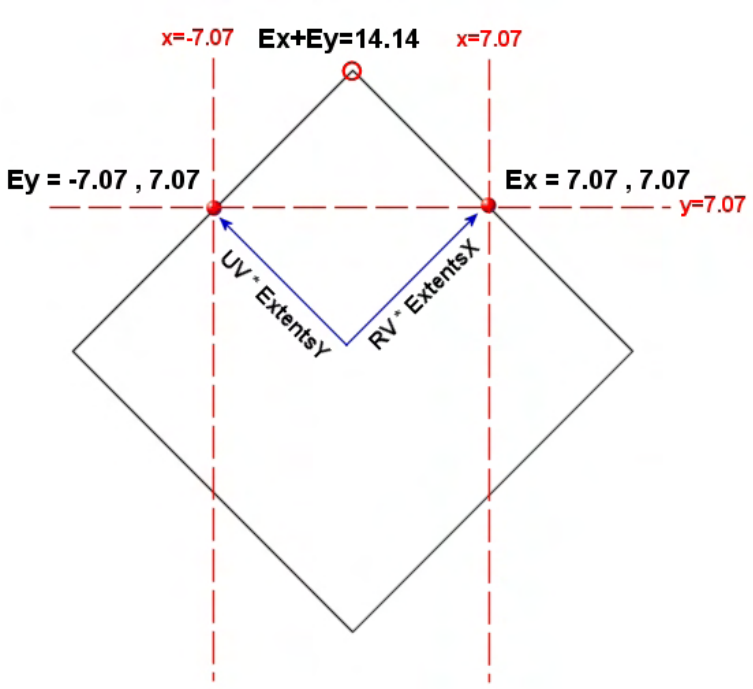

Figure 14.95

Ex = RV*10 = [7.07 , 7.07]
Ey = UV*10 = [-7.07 ,7.07]

So with these two points, how do we calculate the new extents of the rotated box along the world X and Y axes so that we can build a new AABB that encompasses it?

It just so happens that summing the absolute x components of each vector will tell us the size of the box along the world X axis and summing the y components of both vectors will tell us the height of the rotated box in world aligned space. For example:

NewExtents.x = abs(Ex.x) + abs(Ey.x) = 7.07 + 7.07 = 14.14
NewExtents.y = abs(Ex.y) + abs(Ey.y) = 7.07 + 7.07 = 14.14

As you can see, by summing the like components of the scaled and rotated vectors, we can compute exactly how much of the world X and Y axes this rotated OBB covers. NewExtents.x now describes the distance from the center of the box to the tip of the diamond on the right hand side of the rotated box. NewExtents.y describes the distance from the center of the box to the tip of the diamond at the top of the OBB (see Figure 14.96).

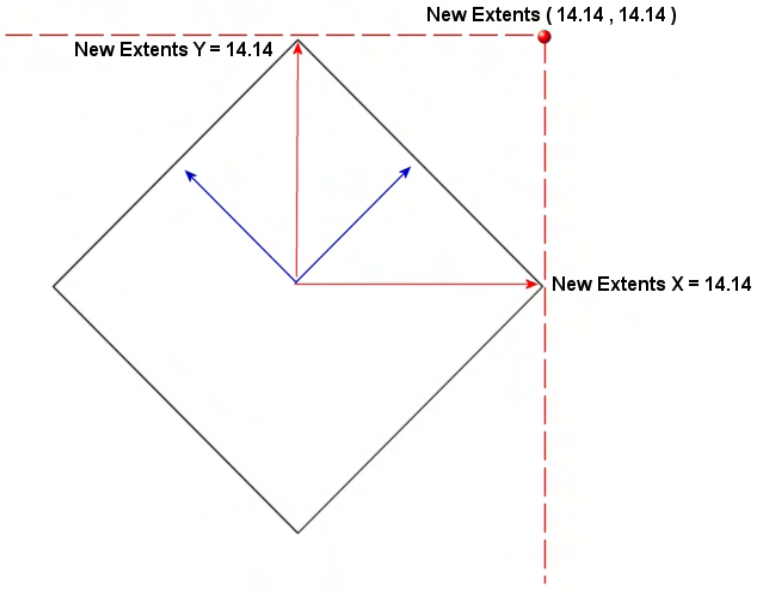

Figure 14.96

Looking at figure 14.96 we can see that the new diagonal half length of the box is therefore:

NewMaxExtents = [New Extents.x , New Extents.y] = [14.14 , 14.14]

Let us now take a look at the rest of the code to the function. In the previous section we calculated the rotated and scaled up, right, and look vectors of the OBB and stored them in the vectors Ex, Ey and Ez (the blue arrows in Figure 14.96). As we just discovered, all we have to do is sum the absolute values of the like components in each vector to get the new extents vector for the box.

```
    // Calculate new extents actual
    Extents.x = fabsf(Ex.x) + fabsf(Ey.x) + fabsf(Ez.x);
    Extents.y = fabsf(Ex.y) + fabsf(Ey.y) + fabsf(Ez.y);
    Extents.z = fabsf(Ex.z) + fabsf(Ey.z) + fabsf(Ez.z);
```

At this point, Extents holds the diagonal half length vector of the AABB we wish to create (which will bound the rotated original AABB). We can calculate the minimum extent position vector for the box by subtracting the new extents vector (diagonal half length vector) from the box center, and calculate the new maximum extents position vector by adding it to the box center. Finally, we also add the minimum and maximum extents vectors of the new AABB to the translation vector stored in the fourth row of the passed matrix. This means the new AABB is not only recalculated to encompass the rotation applied to the original AABB, but is also translated into the position described by the passed matrix.

```
    // Calculate final bounding box (add on translation)
    Min.x = (BoundsCentre.x - Extents.x) + mtxTransform._41;
    Min.y = (BoundsCentre.y - Extents.y) + mtxTransform._42;
    Min.z = (BoundsCentre.z - Extents.z) + mtxTransform._43;
    Max.x = (BoundsCentre.x + Extents.x) + mtxTransform._41;
    Max.y = (BoundsCentre.y + Extents.y) + mtxTransform._42;
    Max.z = (BoundsCentre.z + Extents.z) + mtxTransform._43;
}
```

And there we have it. This is a very handy way to calculate a new AABB for an AABB that you wish to transform into another space. The result is an AABB which completely contains the original rotated AABB. Keep in mind that this AABB has the potential to be much larger than its untransformed predecessor, which means that query accuracy can be decreased as a result of the looser fitting volume.

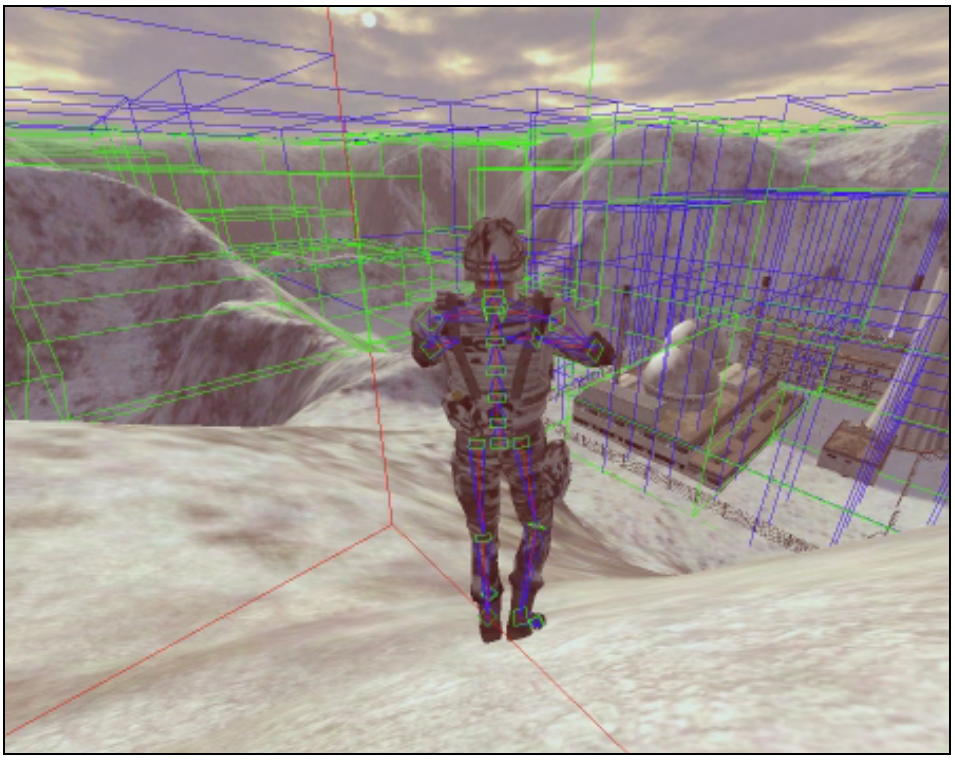
Conclusion

In Lab Project 14.1 you will see a lot of code associated with tree rendering which we have not yet covered. That is because this lab project will span two lessons, with the render system being explained in the next one. For now, you should focus your attention on the main implementation of our tree classes and the changes made to the collision system that allow us to use the spatial tree as a broad phase.

In the next lesson we will see the same spatial tree being used to speed up rendering. This will lay the foundation for a rendering system that will be utilized by our spatial trees and by the powerful BSP/PVS rendering engine we will create as we wrap up this course.

Chapter Fifteen

Hierarchical Spatial Partitioning II



Introduction

In the previous lesson we developed various spatial trees for use with our collision system, allowing us to perform polygon queries on large scenes in a fraction of the time it would have otherwise taken. In this lesson we will add to the code that we developed and implement a hardware-friendly rendering system using the same spatial trees. Since our spatial tree will ultimately be responsible for rendering its static polygon data, we will provide a means for allowing the tree to render only the polygon data that is currently visible (i.e., sections of the scene that are contained or partially contained inside the camera frustum). From the application's perspective, rendering the tree will be similar to rendering a mesh. CBaseTree will expose a DrawSubset method (just like CActor and CTriMesh) which will instruct the tree to render all visible polygons that use a given attribute in a single call. This will allow the application to set the textures and materials used by a given subset before instructing the tree to render all currently visible polygons that use it. This will ensure that the static data in our tree can be batch rendered, minimizing the texture and material state changes that have to be performed by the application.

All of the tree types we studied have the same characteristics with regards to rendering. This will make CBaseTree an ideal location for the implementation of the render system. Thus we benefit from having only one implementation of the system that is shared by all derived types. All of our trees have leaves which are either currently visible or outside the frustum. They may or may not contain polygon data which will have to be rendered if the leaf is indeed considered visible. Theoretically, our rendering system has a simple job; traversing the tree and rendering only the polygons stored in visible leaves. However as trivial as this may seem, a naïve implementation can have drastic performance implications as we will discuss in the next section. We will have to develop a system that keeps the number of traversals to a minimum and introduces as little CPU processing overhead as possible when determining which data should be rendered. On the latest graphics cards, which are capable of rendering very large numbers of triangles, we could easily end up with a situation where rendering the entire scene brute force could far outperform our hierarchical frustum culled visibility system, if an inefficient system is put in place.

In the second part of this lesson we will add dynamic object support to our spatial trees. Although the application will be responsible for rendering its dynamic objects, by storing them in the spatial tree and having access to the leaves in which their bounding volumes exist, we can benefit from the visibility system such that the application need only render a dynamic object if it currently exists in a leaf that is flagged as visible. We will add methods to CBaseTree to insert a new dynamic object into the tree which will be called when the dynamic object is first created. The tree will have no knowledge of exactly what type of object has been assigned to it; it will view the concept of dynamic objects in a rather abstract way. This will ensure that our tree will not become dependent on certain object types such as CActor or CTriMesh. From the tree's perspective, each dynamic object will simply be an AABB and a context pointer which only has meaning to the application. Methods will also be added to the tree so that the application can update the current position of a dynamic object that is registered with the spatial tree. This will instruct the tree to remove the dynamic object's pointer from any leaves in which it is currently contained and use its AABB to find the new leaves its pointer should be added to. The tree will expose methods such as GetVisibleLeaves which will return a list of only the leaves in the tree which are currently visible. The application can then loop through these leaves and render only the dynamic

objects it finds stored there. Any dynamic objects assigned to invisible leaves will not be processed at all. For each dynamic object registered with the system the tree will maintain a list containing all the leaves that object is currently contained within. This allows the application to query the leaf list for a given dynamic object so that the application has knowledge of the leaves in which it is contained (whether those leaves are visible or not). In this section, we will also cover the application code that has been changed to support dynamic objects being used with an ISpatialTree derived class.

Let us begin our discussions by tying up the spatial tree's management of its static polygon data. In the previous chapter we discussed how to add, build, and run collision queries on this data. Now we must implement the final piece, the code that will render this static geometry using hierarchical frustum culling.

15.1 Rendering Spatial Trees

When we concluded our coverage of spatial trees in the previous chapter, each leaf stored the polygons it contained as an array of CPolygon pointers. This polygon data is located in system memory to make sure that it is easily accessible for collision queries. Consequently, it is not currently able to be efficiently rendered. We know that in order to get maximum performance from our rendering system we will want the geometry stored in vertex and index buffers located in video memory so that the GPU on the graphics hardware can access that data for transformation/lighting purposes as quickly as possible. However, we certainly would not want the only copy of the data our tree uses to be stored in vertex and index buffers since this would require the locking and reading these buffers during collision queries which would result in very inefficient collision tests. What we will need to do is create a second copy of the scene data that is stored in vertex and index buffers that can be optimally rendered by the hardware. This also means that we can perform optimizations on the renderable version of the data. For example, in this lesson a key optimization will be performing a weld to get rid of duplicate vertices. This is an important step since scenes often have separate vertices for each polygon, even when polygons share an edge and have the same attributes.

The classic example of why it is efficient to perform a weld on the render geometry can be seen if you were to place a cube in GILES™ and export it to an IWF file. For various reasons, GILES™ stores all of its data at the per-face level (even vertices), which means it will never share vertices between faces. We know that if we were to place a cube and assign the same attribute to each face of that cube, we would only need to have eight vertices that are all indexed by the six faces (twelve triangles) of that cube. However, GILES™ will actually export four separate vertices per face (quad) resulting in a cube consisting of 24 vertices, regardless of vertex location, material, UV coordinates, etc. Thus, in any given corner of the cube, there exists three vertices in the same location (one for each face that meets at that corner point). For rendering purposes, it is generally going to be preferable to have a shared pool of eight vertices that are indexed by all the faces of the cube. This is essentially what a weld does for us -- it finds these duplicated vertices and replaces them with a single vertex. All the faces that used those previous vertices then have their indices remapped to the new single vertex. The cube looks exactly the same, but we have just eliminated 2/3^{rds} of our vertex data. If we imagine the savings that might be gained by welding an entire scene, we can see that this would allow us to fit much more geometry into a single vertex buffer and thus, minimize the number of vertex buffers we will need to store our scene

geometry. Remember that changing between vertex buffers can be an expensive operation, so we will want to do it as infrequently as possible. By minimizing the number of vertex buffers needed to store the scene, we minimize the number of vertex buffers we need to set and render from in a given frame.

There are many ways a rendering system can be implemented for a spatial tree. Indeed, quite a few designs were attempted during the development of this course. This was time consuming but fortunate as we discovered quite significant performance differences between the various systems. Even system designs that seemed quite clever and robust on paper performed terribly when compared against simple brute force rendering on high end machines with the latest graphics hardware. To be fair, a number of the maps and levels we tested had fairly low polygon counts (by today's standards), so we were not too surprised to see that they could be easily brute force rendered by the latest nVidia and ATI offerings. Also note that these scenes were not being rendered with complex shaders or multiple render passes, so the latest hardware could easily fill the frame buffer without any trouble. This was certainly true in tests where we used pre-lit scenes with a single texture.

Although this might seem an unfair test for any visibility system, the fact that brute force rendering was significantly outperforming these various system implementations on high end hardware, even when only half the scene was visible, is an important point that is really worth keeping in mind. It is a common mistake to assume that because the spatial visibility system might be rendering only half the scene when the player is in a given location within the game world, versus the brute force approach which is always rendering the entire scene, that the latter would always be slower. But it is critical to factor in the hardware in question. If the hardware is able to brute force render the entire scene without difficulty, the difference then becomes one of what is involved in the spatial system's determination of which polygons should be rendered. That is, we found in various spatial tree visibility systems that we implemented that the processing and collection time for visible data often exceeded the time it took to render the whole scene using brute force.

> **Note:** To be clear, we are talking solely about the rendering of the static scene polygon data here, which is perhaps being a bit unbalanced with respect to such spatial visibility schemes. One must also factor in the savings of quickly identifying and rendering dynamic objects which are only contained in visible leaves. A typical scenario might contain dozens of skinned characters for example, of which only two are contained in visible leaves. If these characters were each comprised of thousands of triangles, the savings over brute force would generally become more apparent. In this section though, we are focusing on trying to efficiently render the static scene in a way that helps rather than hinders performance on high end systems.

When the same systems were compared on much lower end machines, the situation was much better for hierarchies. That is, the extra CPU processing involved in collecting only the visible data made all the difference to the aging video hardware. Such cards could not render the entire scene brute force at interactive frame rates and the various visibility systems helped to achieve much higher frame rates. One might be tempted to conclude that the spatial tree's visibility system could be put in place to help our games run at acceptable speeds on lower end machines even if they provide no real benefit on the latest cutting edge systems (which seemed not to need much help). This is certainly a valid consideration, as it allows a game to run on a much wider variety of machines (which could mean the difference between decent sales and great sales for a commercial title). Certainly it is generally in a software company's best interest to implement systems that support a wide variety of target platforms as it opens up the potential market for the game. A recent survey showed that the vast majority of computer owners that play games

are still using nVidia geForce™ 2/3 (or equivalent) hardware, so there is certainly something to be said about that.

However, what was unacceptable about many of the system designs we tried was that while speeding up performance on low end machines, performance on high end machines was degraded (sometimes significantly so). Essentially, the time required to traverse the tree and collect the visible data became the main bottleneck. As mentioned, this situation would likely be quite different if we were rendering a huge scene with high polygon counts or a scene that required many rendering passes per–polygon to achieve advanced lighting and texturing effects. In such cases, even the latest graphics cards would find themselves hard pressed to perform brute force renders. This is where our spatial tree's visibility system could really make a difference as it only asks the hardware to render the geometry that is currently visible. This would once again allow for a reduction in the list of primitives to be rendered each frame which will hopefully represent an amount that can be easily rendered by the hardware.

We should also not neglect the far plane case when imagining how our spatial tree's visibility system can help out even powerful graphics cards. Imagine for example a game that implements a continuous terrain such as those found in such products as Microsoft Flight Simulator®. The terrains in such games would not only be too large to render brute force, but even on the latest hardware they might also be too large to even fit in memory at once. The terrain data would have to be streamed from disk as and when it comes into view and released when it is no longer visible. With our spatial tree's visibility system, any leaves that are outside the frustum could have their geometry data flushed from memory. With our hierarchical traversals, we could very easily detect which leaves are within the frustum each frame and stream the terrain data for that leaf from disk if it is not already loaded. We can then collect the data from each visible leaf and pass it to the pipeline to render. This task would be almost impossible to achieve without a spatial manager. It is for this reason that a spatial manager and visibility systems generally will be at the heart of nearly every commercial quality game title.

Although the benefits of a spatial tree for rendering purposes are numerous, there will be times when you will be rendering small and simple scenes which modern hardware can brute force render more efficiently than our spatial tree's visibility system. Although not using a spatial manager and visibility system in the days of the software engine would have been unthinkable, the latest graphics cards do their jobs very well and require less help from the application than in days gone by. As mentioned, when rendering simple scenes, trying to help the card instead of letting it just render everything can actually hinder performance in many cases. The visibility system we choose to implement then has to be one that prepares the visible data so efficiently that the time requirements are negligible in such situations. A classic example of why this is so important can be understood when we imagine the player located in the bottom left corner of the scene looking towards the top right corner of the scene with a wide FOV and a near infinite far plane. In such cases, the entire scene would most likely be visible, so the quickest solution would always be to perform an optimized brute force render of the entire scene, batched by subset. However, our visibility system would have to perform a tree traversal and collect the data at each leaf just to determine that the entire scene should ultimately be rendered anyway, just as in the brute force case. The issue is that our visibility system had to run some form of logic to ascertain this fact before it could start rendering anything. The brute force approach had no CPU processing to perform and could start rendering straight away. In such situations, the brute force approach is generally going to beat a basic frustum visibility system hands down. What we need to do is make sure that we implement a system that minimizes the damage to frame rate in these situations, but that when the player is

positioned at a location within the scene such that only a few leaves are visible (the general case), the visibility system will outperform the brute force system.

To sum up, we are going to try to design a system that significantly speeds up our rendering on both low and high end systems in the best case; in the worst case, where the scene could easily be brute force rendered by a high end graphics card, we want our implementation to speed up rendering on a low end machine but not under-perform brute force rendering on a high end system by any significant degree.

15.1.1 Different Rendering Schemes

There are many different schemes ranging from easy to difficult that can be employed to collect and render the visible data from a spatial tree. Unfortunately, the performance of such algorithms tends to vary from poor to good in that same order. In this section we will discuss some of the approaches that one might consider employing. We will discuss techniques that span the naïve to the complex and end with a discussion of the system that we ultimately ended up going implementing in CBaseTree.

The UP Approach

The simplest way to render the visible the data is to draw the system memory polygon data stored at each visible leaf. DirectX has the IDirect3DDevice9::DrawPrimitiveUP method that allows us to render data directly using a system memory user pointer. With such an approach we do not need to make a copy of the polygon data in vertex or index buffers; we can pass a pointer to each CPolygon's vertex array directly into the DrawPrimitiveUP method. One approach would be to have an empty vertex array allocated for each subset used by the tree's static data prior to performing a visibility pass. These vertex arrays would be populated with the vertex data from each CPolygon from every currently visible leaf when the tree is traversed. After the visibility traversal is complete, this collection of vertices could be rendered. This array would then be flushed before the next visibility pass is performed.

As an example, if we imagine the static data in the tree contains polygons that use five different attributes in total, our tree would use five vertex arrays as bins in which to collect the vertex data from the visible leaves and add them to the array that matches their attribute ID. These arrays/bins would be emptied prior to the visibility process being performed each frame. We could implement a ProcessVisibility method that would be called by the application prior to rendering each subset of the tree. This method would traverse the tree, testing each node's bounding box against the camera's frustum so that any node that is currently outside the frustum will not have its children traversed into. Any child nodes and leaves underneath that node in the tree will not be traversed or processed and as such, any polygon data contained down that branch of the tree will be quickly and efficiently rejected from the collection process.

When a leaf is found that is visible, its visible Boolean will be set to true and a loop through each polygon stored there will be performed. For each polygon, we will check its attribute and copy its vertex data into the matching vertex bin. So if the current polygon we are processing in a leaf had an attribute

ID of 4, we would copy its vertices (one triangle at a time) into the 5th vertex array (VertexArray[4]). After the tree has been traversed, we would have built five vertex arrays and flagged each visible leaf. At this point, the ProcessVisibility method would return program flow back to the application.

The next stage for the application would be to loop through each subset and call the tree's DrawSubset method after setting the correct device states for that attribute. For example, the application would set the texture and material for subset 0 and call the tree's DrawSubset method, passing in this attribute ID. As the vertex array has already been compiled for all visible triangles that use this subset, this method can just call the IDirect3DDevice9::DrawPrimitiveUP method passing in VertexArray[0] and the number of triangles stored in this array. We would also state that we would like it rendered as a triangle list. Once the application had called DrawSubset for each attribute used by the tree, all visible triangles would have been rendered. By collecting the visible triangles into arrays first, we minimize the number of draw calls which would otherwise be in the tens of thousands if we rendered each polygon's vertices as and when it was located in a visible leaf during the visibility pass.

So we can see that using this approach, it is the ProcessVisibility method that actually traverses the tree and collects the triangle data for each subset. The DrawSubset method would simply render the vertex bin/array that matches the passed attribute that was compiled during the visibility pass.

What is wrong with this approach?

Although this method sounds delightfully easy to implement, it is a definite example of the wrong way to design this system. Performance would be simply terrible for a variety of reasons. First, as we traverse the tree, we have to perform a system memory copy of the vertex data from each CPolygon into the appropriate vertex bin. This would need to be done for every polygon currently visible. As vertex structures can often be pretty large, these memory copies really drain performance. When the entire scene is visible, we will be copying hundreds or thousands of vertices each frame and seriously tying up the CPU. The brute force approach in such situations would have none of this overhead and could simply just render the scene prepared in static vertex and index buffers with just five draw calls.

The second major flaw with this system is the use of the DrawPrimitiveUP method. Although it looks like the use of this function handily avoids the need to employ vertex buffers, the real concern is what happens behind the scenes. When we call the DrawPrimitiveUP method, a temporary vertex buffer will be created and locked and the vertex data we pass will then have to be copied into this vertex buffer (yet more copying of memory) before it is unlocked. After unlocking this vertex buffer, the pipeline may then have to commit this data to video memory, involving yet another copy of the vertex data over the bus into video memory. Transforming all the vertex data for the currently visible scene could mean a huge number of vertices will have to be passed over the bus each time.

As you can see, although this system it simple to implement, the performance would be quite poor. With an outrageous amount of memory copying to perform, this system is typically outperformed by brute forcing even on low end hardware. Memory copying is performance killer and in this case we are implementing three major copy stages. This is clearly not the way to go.

The Dynamic Index Buffer Approach

The dynamic index buffer method is discussed in many published texts and as such is worth discussing here. With this approach we would invoke a process just after the tree is built which prepares the render data. It would allocate a static vertex buffer for maximum performance which will typically be allocated in video memory on T&L capable cards. We will also allocate a *dynamic* index buffer for each attribute used by the static scene stored in the tree. These index buffers will be flushed prior to each ProcessVisibility call.

The additional build process that is employed only once just after the tree is first built would loop through each leaf in the tree and copy the vertex data for each polygon into the static vertex buffer. As all the vertices of all polygons in all leaves will be stored in this vertex buffer we will also need to store the indices of each polygon in the leaves themselves. This is so we know for a given visible polygon, which section of the vertex buffer it is contained in and the sections that should be rendered or skipped. As each polygon is added to the vertex buffer, we will store the indices of its vertices in the leaf. After the post-build process is performed, we would have a single vertex buffer containing all the vertices of the static scene, and in each leaf we would have the indices for all the vertices of each polygon so that we know where they exist in the vertex buffer. We will also have an array of empty dynamic index buffers (one for each subset) which will be filled with the visible polygon indices during the ProcessVisibility call.

When the ProcessVisibility call is made by the application prior to rendering the tree's subsets, this function will first make sure that all the dynamic index buffers are empty. Then it would traverse the tree searching for visible leaves as in the previously described method. For each visible leaf we find, we would loop through each of its polygons and add its indices to the dynamic index buffer that is mapped to the attribute for that polygon. For example, if a given polygon had an attribute ID of 4, we would copy its indices into the fifth index buffer (indexbuffer[4]). When the ProcessVisibility method returns program flow back to the application, the tree would have the indices of all the visible triangles for a given attribute in each index buffer. The application would then bind the appropriate texture and material, set the appropriate states, and then call the tree's DrawSubset method to draw the required polygons. This method would simply call the IDirect3DDevice9::DrawIndexedPrimitive method for each dynamic index buffer it contains. We would pass DrawIndexedPrimitive the vertex buffer used by the entire scene and the index buffer of the current subset we are rendering. That index buffer would describe the indices of all the triangles in the vertex buffer that are visible for the current subset being rendered. After this has happened for each subset, all visible triangles will have been rendered. Thus, the number of DrawIndexedPrimitive calls would be equal to the number of subsets used by the polygons in the tree.

What is wrong with this approach?

This design does perform much better than the previously discussed approach due to the fact that the vertex data was already contained in a video memory static vertex buffer. This meant that the sizable vertex structures did not have to undergo the multitude of copy phases. The vertex data was created just once at application startup and committed to video memory. However, on simple levels, brute force rendering significantly outperformed this technique on high-end hardware even when half the scene was being rejected in the visibility pass. This was especially true in the case of a clipped tree where the

polygon count was raised between 30% and 80% due to the polygon splitting performed in the build process. We can see for example that in the extreme case where there was an 80% increase in the polygon count, even when half the scene was being rejected, the polygon count had almost doubled and as such, half of our visible scene contained nearly as many polygons as brute force rendering the original polygon data. Therefore, brute force was still able to render the original scene faster than our clipped spatial tree could render only half of its split scene.

When using a non-clipped tree, things were better, but we still found that the memory copies performed at each visible leaf (polygon indices copied into the index buffer) are a bottleneck. Although index data is much smaller than vertex data and not nearly as expensive to copy or commit to video memory, when the entire scene was within the frustum, we were still dealing with tens (even hundreds) of thousands of indices to copy into the index buffer during each visibility determination pass. Combined with the fact that a dynamic index buffer typically performs a little slower than a static index buffer and we still had a system that, while much improved over the previous method, suffered poor performance compared to brute force when there was medium to high visibility in non-trivial, but not overly complex, scenes.

What was clear was that in order to get better performance we needed to eliminate the copying of vertex and index data and instead store the renderable data in static vertex and index buffers in the post build phase. This would allow our vertex and index data to reside in optimal memory using an optimal format for the driver. In the next section, we will discuss the rendering system we finally wound up implementing, which provided much better performance than the previous systems.

15.2 The CBaseTree Rendering System

The CBaseTree rendering system is not as complicated as it may first seem when looking at the code. Unfortunately, the code is made significantly less trivial by the fact that multiple vertex buffers may have to be used if the vertex count of the static scene exceeds the maximum vertex buffer size supported by the hardware. This necessitates the introduction of an additional level of structures that makes things a little difficult to follow at first. Because this reduces clarity of what is essentially a rather simple system, we will first discuss the system with this complication removed. That is, we will discuss this system assuming that we can use an infinitely large vertex buffer and as such, all the static geometry in the tree can always be contained within it. Once we understand the system, we will discuss how it needs to be adapted to cope with multiple vertex buffers.

The system operates in three stages much like the previous method we discussed. The first is executed only once when the tree is first built. It is this component that copies the vertex data of every leaf into a tree owned vertex buffer and the indices of every polygon into static index buffers (one for each subset). You will recall from our previous lesson that prior to the Build function of a derived class returning, it makes a call to the CBaseTree::PostBuild method to calculate the bounding boxes for CPolygons in the tree. This method also issues a call to a new CBaseTree member called BuildRenderData as shown below.

```
bool CBaseTree::PostBuild(  )
{
    // Calculate the polygon bounding boxes
    CalculatePolyBounds( );

    // Build the render data
    return BuildRenderData( );
}
```

It is the CBaseTree::BuildRenderData method that will build the static vertex buffer containing all the vertices of the tree's static geometry. It will also create an index buffer for each subset used by the tree and store the indices of each triangle in these buffers in leaf order. Let us discuss how our system will work and what processing this initial stage will have to perform.

This function will create a static vertex buffer to contain the vertex data and N static index buffers, where N is the number of attributes used by the static tree geometry. It will then loop through each leaf in the tree. For each leaf it is currently processing it will loop through all the CPolygon structures stored there. For each polygon, it will add its vertices to the vertex buffer and will test the attribute ID of the polygon so that its indices are generated and added to the correct index buffer. For example, if we are processing a polygon that uses attribute 4, we will add its vertices to the vertex buffer and then generate the indices for each triangle in the polygon based on the position it has been placed within the vertex buffer. Once we have the indices generated for each of its triangles we will add them to the fifth index buffer (index buffer 4) since this is the index buffer that will contain the indices of all triangles that use attribute 4.

The next bit is vitally important. When we add the indices of each polygon in the leaf to their respective index buffers, we will store (in the leaf) the first index where the triangles for this leaf start in each index buffer it uses. For example, if we are processing a leaf and we find that there are 6 triangles that use subset 2, we will add the indices of those six triangles to index buffer [1] and the leaf will be given the index where its indices begin in that index buffer and the number of primitives it contains for that leaf. As we process each leaf, we know for example that for a given subset that has polygons in leaf A, all of leaf A's indices will be added to that subset's associated index buffer in a continuous block. Going back to our previous example, if we find that a leaf has 6 triangles that use attribute 2 and the index buffer already contains 100 indices that were added when processing other leaves, the leaf will keep track of the fact that for subset 2, its polygons start at index 100 and the next 6 triangles from that point in this index buffer are its primitives. We will see why this is important in a moment.

Therefore, after this process is complete, if a given leaf contains polygons that use 4 subsets for example, that leaf will store an array of four RenderData structures (one for each subset it contains). Each RenderData structure contains the index at which this leaf's indices begin for a given subset in the associated index buffer and the number of triangles in that subset contained in the leaf. Thus, each RenderData structure stored in the leaf describes an index buffer range for a given subset. If the RenderData item stored in a leaf has an attribute ID of 5, it will describe a block of indices in the 6th index buffer (the static index buffer for triangles of subset 5) where this leaf's triangles start and end. We know then that if this leaf is visible, this section of that index buffer will need to be rendered.

We will also introduce a new class called CLeafBin. CLeafBin is really a wrapper class around an index buffer for a given subset containing methods to render its index buffer efficiently. As we need to run the collection of our render data as fast as possible, each RenderData item stored in a leaf will also store a pointer to the leaf bin for which it is associated. This way, during the traversal, when a visible leaf is found, for each RenderData structure stored (one for each subset contained in that leaf) in the leaf we can access the pointer to the associated leaf bin and inform it of a range in its index buffer that will need to be rendered.

Figure 15.1 shows a simplified diagram of the rendering system. In this example we will assume the tree contains only four leaves and uses only three attributes (the texture images describe the attributes). Study the image and then we will discuss its components.

In this example the tree contains only four leaves and these leaves can be seen in the top left corner of the image. Leaves 1 through 3 contain polygon data from two different subsets and leaf 4 contains polygon data from only one. The line dividing leaves 1 through 3 down their center is being used to indicate that these leaves have two RenderData structures because these leaves contain polygons from two different subsets. The fourth leaf contains polygon data from only the second subset and as such contains only one RenderData structure. At the bottom of the image we can see that as the tree's polygon data uses only three subsets, we allocate three leaf bins. Each leaf bin contains the static index buffer that will contain the indices of all the triangles in the tree that use that subset. Just like the tree's vertex buffer, these index buffers will also be populated just once after the tree has first been built. Do not worry about what the RenderBatch structures in each leaf bin are for at the moment; we will see how these will be used a little later to collect runs of visible triangles during the visibility determination process.

When the tree is first compiled, the leaf bin index buffers and the tree's vertex buffer will be empty. At this point, no leaves will contain RenderData structures. It is the job of the CBaseTree::BuildRenderData function to allocate these structures and populate the index buffers of each leaf bin and the vertex buffer of the spatial tree with data.

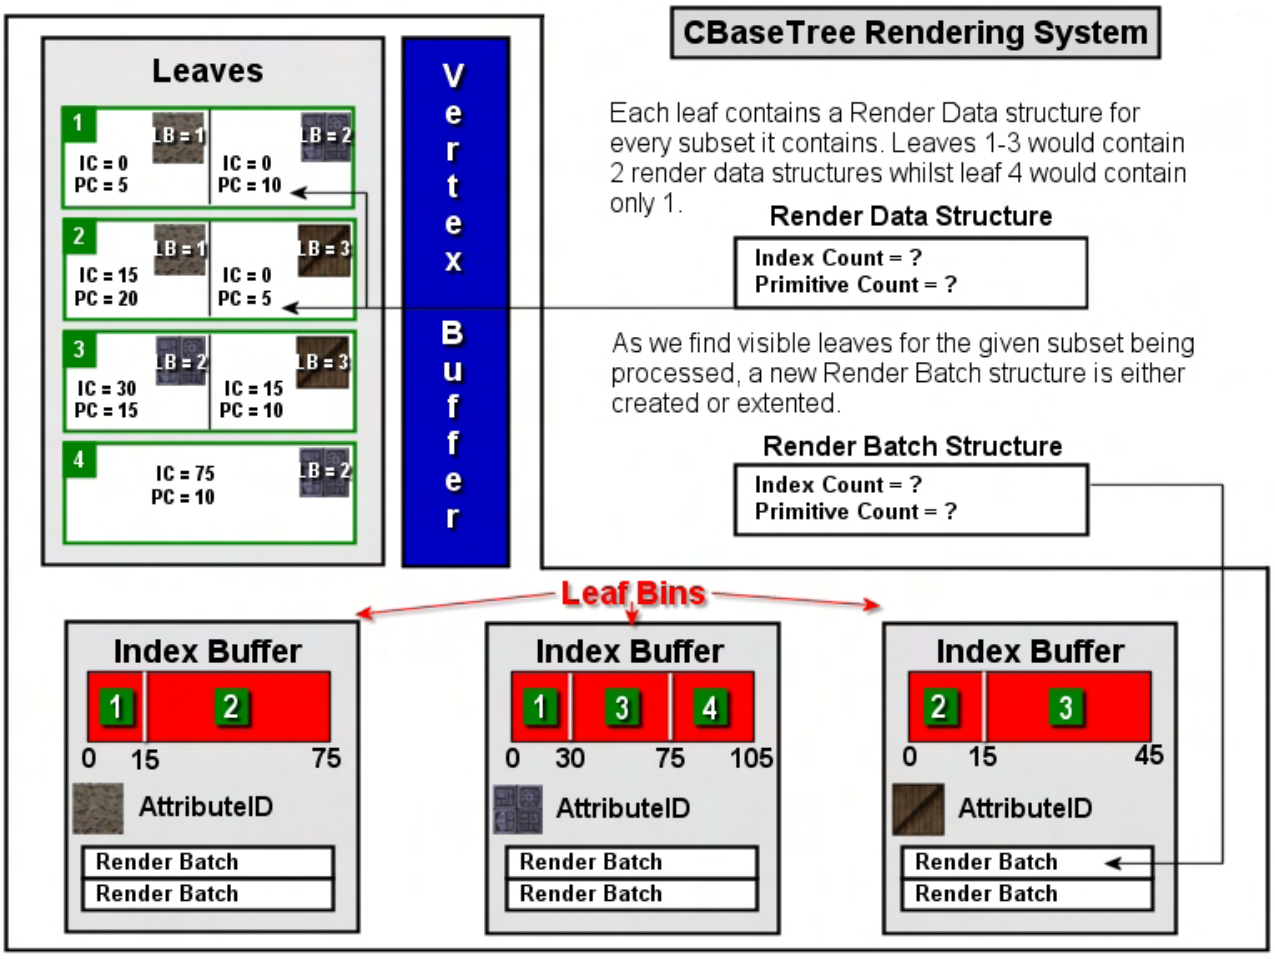


Figure 15.1

When the BuildRenderData function is first called, let us assume that it processes leaf 1 first. As it loops through each polygon, it finds that it contains 5 triangles that use subset 1 (the brick texture). It knows that it has to add the vertices of each of these triangles to the vertex buffer and the indices of each triangle (15 indices in total) to the index buffer stored in leaf bin 1 (the leaf bin associated with the first subset). It then notices as it adds these 15 indices to the index buffer that there are currently no indices in this index buffer. This means that this leaf's indices for subset 1 will be stored at the beginning of the index buffer contained in leaf bin 1. A new RenderData structure is allocated and added to the leaf which contains the subset ID of the leaf bin this data has been added to, the index into the index buffer of this leaf bin where the leaf's indices begin, and the number of triangles it has added to this index buffer. We can see if we look at the left half of leaf 1 in the diagram that its RenderData structure for leaf bin 1 contains an index count of 0, which describes where this leaf's subset 1 polygons begin in leaf bin 1 index buffer. It also contains a primitive count of 5. If we look at leaf bin 1, we can see that all 15 indices for the 5 triangles in leaf 1 have been stored at the beginning leaf 1's index buffer, exactly as described by the leaf's RenderData structure for this leaf bin.

Next we find that leaf 1 also contains 10 triangles which use subset 2. The vertices of each of these triangles are added to the vertex buffer and the indices of each vertex in the leaf that uses this subset are

generated and added to the index buffer of leaf bin 2. We are assuming in this example that these polygons are all triangles and as such this would add 30 indices to the index buffer in leaf bin 2. Once again, we create a new RenderData structure and store in it the leaf. This second RenderData structure will contain the leaf's information for leaf bin 2. We also notice that as this is the first time this subset has been encountered, there are currently no indices in the index buffer of leaf bin 2, so the RenderData structure for this leaf bin will store an index count of 0 and a primitive count of 10. At this point, leaf 1 has been processed. We know that it contains a RenderData structure for each subset it uses and each of these structures describes where its triangles exist in the associated leaf bin's index buffer. We can see for example that if this leaf is visible, when the application calls ISpatialTree::DrawSubset and passes in a subset ID of 1, we must make sure that the 5 triangles described by the first 15 indices in leaf bin 1's index buffer are rendered since these contain the triangles in leaf 1 for this subset. Likewise, when the application calls the DrawSubset method again to ask the tree to render subset 2, we know that if leaf 1 is visible, we must render the first 30 indices in leaf bin 2's index buffer.

We then move on to leaf two where we find 20 triangles that use subset 1 and 5 triangles that use subset 3. We add the vertices of each triangle to the vertex buffer and generate the indices for each triangle so that they correctly index into that vertex buffer. The 60 indices generated for the 20 triangles that belong to subset 1 are added to leaf bin 1's index buffer and a new RenderData structure is created and linked to this leaf bin via an attribute ID. Because there are already 15 indices in this index buffer, we know that the 60 indices for leaf 2's triangles must start at index 15 in leaf bin 1's index buffer. Therefore, we store an index count of 15 and a primitive count of 20 in this leaf's RenderData structure. This structure now tells us that the indices for the subset 1 triangles stored in this leaf begin at position 15 in leaf bin 1's index buffer and that there are 20 of them. We then process the other polygons in leaf 2 which in this example use subset 3. As this leaf bin has not yet had any data added to its index buffer, we know that it was empty before we added our indices for this leaf and therefore, a new RenderData structure is allocated and linked to this leaf bin via the subset ID. The index count of this structure is set to 0 as this leaf's indices for subset 3 polygons start at the beginning of this index buffer, and the primitive count is set to 5. The two RenderData structures stored in leaf 2 tell us that it contains polygons from two subsets, subsets 1 and 3. The indices of the triangles in this leaf that use subset 1 begin at index 15 in leaf bin 1's index buffer and there are 20 of them. We know that we can render this block of triangles if this leaf is visible. The second RenderData structure in leaf 2 tells us that this leaf also contains 5 triangles from subset 3 that start at position 0 in leaf bin 3's index buffer.

After this process has been repeated for all polygons in all leaves we will have the following:

- A static vertex buffer containing the vertices of all triangles in the tree.
- A Leaf Bin for every subset used by the tree's static data. Each leaf bin contains a static index buffer containing the indices of the tree's polygon data assigned to this subset.
- Each leaf will contain a RenderData structure for every subset its polygons use.
- Each RenderData structure stored in a leaf will describe where that leaf's indices start in its associated leaf bin and the number of triangles stored there (starting at that index).

If you refer back to Figure 15.1 you should be able to see how the index counts are calculated for each RenderData structure in each leaf. We can see for example leaf 4 contains only triangles that use subset 3. The indices of these triangles start at position 75 in the index buffer of leaf bin 2 and there are 10 triangles * 3 indices = 30 of them. The reason this leaf's indices start at 75 in leaf bin 2's index buffer is

that leaf 1 added 5*3=30 indices to this buffer first, followed by leaf 3 which added a further 15*3=45, taking the number of indices stored in this buffer up to 75 prior to leaf 4 being processed.

If you examine the contents of the three leaf bins in Figure 15.1 this should further clarify the relationship. At the end of the render data building process in this example, leaf bin 1 would contain 75 indices. The first 15 would describe the 5 triangles in leaf 1 which should be rendered if leaf 1 is deemed visible during the visibility processing pass. The indices from 15 to 75 describe the 20 triangles added to this index buffer from leaf 2. Therefore, we know that if leaf 2 is visible, indices 15 through 75 in leaf bin 1 should be rendered (when DrawSubset is called and passed a subset ID of 1). Furthermore, we can see that the RenderData structures in leaves 1 and 2 linked to this leaf bin describe these index ranges.

If we look at leaf bin 2 we can see that its index buffer contains triangles from three leaves and therefore, three leaves will contain RenderData structures linked to this leaf bin. Leaf 1 has added 30 indices to the beginning of this leaf bin to describe its 10 triangles that use subset 2. Leaf 3 also added 45 indices to this index buffer (starting at position 30) which describes its 15 triangles that use this subset. Finally, we can see that leaf 4 added a further 30 indices to this leaf bin describing the 10 triangles that it contains that belong to subset 2. Before continuing, study the diagram and make sure you understand the relationship between the leaf bins and the RenderData structures stored in each leaf.

The process described above is all performed by the CBaseTree::BuildRenderData method. This function is called once the tree is compiled and it builds and populates the RenderData structures stored at each leaf, the leaf bins for each subset, and the global vertex buffer that the index buffers in all leaf bins index into. The logical next question is, with this static data at our disposal, how do we efficiently collect and process it during the ISpatialTree::ProcessVisiblity call in a way that it can be efficiently rendered during a call to the ISpatialTree::DrawSubset method?

15.2.1 Render Batches

The heart of the rendering system lies in the leaf bin's ability to dynamically generate and store RenderBatch structures every time a visibility pass is performed on the tree (via a call to the ProcessVisibility function). A render batch essentially describes a list of triangles in a given leaf bin which are visible and stored consecutively in its index buffer. We can see in Figure 15.1 that render batch structures are generated and stored in the leaf bins (this takes place during the visibility pass). Each RenderBatch structure will describe a single call to the IDirect3DDevice9::DrawIndexedPrimitive method. Let us just take a look at that method to refresh our memory about its parameters. We will then be able to more easily see why a single RenderBatch structure represents a single call to this function.

```
HRESULT DrawIndexedPrimitive
(
    D3DPRIMITIVETYPE Type,
    INT BaseVertexIndex,
    UINT MinIndex,
    UINT NumVertices,
    UINT StartIndex,
    UINT PrimitiveCount
);
```

The important parameters to focus on, at least with respect to the current topic being discussed, are the last two. We pass in the location of the first index of a block of triangles we wish to render as the StartIndex parameter. The last parameter describes how many triangles (starting at StartIndex) we would like to render. Therefore, every time we call this method to render a series of triangles, the indices of those triangles must be consecutively ordered in the index buffer. For example, if we have an index buffer and we wish to render triangles 0 to 10 and triangles 40 to 50, we will have to issue two calls to this method, as shown below.

```
pDevice->DrawIndexedPrimitive( D3DPT_TRIANGLELIST,
                               0,
                               0,
                               NumOfVertices,
                               0,
                               10 );

pDevice->DrawIndexedPrimitive( D3DPT_TRIANGLELIST,
                               0,
                               0,
                               NumOfVertices,
                               120,            // 40*3
                               10 );
```

In the above example, NumOfVertices is assumed to contain the number of vertices in the vertex buffer bound to the device for these calls.

What is apparent by looking at the above example is that because our vertex and index buffers are static, when collecting the indices that need to be rendered from each visible leaf, we will not be able to render the triangles from multiple visible leaves with a single draw call unless these indices have been added to the index buffers of each leaf bin such that their indices follow on consecutively in the index buffer. Therefore the job of the leaf bins during a visibility pass will be to allocate RenderBatch structures to try to maximize the number of primitives that can be rendered in a single batch by detecting adjacent runs of visible triangles in the index buffer from different leaves. This will minimize the number of draw calls that will need to be made.

A RenderBatch structure is a very simple structure at its core that simply stores a start index and a primitive count as shown below. Essentially, each RenderBatch structure just represents a block of adjacent triangles in the index buffer that are currently considered visible and can be rendered via a single draw call.

```
struct RenderBatch
{
    ulong IndexCount;
    ulong PrimitiveCount;
};
```

To understand how it works, let us go back to the example tree illustrated in Figure 15.1 and assume for now that all four leaves are visible and that all the render data has been constructed as previously described. When the ProcessVisibility function is called by the application to determine leaf visibility,

the first thing it does is clear each leaf bin's RenderBatch list. That is because the job of the visibility pass will be to construct a list of render batch structures which can be executed to render the visible data.

The ProcessVisibility method will traverse the hierarchy searching for visible leaves. When a leaf is encountered which is visible, it will loop through each RenderData structure stored in that leaf. Remember, the number of RenderData structures stored in the leaf will be equal to the number of attributes/subsets used by the polygons in that leaf. Each RenderData structure would also store a pointer to the leaf bin to which it is assigned.

In the above example we would visit leaf 1 first and would determine that it is visible. We would then loop through the number of RenderData structures stored there, which in this example would be two. The first RenderData structure describes the index start and primitive count of all the triangles in leaf 1 that are stored in leaf bin 1. Therefore, we would call the leaf bin's AddVisibleData method, passing it the index count of the RenderData item and the number of primitives (shown in the following pseudo code). That is, we are informing the leaf bin of a run of visible triangles in its index buffer.

```
if (pLeaf->IsVisible)
{
   // Loop through each Render Data structure in this leaf
   for ( i = 0; i < pLeaf->RenderDataCount; i++  )
   {
       // Get current Render Data structure
       pRenderData = pLeaf->RenderData[i];

       // Fetch the leaf bin this Render Data structure is linked to
       pLeafBin = pRenderData.LeafBin;

       // Pass the index start location and primitive count into leaf bin
       pLeafBin->AddVisibleData( pRenderData->IndexCount ,
                                 pRenderData->PrimitiveCount );
   }
}
```

The above code essentially describes the visibility determination process. For each leaf we loop through the number of render data structures stored there. We fetch each one and retrieve a pointer to the leaf bin that this structure is defined for. We then pass in the index count and primitive count members of the render data item into the leaf bin so that it knows this block of triangles needs to be rendered.

Of course, it is the leaf bin's AddVisibleData method which is responsible for either creating a new render batch or adding the passed triangle run to a render batch that has been previously created. The latter can only be done if the value of IndexCount passed into the function carries on consecutively from the indices of the last visible leaf that was visited and added to that render batch. The following code snippet shows what the basic responsibility of this function will be.

In this code, certain member variables of CLeafBin are assumed to exist. There is assumed to be an un-initialized array of RenderBatch structures large enough to store the maximum number of render batches that could be created during a visibility pass for a given subset. This allows us to avoid the need to resize the RenderBatch array of the leaf bin every time it needs to have more elements added or emptied at the start of a new visibility pass. We simply reset the leaf bin's m_nBatchCount member to zero at the

beginning of each visibility pass and increment it each time a new render batch needs to be created. A new render batch only needs to be created if the block of triangles described by the input parameters to the function does not follow on from those stored in the current render batch being compiled. Look at the code first and then we will discuss its basic operation. Understanding this logic is vitally important as it is the key collection process in our rendering system. It is our means of rendering as many consecutively arranged triangles in a single draw call as possible.

```
void CLeafBin::AddVisibleData( unsigned long IndexStart,
                               unsigned long PrimitiveCount )
{

    ULONG LastIndexStart      = m_nLastIndexStart,
          LastPrimitiveCount  = m_nLastPrimitiveCount;

    // Build up batch lists
    if ( LastPrimitiveCount == 0 )
    {
        // We don't have any data yet so just store initial values
        LastIndexStart     = IndexStart;
        LastPrimitiveCount = PrimitiveCount;

    } // End if no data
    else
    if ( IndexStart == (LastIndexStart + (LastPrimitiveCount * 3)) )
    {
        // The specified primitives were in consecutive order,
        // so grow the primitive count of the current render batch
        LastPrimitiveCount += PrimitiveCount;

    } // End if consecutive primitives
    else
    {
        // Store any previous data for rendering
        m_pRenderBatches[pData->m_nBatchCount].IndexStart     = LastIndexStart;
        m_pRenderBatches[pData->m_nBatchCount].PrimitiveCount = LastPrimitiveCount;
        m_nBatchCount++;

        // Start the new list
        LastIndexStart     = IndexStart;
        LastPrimitiveCount = PrimitiveCount;
    } // End if new batch

    // Store the updated values
    m_nLastIndexStart     = LastIndexStart;
    m_nLastPrimitiveCount = LastPrimitiveCount;
}
```

The leaf bin object is assumed to have member variables that are used temporarily by the visibility pass to track the last index start and primitive count passed into the function. These will be set to zero at the start of the visibility determination process for a given frame. At the end of the function the parameters passed in are stored in these member variables so that they are accessible to us when the next visible leaf is encountered and this method is called again. These variables represent our means of determining whether the index start parameter passed in describes the start of a run of triangles that follows on

consecutively from the data that was added to the render batch in the previous call. If so, these triangles can be added to the current render batch simply by incrementing the primitive count of the render batch currently being compiled. Otherwise, the new triangles we wish to add do not follow on consecutively in the leaf bin's index buffer, so we will need to end our current batch and start compiling a new render batch. Let us analyze the above function a few lines at a time so that we are sure we really understand how it works.

This function is called from a visible leaf when processing its render data structures. For example, if the RenderData structure for a visible leaf is linked to leaf bin 1, then the index count and primitive count stored in that structure are passed into the AddVisibleData method of the relevant leaf bin during the visibility pass for the tree. We are essentially informing the leaf bin that the current leaf has triangle data which is relevant to the leaf bin's attribute ID and should therefore be rendered.

```
void CLeafBin::AddVisibleData( unsigned long IndexStart,
                               unsigned long PrimitiveCount )
{

    ULONG LastIndexStart      = m_nLastIndexStart,
          LastPrimitiveCount  = m_nLastPrimitiveCount;
```

The IndexStart parameter will contain the position in the leaf bin's index buffer where this leaf's triangles begin and the primitive count will describe the number of triangles (starting from the IndexStart parameter) in the leaf bin's index buffer that belong to the calling leaf.

The first thing we do in the above code is fetch the LastIndexStart and LastPrimitiveCount members into local variables. These will both be set to zero at the start of the visibility pass and as such, will be zero when this function is first called when the first visible leaf is encountered for a given leaf bin. If these are zero, then it means we have not yet created any render batch structures in this visibility pass and this is the first time the function has been called. If this is the case, we simply store the passed index start and primitive count in the LastIndexStart and LastPrimitiveCount members. We are essentially starting a new batch collection process. At the bottom of this function we will then store these values in the m_nLastIndexCount and the m_nLastPrimitiveCount members so that when the next leaf which is found to be visible sends its data into this function, we have access to the information about the batch we are currently compiling. No other action is taken if this is the first time this function has been called for a given visibility pass, as shown in the following conditional code block.

```
    // Build up batch lists
    if ( LastPrimitiveCount == 0 )
    {
        // We don't have any data yet so just store initial values
        LastIndexStart     = IndexStart;
        LastPrimitiveCount = PrimitiveCount;
    } // End if no data
```

However, if LastPrimitiveCount does not equal zero then it means this is not the first time this method has been called for this leaf bin during the current visibility pass. In other words, this is not the first visible leaf that has been encountered that contains triangle data for this subset. If this is the case, then LastIndexStart will contain the location of the index that starts a consecutive run of triangles we are

currently collecting and LastPrimitiveCount will contain the number of triangles we have collected in the adjacent run so far. If the index start that has been passed into the function is equal to that of the start of the current batch we are building (LastIndexStart) plus the number of adjacent indices we have collected for this run so far (LastPrimitiveCount), it means the triangles of the leaf that called this method are arranged in the leaf bin's index buffer such that they continue the adjacent run of triangles we are currently trying to collect (i.e., the current batch we are compiling). When this is the case, we can simply increase the current primitive count for the current batch.

```
    else
    if ( IndexStart == (LastIndexStart + (LastPrimitiveCount * 3)) )
    {
        // The specified primitives were in consecutive order,
        // so grow the primitive count of the current render batch
        LastPrimitiveCount += PrimitiveCount;

    } // End if consecutive primitives
```

Finally, if none of the above cases are true it means that the index start passed in describes the location of a run of triangles for the leaf that does not exist immediately after the run of triangles we have compiled for the current batch. Thus, we have reached the end of a run of triangles that can be rendered in one batch. At this point, LastIndexStart and LastPrimitiveCount (with their values set in the previous call) will contain the start index and primitive count of a block of adjacent triangles that were being collected up until this call and therefore describe a block of triangles that can be rendered. We can add no more triangles to this batch. The current leaf data that was passed into this function cannot be added to this batch, so the previous index start and the primitive count collected so far are stored in a new RenderBatch structure, added to the leaf bin's RenderBatch array, and the number of render batches is increased. The LastIndexStart and LastPrimitiveCount members are then set to those values that were passed into the function, thus beginning a new cycle of trying to collect adjacent runs for a new batch. The remainder of the logic is shown below.

```
    else
    {
        // Store any previous data for rendering
        m_pRenderBatches[pData->m_nBatchCount].IndexStart     = LastIndexStart;
        m_pRenderBatches[pData->m_nBatchCount].PrimitiveCount = LastPrimitiveCount;
        m_nBatchCount++;

        // Start the new list
        LastIndexStart     = IndexStart;
        LastPrimitiveCount = PrimitiveCount;
    } // End if new batch

    // Store the updated values
    m_nLastIndexStart     = LastIndexStart;
    m_nLastPrimitiveCount = LastPrimitiveCount;
}
```

Understanding this process of collecting render batches is easier if we use some examples. Figure 15.2 shows the example arrangement we discussed earlier. We will now discuss the visibility processing step

performed when ProcessVisibility is called. In this example we will assume that all leaves except leaf 3 are visible. Just remember that no render batches exist in any leaf bins at the start of a visibility pass.

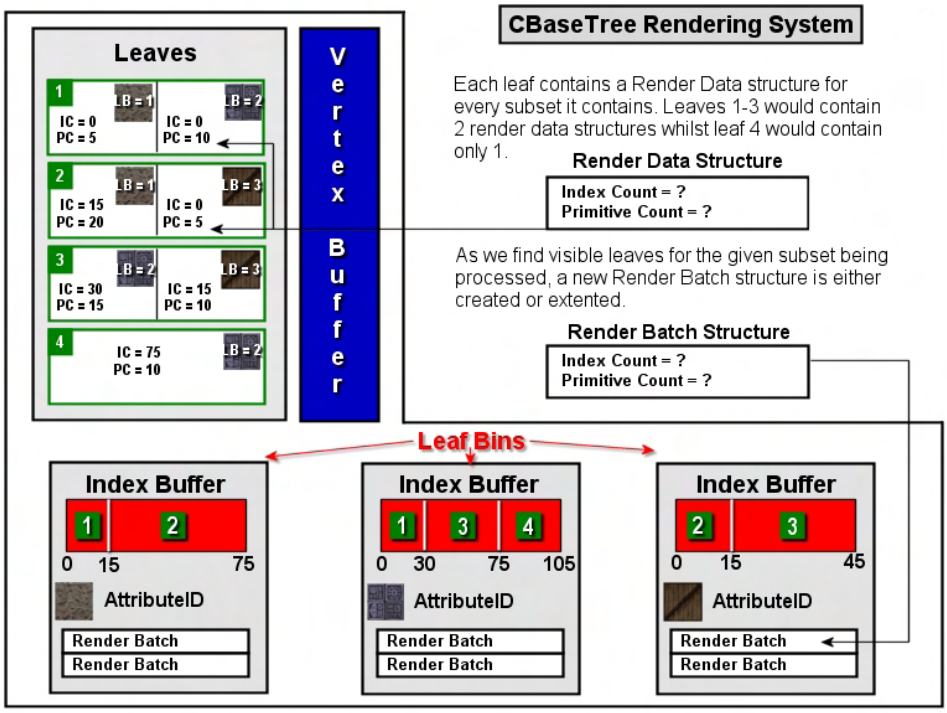

Figure 15.2

Leaf 1 is visited first and its first render data structure is processed. As this describes triangles that are contained in leaf bin 1, this leaf bin's AddVisibleData method is called and passed an index start of 0 and a primitive count of 5. As leaf bin 1 has not yet had this method called for any other leaf during the current visibility pass, we simply store 0 and 5 in its LastIndexStart and LastPrimitiveCount members. We then process the second render data structure in this leaf for leaf bin 2 and call its AddVisibleData method as well. An index start value of 0 is passed and a primitive count of 10 is passed. Since this is the first time leaf bin 2's AddVisibleData method has been called, the same thing happens. We simply store the passed index start and primitive count values in the LastIndexStart and LastPrimitiveCount members. At this point, no render batches have been created in any leaf bin, but in leaf bins 1 and 2, we have started compiling a batch.

Next we find that leaf 2 is visible, so we process its two render data structures. The first one is for leaf bin 1 again, so its AddVisibleData method is called and passed an index start of 15 and a primitive count of 20. However, this time when the method is called we detect that the index start passed in 15, is equal to the LastIndexStart value recorded (0) plus the last primitive count recorded (5) multiplied by 3. Therefore, we know that the triangles of leaf 2 stored in this leaf bin's index buffer follow on exactly from the triangles of leaf 1 that were passed in the previous call to this function. In this case, we can simply leave the LastIndexStart value of the leaf bin at its previous value (0) (which describes the starting location for the batch we are compiling) and increase the LastPrimitiveCount by the primitive count passed in. The value of LastPrimitiveCount is therefore increased from 5 (leaf 1's triangles) to 25 (adding leaf 2's 20 triangles). The current batch we are compiling now describes 25 triangles that can be rendered with a single draw call.

At this point in the discussion we will skip ahead to the end of the process as we can see that no further visible leaves exist that contain triangle data for this leaf bin. Therefore, at the end of the process we will simply create a single render batch for leaf bin 1 that has an index start of 0 and a primitive count of 25.

This render batch can be rendered with a single DrawIndexedPrimitive call and we can see that we have been able to merge the triangles from leaf 1 and leaf 2 that use this subset into a single render batch. Later, when the application calls ISpatialTree::DrawSubset and passes in the subset ID assigned to the first leaf bin, we can simply extract the index start and primitive count values from the leaf bin's only render batch and pass them as parameters to the DrawIndexedPrimitive call. This system of collecting adjacent runs into render batches allows us to lower the number of draw calls that will have to be made to render the triangles of a single leaf bin by consolidating adjacent runs into render batch instructions. Let us now continue with our example so that we can see where and why multiple render batches will sometimes need to be created for a given leaf bin.

When we left off in our example, we had just processed the first render data structure in leaf 2. When we process the second render data structure in this leaf (for leaf bin 3) we call leaf bin 3's AddVisibleData method and pass in an index start of 0 and a primitive count of 5. As this is the first leaf we have encountered that has data for leaf bin 3, this method simply copies the values of the past index start and primitive count parameters into leaf bin 3's LastIndexStart and LastPrimitiveCount members, thus starting the compilation of a new render batch..

Now we get to leaf 3 and determine that it is outside the frustum and therefore not visible. So we can skip it and its triangle data is never added to any leaf bins. We can once again skip ahead to the end of the process and see that in this instance, leaf bin 3 will have a single render batch generated for it with an index start of 0 and a primitive count of 5.

Finally, we get to the next visible leaf (leaf 4). This leaf contains 10 triangles that are stored in leaf bin 2 starting at location 75 in the index buffer. Therefore, we pass the values of 75 and 10 into leaf bin 4's AddVisibleData function. Now for the important part!

Leaf bin 2 has already been called during this visibility pass when leaf 1 was processed. Leaf 1 passed in a primitive count of 10 and a starting index 0. Therefore, the LastIndexStart member in this leaf bin will currently hold a value of 0 and the LastPrimitiveCount member will currently hold 10. We can see just by looking at the index buffer for leaf bin 2 in Figure 15.2 that leaf 4's triangles do not follow on from leaf 1's triangles. Leaf 3's triangles are inserted between them, but these triangles are not to be rendered because leaf 3 is not visible. In the code we just showed, we tested if the passed index start value described a consecutive run by testing to see if multiplying LastPrimitiveCount by 3 and adding it to LastIndexStart was equal to the index start value passed in. If they are the same, then the triangles we pass in continue on from those last added to the current batch we are compiling. Let us just perform a dry run of the function code shown above to make sure that this is definitely not considered an adjacent run:

```
if ( IndexStart == LastIndexStart + (LastPrimitiveCount * 3) ) )
{
  Increase LastPrimitiveCount
}
```

When this function is called by leaf 4, a value of 75 will be passed as the IndexStart parameter since this is where this leaf's triangles start in the index buffer for leaf bin 2. Furthermore, LastIndexStart will currently be set to 0 and LastPrimitiveCount will currently be set to 10 (leaf 1's primitive count) so this equates to the following test:

```
if ( 75 == 0 + (5 * 3)) )
{
  Increase LastPrimitiveCount
}
```

This equates to:-

```
if ( 75 == 15 )
{
  Increase LastPrimitiveCount
}
```

Clearly we can see that the above condition is not true and the triangles in leaf 4 cannot be rendered in the same draw call as those already collected from leaf 1. Therefore, the current value of LastIndexStart and LastPrimitiveCount will be stored as a new render batch in leaf bin 2 and LastIndexStart and LastPrimitiveCount will be set to the values stored in leaf 4's render data structure. When the process is over, these will also be added as a new render batch so that when visibility processing is complete, leaf bin 1 will have one render batch which renders the triangles from leaves 1 and 2 in a single draw call. Leaf bin 2 will have two render batches. One will render the triangles from leaf 1 and the other will render the triangles from leaf 4. This will have to be done with two separate draw calls. Leaf bin 3 will also contain a single render batch describing the triangles from leaf 2 that are visible and can be rendered with a single draw call.

Although this is a simple example, it is easy to imagine that during the tree traversal we will find many leaves that are visible and that have their triangle data arranged consecutively in the index buffers of the leaf bins to which they pertain. When such cases occur, we can render the triangles from multiple leaves with a single draw call instead of having to issue a DrawIndexedPrimitive call for each visible leaf that contains renderable data.

One thing that is immediately obvious about this system is that its success is dependant on the order in which we add the indices to the index buffer of each leaf bin during the BuildRenderData method. We can see in Figure 15.2 for example that because we process each leaf in the tree and add their indices to each leaf bin in the same order that we traversed those leaves during the visibility pass, we maximize the chance of collecting adjacent runs of triangles in multiple leaves. If we added leaf 2 to the index buffer first, followed by leaves 4, 3 and 1 (in that order) but still traversed the tree during the visibility pass in the 1,2,3,4 leaf order, we would get no adjacent runs and would end up having to perform a draw call for each leaf. That is, the number of render batches stored in each leaf bin would be equal to the number of leaves that contain polygons that use that leaf bin's attribute. This could be a very costly number of draw calls if every leaf was visible.

Luckily, we know that if every leaf is visible then our traversal methods will traverse that tree in the same order every time. Therefore, in the BuildRenderData method, one of the first things we will do is feed the entire scene's bounding box into the CollectLeavesAABB method. As we have passed the scene's bounding box to this function which encompasses all child leaves, the entire tree will be traversed and a list of all the leaves returned. However, the CollectLeavesAABB method would have added the leaves to the passed leaf list in the order in which the tree is traversed. That is, if the entire scene is visible during the ProcessVisibility call, this is the exact order in which the leaves will be

visited. Therefore, we will populate the leaf bins in that order by simply iterating through the leaf list returned from CollectLeavesAABB so that the indices of a leaf in the index buffer follow the indices of the previous leaf that will be visited during the traversal. In the case where the entire scene is visible, we will be adding visible data to each leaf bin's render batch system in the exact order that they are stored in the leaf bin's index buffer during the build phase. In this scenario, each leaf bin would create only one render batch that describes all the triangles stored in its index buffer. This means in the case where everything is visible, the number of draw calls will be reduced to the number of subsets/leaf bins in use by the tree.

Of course, when only some of the tree is visible there will be entire branches of the tree that are rejected from being further traversed and therefore, this will essentially end the render batch currently being compiled for each leaf. This is because the branch of the tree we have just rejected will describe a large section of the index buffer that we do not want to render and therefore ends any block of adjacent triangles we are trying to find. However, we at least know that if an entire branch of the tree is visible, because the visibility traversal order is the same order in which we added to the leaves to the index buffer of each leaf bin, all the leaves down that visible branch will be contained in the leaf bins as a continuous block of indices that can be represented as a single render batch and rendered with a single draw call.

15.2.2 Rendering the Tree

After the CBaseTree::ProcessVisibility call has been made by the application for a given frame update, the render batches for each leaf bin will have been constructed and will contain the triangles that need to be rendered for each leaf bin/subset. The application renders a given subset of the tree by calling the ISpatialTree::DrawSubset method. The code to such a function is shown below. Basically, it passes the drawing request on to the leaf bin's Render function. This is not the actual code from our lab project and all error checking has been removed. We only introduce it at this time to provide some insight into how the code will work. In the following function, the GetLeafBin method is exposed by CBaseTree and fetches the pointer to the leaf bin for the passed subset ID.

```
void CBaseTree::DrawSubset( unsigned long nAttribID )
{
    // Retrieve the applicable leaf bin for this attribute
    CLeafBin * pLeafBin = GetLeafBin( nAttribID );

    // Render the leaf bin
    pLeafBin->Render( m_pD3DDevice );
}
```

As the tree stores a leaf bin for each subset, this function simply fetches the leaf bin from its leaf bin array for the passed subset ID (attribute ID) and then issues a call to its Render function. Since the leaf bin has already compiled the render batches during the ProcessVisibility call, all it has to do is loop through each currently stored render batch and call the DrawIndexedPrimitive function to render the adjacent triangles described by each batch.

The code to such a function is shown below. Once again, this is not the actual code we will be using and it has had some error checking removed, but it does provide insight into the simple task assigned to the CLeafBin::Render method.

```
void CLeafBin::Render( LPDIRECT3DDEVICE9 pDevice )
{
    ULONG j;

    // Bin leaf bins index buffer to the device
    pDevice->SetIndices( pData->m_pIndexBuffer );

    // Render the leaves
    for ( j = 0; j < m_nBatchCount; ++j )
    {
          RenderBatch &Batch = m_pRenderBatches[j];

          // Render any data
          pDevice->DrawIndexedPrimitive( D3DPT_TRIANGLELIST,
                                         0,
                                         0,
                                         m_nVertexCount,
                                         Batch.IndexStart,
                                         Batch.PrimitiveCount );
    } // Next Batch
}
```

As you can see, this function is delightfully short and easy to follow. When the application requests that the tree render one of its subsets, we can see that it is really asking one of the leaf bins to render all of its visible triangles. The function first binds the leaf bin's index buffer to the device and then loops through each RenderBatch structure compiled during the ProcessVisibility pass for that leaf bin. For each render batch, it calls the DrawIndexedPrimitive method of the device passing in the start index and primitive count stored in the current render batch being processed. This describes the block of adjacent triangles in the index buffer represented by that render batch. In this example we will assume that m_nVertexCount is a member variable of CLeafBin and that it contains the number of vertices in the tree vertex buffer (i.e., the vertex buffer indexed into by all leaf bins).

Hopefully, you now see that our basic system is fairly logical and easy to understand. It is also fast because it allows us to work with static vertex and index buffers. Of course, this comes at the expense of potentially many more draw calls having to be issued than in the dynamic index buffer method, but it eliminates the abundance of memory copies that had to be performed to fill the dynamic index buffers during the visibility traversal. This proved to be more than a worthwhile tradeoff as our render batch system far outperformed the dynamic buffer approach in every test we ran.

15.2.3 Multiple Vertex Buffers

Thus far, we have been able to keep our system very simple with only a few structures needed to accomplish our goal. Essentially, we have leaves that contain information which describe their run of adjacent triangles in each leaf bin's index buffer, we have a leaf bin for each subset in use by the tree,

and we have RenderBatch structures that are built and collected in each leaf bin during a visibility pass. Finally, rendering a subset of the tree simply means asking the leaf bin associated with that subset to execute all its render batch instructions that were generated during the last visibility pass. Up until now we have assumed that all the vertices of all the polygons compiled into the tree can be stored in a single vertex buffer which is owned by the tree and indexed into by the single index buffer stored in each leaf bin. Unfortunately, vertex buffers cannot be of infinite size and furthermore, the maximum size of a vertex buffer which we can index into depends on the capabilities of the 3D device on which the application is running. One graphics card might be perfectly happy with using indices that reference vertices in a single buffer up to and beyond 16,000,000 (for example), while another card may insist on using vertex buffers containing less that 125,000. At the end of the day, we will need to make sure that the number of vertices we store in any vertex buffer is not greater than the maximum vertex index supported by the card. Therefore, if we find for example that we have 128,000 vertices comprising the static geometry of our spatial tree, but the system on which the application is currently running supports a maximum vertex buffer size of 64,000, we will have to store our 128,000 vertices in two vertex buffers (each holding 64,000). Each smaller vertex buffer is within the scope of the device's capabilities and as such, when we render the tree, we will have to render each vertex buffer (and their associated index buffers) separately.

This obviously has some ramifications for our system and forces us to add an additional layer of structures that we would rather not have to add. However, as we have discussed the system in the first part of this lesson without the multiple vertex buffer complication, adding it to our discussion now and discussing the changes that will have to be made will be much simpler to follow.

Because our tree may be using multiple vertex buffers to store its static geometry, we will have to make some fairly serious modifications to our system. First, during the BuildRenderData phase we will have to detect when the vertex buffer we are currently adding vertices to is full (i.e., it exceeds the maximum vertex indexing capabilities of the device) and create a new vertex buffer. To keep things simple, we will also create new index buffers for each leaf bin when this happens so that in each bin, we have separate index buffers for every vertex buffer being used by the tree. That is, if the tree is using five vertex buffers to store its geometry and a particular leaf bin contains triangles from each of these five vertex buffers, it will have five index buffers generated for it. So we will keep a logical pairing between vertex buffers and index buffers. We know when rendering the leaf bin that if it has five index buffers, we will have to loop through each, set the corresponding vertex and index buffers, and then render the triangles in that index buffer.

We will also need to know which vertex buffer a given leaf's RenderData structure is relative to. For example, we know that the RenderData structure in a leaf describes the index start and primitive count of one of its subsets. If its AttributeID is 2, this means it describes triangles in leaf bin 2. The problem is, leaf bin 2 may now have multiple index buffers, so we will need to store which index buffer / vertex buffer combination should be bound to the device in order to render the batch of triangles stored at that leaf. For example, we might imagine a case where leaf 1 has a RenderData structure that describes triangles in vertex buffer 1 and index buffer 1, but leaf 100's RenderData structure could contain exactly the same index start and primitive count values for the exact same subset but describe a run of adjacent triangles in the leaf bin's second vertex / index buffer pair. So we can see that each leaf's RenderData structure will have to store the numerical index of the vertex/index buffer pair that contains the vertices

of the triangles it describes. We might imagine at this stage then that the RenderData structure would look something like this:

```
struct RenderData
{
   unsigned long IndexCount;
   unsigned long PrimitiveCount
   unsigned long VBIndex;
   unsigned long AttributeID;
   CLeafBin     * pLeafBin;
}
```

Looking at this structure we can see that it contains not only the start index of where its indices start in the associated leaf bin's index buffer and the number of triangles stored there, but also contains the numerical index of the vertex buffer/index buffer combination that store the triangle data. We can see in this example how it might also contain the attribute ID which describes the subset/leaf bin this RenderData structure is associated with and a pointer to the leaf bin that stores triangles for this subset.

Storing the leaf bin pointer in the RenderData structure is very useful for speeding up the visibility process. When processing the RenderData structure for a given visible leaf, we have to pass its index count and primitive count into the leaf bin's AddVisibleData method so that it can be added to an existing render batch or used to start a new batch. By having this pointer stored in the data structure, we negate the need to search for the leaf bin with a matching attribute ID. We really need to make the tree traversal and visible polygon collection process as quick as possible, so we do not want to waste time looping through the leaf bin array finding the leaf bin the triangles in this RenderData structure should be added to. Therefore, we will find this during the building process and store the leaf bin's pointer in the RenderData structure for immediate access.

We can now see that the RenderData structure not only describes the number of triangles in a leaf bin and their location within the leaf bin's index buffer, it also describes to the leaf bin which vertex buffer should be bound to the device and which of the leaf bin's index buffers the triangle run is contained in. For example, if VBIndex were set to 3, this would inform the leaf bin that the vertices of these triangles are stored in the third vertex buffer in the tree's vertex buffer array and that its indices are stored in the leaf bin's third index buffer.

Unfortunately the provisions made here for the multiple vertex buffer case do not cover all scenarios we may encounter. For example, imagine the following situation during the BuildRenderData method:

We are currently visiting leaf 10 and we are processing the polygons in that leaf that use subset 6. Assume that there are 20 polygons in this leaf that use subset 6 and that up until this point we have been adding the vertex data to a single vertex buffer. Now imagine that as we add the first 10 triangles of this leaf's subset 6 polygons to the vertex buffer (and its indices to leaf bin 6's index buffer) we discover that we have filled up the vertex buffer. We have encountered a situation where we have to switch to a new vertex buffer (and create a new index buffer to go with it in leaf bin 6) halfway though processing the polygons for a single subset. Although this might happen only rarely, it is certainly possible that triangles from the same leaf that share the same subset are split over multiple buffers. In such a case, the RenderData structure should describe not only the vertex and index buffer to use for a given subset in

that leaf, but should describe all the vertex buffers/index buffers that contain subset 6 in that leaf. If we take this into account, we end up with a RenderData structure stored at each leaf that looks like so:

```
struct RenderElement
{
  unsigned long IndexStart;
  unsigned long PrimitiveCount
  unsigned long VBIndex;
};

struct RenderData
{
   RenderElement *pRenderElements;
   unsigned long ElementCount;
   unsigned long AttributeID;
   CLeafBin     * pLeafBin;
}
```

Let us stop and think about what information we are actually storing here. The RenderElement structure now stores the index count and primitive count for a single vertex/index buffer combination for a given subset. In the above example where the 20 polygons that used subset 6 in a leaf were spread over two vertex/index buffers, the RenderData structure in that leaf for subset 6 would contain two render elements in its array and would describe two runs of triangles in two of the leaf bin's index buffers. The VBIndex of the first would be 0 describing the first vertex buffer and the VBIndex of the second would be 1. When we reach a visible leaf during the visibility process, the leaf bin would now need to be passed the VBIndex of the render element alongside the index start index and primitive count of each element stored there. This is because, now that the leaf bin maintains an array of index buffers (one for each primary vertex buffer being used by the system), an array of RenderBatch lists will now need to be stored also. That is, the leaf bin will need to compile a render batch list for each vertex/index buffer pair in use by the leaf bin.

The following code shows what happens when a visible leaf is encountered during the ProcessVisibility call and the leaf's SetVisible function is called.

```
void CBaseLeaf::SetVisible( bool bVisible )
{
    ULONG                 i, j;
    RenderElement       * pElement;
    CLeafBin            * pLeafBin;
    RenderData          * pData;

    // Flag this as visible
    m_bVisible = bVisible;

    // If we're being marked as visible, inform the renderer
    if ( m_bVisible && m_nRenderDataCount > 0 )
    {
        // Loop through each renderable set in this leaf.
        for ( i = 0; i < m_nRenderDataCount; ++i )
        {
```

```
            pData    = &m_pRenderData[i];
            pLeafBin = pData->pLeafBin;

            // Loop through each element to render
            for ( j = 0; j < pData->ElementCount; ++j )
            {
                pElement = &pData->pElements[j];
                if ( pElement->PrimitiveCount == 0 ) continue;

                // Add this to the leaf bin
                pLeafBin->AddVisibleData( pElement->VBIndex,
                                          pElement->IndexStart,
                                          pElement->PrimitiveCount );
            } // Next Element

        } // Next RenderData Item

    } //  End if visible
}
```

The function first stores the passed visibility Boolean in the leaf's member variable which describes the leaf as either being visible or non visible. If the leaf has been flagged as visible then we need to add the triangles of every RenderData item stored there (one for each subset contained in the leaf) to their associated leaf bins. Notice how we loop through each RenderData structure stored in the leaf's array to add its data to its attached leaf bin. However, the triangles described by a single RenderData structure may be split over multiple vertex buffers (and multiple index buffers in the leaf bin). Therefore, for each RenderData structure we then loop through each RenderElement stored there. There will usually only be a single RenderElement structure stored in a RenderData structure. The exception to the rule occurs when, during the adding of this subset's polygon data to the vertex buffer, a new buffer had to be created such that the RenderData of a leaf for a given subset spanned vertex buffer boundaries. For each render element, we then call the leaf bin's AddVisibleData member. We looked at a single vertex buffer version of this function earlier, but let us now see how that function might look now that multiple lists of render batches will need to be maintained in the leaf bin for each vertex/index buffer pair.

Because the leaf bin no longer contains only a single index buffer and a single render batch list, we will need to introduce an additional structure in the leaf bin, which in this code is called CLeafBinData. This is a simple structure that pairs an index buffer with one of the tree's vertex buffers and stores its associated RenderBatch list during the visibility traversal. The CLeafBin class would now have just the following members (methods not shown):

```
class CLeafBin
{
    unsigned long  m_nAttribID;
    CLeafBinData **m_ppBinData;
    unsigned char  m_nVBCount;
};
```

The first member would describe the subset ID for which this leaf bin houses indices and compiles render batches for. The second is a pointer to an array of CLeafBinData objects. It is a CLeafBinData object that contains the pointers to an index buffer and vertex buffer pair and contains the RenderBatch

list for that buffer pair. As an example, if this leaf bin stored triangles for subset 6, and the vertices of polygons in the tree that use subset 6 are distributed across five vertex buffers, this leaf bin's m_nVBCount member would be set to 5 and would describe the number of elements in the CLeafBinData array. Each CLeafBinData structure then describes the index buffer and render batches used to render the triangles from those buffers.

The members of the CLeafBinData object would be as follows:

```
class CLeafBinData
{
   LPDIRECT3DVERTEXBUFFER9 m_pVertexBuffer;
   LPDIRECT3DINDEXBUFFER9  m_pIndexBuffer;
   unsigned long           m_nLastIndexStart;
   unsigned long           m_nLastPrimitiveCount;
   RenderBatch            *m_pRenderBatches;
   unsigned long           m_nBatchCount;
};
```

There is an important distinction to make between the vertex buffer pointer and the index buffer pointer in this structure. The vertex buffers are created and managed by the tree, not the leaf bins, so this is a pointer to a tree owned vertex buffer. There may be CLeafBinData items in multiple leaf bins that all point to this same vertex buffer as they all have triangles stored within it. The index buffers however are created and managed by the leaf bin and will not be shared by any other bins. That is, an index buffer contains the triangles for a specific leaf bin that are contained in a specific vertex buffer. Notice also that in our original discussion it was the leaf bin that managed the list of RenderBatch structures during the visibility pass. This is now stored in the CLeafBinData structure as we will need to compile render batch lists for each index/vertex buffer used by the bin. This is because we will have to execute the render batches for each index buffer only after we have bound it to the device along with its associated vertex buffer. Finally, the m_nLastPrimitiveCount and m_nLastIndexStart members have also been moved from the leaf bin into the CLeafBinData structure. These members were used during render batch building to remember the settings for the current batch being compiled between function calls. As we now have multiple index buffers in a single leaf bin, we will have to maintain multiple render batch lists and therefore, will need to store these 'm_nLast…' members on a per batch list basis.

We saw just a moment ago how the CBaseLeaf::SetVisible method calls the CLeafBin::AddVisibleData method to add the triangles of each RenderElement in each RenderData structure stored in the leaf. We had a look at a single vertex buffer version of this function earlier. Let us now see what it might look like with multiple vertex buffer support in the leaf bins.

```
void CLeafBin::AddVisibleData( unsigned char VBIndex,
                               unsigned long IndexStart,
                               unsigned long PrimitiveCount )
{
   CLeafBinData * pData = m_ppBinData[ VBIndex ];

   ULONG LastIndexStart       = pData->m_nLastIndexStart,
         LastPrimitiveCount   = pData->m_nLastPrimitiveCount;

   // Build up batch lists
```

```
   if ( LastPrimitiveCount == 0 )
   {
        // We don't have any data yet so just store initial values
        LastIndexStart     = IndexStart;
        LastPrimitiveCount = PrimitiveCount;

   } // End if no data
   else if ( IndexStart == (LastIndexStart + (LastPrimitiveCount * 3)) )
   {
        // The specified primitives were in consecutive order
        LastPrimitiveCount += PrimitiveCount;

   } // End if consecutive primitives
   else
   {
   // Store any previous data for rendering
   pData->m_pRenderBatches[pData->m_nBatchCount].IndexStart= LastIndexStart;
   pData->m_pRenderBatches[pData->m_nBatchCount].PrimitiveCount=LastPrimitiveCount;
   pData->m_nBatchCount++;

        // Start the new list
        LastIndexStart     = IndexStart;
        LastPrimitiveCount = PrimitiveCount;

   } // End if new batch

   // Store the updated values
   pData->m_nLastIndexStart     = LastIndexStart;
   pData->m_nLastPrimitiveCount = LastPrimitiveCount;
}
```

As you can see, the changes are subtle as the render batches are now compiled in the CLeafBinData structures instead of the CLeafBin object's themselves. The function's first parameter is the index of the tree's vertex buffer that the passed index start and primitive count value pertain to. We use the vertex buffer index to fetch the correct CLeafBinData structure from the leaf bin's array (there will be one for each vertex buffer being used by the tree) and from that point on, we are simply growing or starting new render batches in the CLeafBinData structures instead of in the leaf bin itself.

After the visibility process has been performed on the tree, each leaf bin may contain multiple render batches in each CLeafBinData structure. Each structure in this array describes the batches of the visible triangles that need to be rendered for a specific vertex/index buffer pair.

At this point, the application will choose to render the subsets of the tree. We saw earlier that the CBaseTree::DrawSubset call really just forwards the render request on the leaf bin that matched the passed subset ID. We did examine a version of a CLeafBin->Render function, but it lacked multiple vertex buffer support. Here is the new version of the function that instructs the leaf bin to render all render batches associated with all vertex/index buffers it contains.

```
void CLeafBin::Render( LPDIRECT3DDEVICE9 pDevice )
{
    ULONG i, j;
```

```
    // Loop through each vertex buffer
    for ( i = 0; i < m_nVBCount; ++i )
    {
        CLeafBinData * pData = m_ppBinData[ i ];
        if ( !pData ) continue;

        // Set the stream sources to the device
        pDevice->SetStreamSource( 0, pData->m_pVertexBuffer, 0, sizeof(CVertex) );
        pDevice->SetIndices( pData->m_pIndexBuffer );

        // Set the FVF
        pDevice->SetFVF( VERTEX_FVF );

        // Render the leaves
        for ( j = 0; j < pData->m_nBatchCount; ++j )
        {
            RenderBatch & Batch = pData->m_pRenderBatches[j];

            // Render any data
            pDevice->DrawIndexedPrimitive( D3DPT_TRIANGLELIST,
                                           0,
                                           0,
                                           pData->m_nVertexCount,
                                           Batch.IndexStart,
                                           Batch.PrimitiveCount );

        } // Next element

    } // Next Vertex Buffer
}
```

This function has the task of looping through each CLeafBinData structure in its array, binding its vertex and index buffers to the device and then looping through its render batches and rendering each one. Remember, the leaf bin's m_nVBCount member describes the number of vertex buffers in use by the tree and therefore describes the size of each leaf bin's CLeafBinData array. If the tree stored its geometry in five vertex buffers, but the leaf bin only contained triangles stored in the first vertex buffer, there would still be five CLeafBinData objects in its array, although the other four would have no render batches and no index buffers created or stored in them.

So, we loop through each CLeafBinData structure and for each one we process, we bind its vertex and index buffer pair to the device. We then loop through its render batches and call DrawIndexedPrimtive to render each batch. At the end of the outer loop we will have rendered all visible geometry in this leaf bin.

Although this sounds like a complicated system, it will become easier to grasp when we start to cover the actual code in the next section. Seeing how the leaf bins are constructed during the BuildRenderData call should clear up a lot of unanswered questions you may have at this point. The goal of this first section has been to provide you with some insight as to how the system will work and the various structures that will be used to implement it. This should make covering the rather tedious source code a lot easier.

It is now time to start discussing the real source code in the CBaseTree render system. As we have often done, we will cover the source code from a bottom up perspective. That is, we will look at the changes we will have to make at the CBaseLeaf level and filter those changes up until we finally cover the code changes to CBaseTree itself. To not do so would be pointless. For example, if we were to cover the CBaseTree::BuildRenderData method first, you will see that it spends most of its time calling member functions of CBaseLeaf and CLeafBin to accomplish its tasks. By looking at these support objects first, we can make sure that when we do finally get to examining the CBaseTree code, we understand all the function calls it is making and the support structures used.

15.3 CBaseLeaf - Adding Rendering Support

In the previous lesson we discussed much of the CBaseLeaf implementation and we listed and examined all code that related to building and querying the tree. In this section we will look at CBaseLeaf methods and member variables that were not discussed in the previous lesson as they pertained to the render system.

As the previous section indicated, part of the job of the CBaseTree::BuildRenderData method will be to store at each leaf a RenderData structure for each subset contained in that leaf. That is, if the polygon data in a given leaf uses three attributes (i.e., belongs to three different subsets), there will be an array of three RenderData items stored at that leaf.

We also saw that because we need to support multiple vertex buffers, each RenderData item cannot just store a single index start and primitive count since the associated leaf bin will also need to know in which of the tree's vertex buffers the triangles are contained. This also indicates which index buffer that the leaf will have stored these triangles in within the leaf bin. The RenderData structure represents a single subset within a leaf. It contains a pointer to the associated leaf bin that collects triangles for that subset and also contains an array of render elements (Element structures).

15.3.1 The RenderData Structure

The RenderData structure is shown below along with the Element structure which is contained within its namespace. Its definition is contained in CBaseTree.h. The RenderData structure is actually defined inside the CBaseLeaf namespace, but for the sake of clarity in this discussion, we show it outside that namespace.

```
struct RenderData
{
        struct Element
        {
            unsigned long   IndexStart;         // Index of this leaves first tri
            unsigned long   PrimitiveCount;     // Number of Tris
            unsigned char   VBIndex;            // vertex Buffer Index
        };
```

```
        unsigned long AttributeID;    // The attribute ID of this render data item
        CLeafBin    * pLeafBin;       // Pointer to the actual leaf bin
        Element     * pElements;      // The actual render data element array
        unsigned long ElementCount;   // The number of elements stored here.
};
```

Let us discuss the four members of this structure.

unsigned long AttributeID
This member stores the subset ID of the triangles in the leaf that this RenderData structure represents. This will match the attribute ID of the leaf bin pointed at by its pLeafBin member.

CLeafBin * pLeafBin
This member stores a pointer to the leaf that is to collect the triangles in this RenderData structure during a visibility pass if the leaf in which the RenderData structure is contained is deemed visible. We store the pointer to the leaf bin in the RenderData structure so that we can easily call its AddVisibleData method to send it the render elements of this RenderData structure.

Element * pElements
This is a pointer to an array of Element structures. Each element describes a run of triangles that needs to be added to the leaf bin during a visibility pass, along with a vertex buffer index. The vertex buffer index informs the leaf bin's AddVisibleData methods which render batch list the triangles in that element should be added to. Most of the time, a single RenderData structure will contain only one Element in this array which describes (to the associated leaf bin) which vertex buffer/index buffer pair these triangles are associated with and therefore, which render batch list the triangles should be added to in that leaf bin.

The only time when there will exist more than one Element in a leaf's RenderData structure will be if, during the BuildRenderData method, a vertex buffer switch had to be made partway through adding a leaf's subset to a leaf bin. For example, we know that if we have 50 polygons that use subset 5, during the build phase the vertices of these polygons will need to be added to the tree's vertex buffer and the indices of these 50 triangles should be added to the leaf bin's index buffer. Under normal circumstances were no complications to occur, we would then store (inside the RenderData structure for that leaf's subset) a primitive count of 50 and an index start describing where this leaf's run of triangles start in that leaf bin's index buffer. However, what if after adding only 25 triangles during the build process, the vertex buffer becomes full and the remaining 25 of this leaf's subset 5 polygons have to be added to a new vertex buffer? The leaf bin will be informed when the second 25 triangles are added that these exist in the second vertex buffer, not the first. The leaf bin would then create a second index buffer that will be used to index the triangles in the second vertex buffer. If we go back to the leaf and subset in question, we now have a RenderData structure for subset 5 in a leaf that is spread over two vertex and index buffers. Therefore, in such a situation two Element structures will be stored in its RenderData structure's pElements array. The first element will describe the array of subset 5 triangles in the first vertex/index buffer and the second element will describe the second run of subset 5 triangles in the second vertex/index buffer. As we discussed, during the visibility pass, each element will be passed to the leaf bin which will maintain render batch lists for each vertex/index buffer combination it uses.

unsigned long ElementCount
This member describes the number of elements stored in the previously described array. As discussed, this will usually be 1 unless the polygons in this leaf that belong to the subset represented by this RenderData structure span multiple vertex buffers.

15.3.2 CBaseLeaf – The Source Code

CBaseLeaf is no stranger to us as it was covered quite heavily in the previous chapter. In this chapter however we will cover its methods and members pertaining to the rendering system. Although we show the entire class below contained CBaseTree.h (minus dynamic object support which will be added later in the lesson), you will see that there are only a handful of new methods and members that we did not cover in the previous lesson. These are highlighted in bold.

```
class CBaseLeaf : public ILeaf
{
public:

    // Constructors & Destructors for This Class.
    virtual ~CBaseLeaf( );
             CBaseLeaf( CBaseTree * pTree );

    // Public Virtual Functions for This Class (from base).

    virtual bool            IsVisible           ( ) const;

    virtual unsigned long   GetPolygonCount     ( ) const;
    virtual CPolygon *      GetPolygon          ( unsigned long nIndex );
    virtual unsigned long   GetDetailAreaCount  ( ) const;
    virtual TreeDetailArea* GetDetailArea       ( unsigned long nIndex );
    virtual void            GetBoundingBox      ( D3DXVECTOR3 & Min,
                                                  D3DXVECTOR3 & Max ) const;

    // Public Functions for This Class.
    void                    SetVisible          ( bool bVisible );

    void                    SetBoundingBox      ( const D3DXVECTOR3 & Min,
                                                  const D3DXVECTOR3 & Max );
    bool                    AddPolygon          ( CPolygon * pPolygon );
    bool                    AddDetailArea       ( TreeDetailArea * pDetailArea );

    RenderData            * AddRenderData       ( unsigned long nAttribID );
    RenderData::Element   * AddRenderDataElement( unsigned long nAttribID );
    RenderData            * GetRenderData       ( unsigned long nAttribID );

protected:

    // Protected Structures, Enumerators and typedefs for This Class.
```

```
    typedef std::vector<CPolygon*>          PolygonVector;
    typedef std::vector<TreeDetailArea*>    DetailAreaVector;

    // Protected Variables for This Class

    PolygonVector       m_Polygons;         // Array of leaf's polygon pointers
    DetailAreaVector    m_DetailAreas;      // Array of detail area pointers.
    bool                m_bVisible;         // Is this leaf visible or not?
    D3DXVECTOR3         m_vecBoundsMin;     // Minimum bounding box extents
    D3DXVECTOR3         m_vecBoundsMax;     // Maximum bounding box extents.

    RenderData         *m_pRenderData;      // Renderable data information
    unsigned long       m_nRenderDataCount; // Number of render data items .

    CBaseTree          *m_pTree;            // The tree to which this leaf belongs.
};
```

There are only three new members that have been added to the leaf which are used to store the RenderData structures.

RenderData *m_pRenderData
This array will contain a RenderData structure for each subset of polygons that exist in the leaf. The RenderData structure was discussed above and contains the runs of triangles (called elements) stored in the leaf bin's index buffers. If a leaf contains polygons that belong to five different subsets, the leaf will store five RenderData structures in this array. We can think of each RenderData structure as being an input of visible triangles into a specific leaf bin when the leaf is found to be visible.

unsigned long m_nRenderDataCount
This member describes the number the RenderData structures in the above array. This implicitly tells us the number of subsets contained in this leaf and the number of leaf bins we will have to provide render elements for if this leaf is found to be visible.

bool m_bVisible
This Boolean is set to either true or false by the visibility determination process. If the ProcessVisibility method of the spatial tree determines that this leaf is inside the view frustum, it will be set to true; otherwise it will be set to false.

Notice that CBaseLeaf also has several new methods which relate to the visibility system. These methods will never be called by the application, as they are used by the tree when building and preparing the render data and processing tree visibility. We will discuss each of these methods next.

IsVisible – CBaseLeaf

This method is an exception to the rule with respect to the other leaf visibility methods in that it will often be used by the application to query the visibility status of a leaf. For example, the application may send an AABB down the tree to collect all leaves that fall within that bounding volume. The CollectLeavesAABB method would be used to fill a leaf list with these CBaseLeaf pointers. The application could then iterate through the returned leaf list and call the IsVisible method to determine if that leaf is currently visible and needs to be processed.

The method itself is a simple one line function that returns the value of its m_bVisible member variable. It will contain the visibility status of the leaf as calculated in the last visibility pass through the tree (i.e., the most recent call to CBaseTree::ProcessVisibility).

```
bool CBaseLeaf::IsVisible( ) const
{
    return m_bVisible;
}
```

AddRenderData – CBaseLeaf

The CBaseLeaf::AddRenderData method should never be called by the application. It is only called by the spatial tree during the BuildRenderData call when the data is being prepared in its renderable form. It is at this stage (just after the tree has been built) that each leaf is processed and the RenderData structures are generated and stored in each leaf (one for each subset contained in that leaf).

Since the leaf stores its RenderData structures in an array, this array will have to be grown every time we wish to add a new RenderData structure to it during the building of the render data. Remember, at the start of the BuildRenderData call, no leaves will contain any RenderData structures. These will need to be allocated and added to a leaf's RenderData array as and when we examine the polygons of that leaf and find a polygons in that leaf with an attribute ID which we have not yet generated a RenderData structure for. The CBaseTree::BuildRenderData method will call this method when it would like to make room in the leaf's RenderData array for a new structure. The function is passed the attribute ID of the subset that this RenderData structure represents in the current leaf. The function will resize the leaf's RenderData structure array and store the attribute ID in the new RenderData structure. A pointer to this new element in the array will then be returned to the function so that it can be used to populate the new RenderData structure with render elements.

This code is like most we have seen that resizes arrays. It first allocates a new empty array of RenderData structures that is large enough to store the number of elements currently in the RenderData array plus the one new element we wish to add. We then copy over all the data from the previous array into the new array before releasing the old array and assigning the leaf's pointer to point at this new array instead. We also store the passed attribute ID in the newly added RenderData structure so that we know which subset set this RenderData structure will store polygons for.

```
CBaseLeaf::RenderData * CBaseLeaf::AddRenderData( unsigned long nAttribID )
{
    RenderData * pBuffer, * pData;

    // First allocate space for all the element items
    pBuffer = new RenderData[ m_nRenderDataCount + 1 ];
    if ( !pBuffer ) return NULL;

    // Any old data?
    if ( m_nRenderDataCount > 0 )
    {
        // Copy over the old data, and release the old array
        memcpy( pBuffer, m_pRenderData, m_nRenderDataCount * sizeof(RenderData) );
        delete []m_pRenderData;

    } // End if any old data

    // Get the element we just created
    pData = &pBuffer[ m_nRenderDataCount ];

    // Clear the new entry
    ZeroMemory( pData, sizeof(RenderData) );

    // Store the attribute ID, it's used to look up the render data later
    pData->AttributeID = nAttribID;

    // Store the new buffer pointer
    m_pRenderData = pBuffer;
    m_nRenderDataCount++;

    // Return the item we created
    return pData;
}
```

Notice that when this new RenderData structure is added to the array it is initially empty. It contains no Elements in its pElements array, which means initially it will be linked to no leaf bin and will not contain any triangles. The calling function will use the returned pointer to set its leaf bin pointer and add Elements to it.

GetRenderData - CBaseLeaf

Although the application should never need to call a function such as this, it will be used by the BuildRenderData method when it wishes to retrieve a pointer to one of the leaf's RenderData structures. A classic example of this is when the BuildRenderData method is processing the polygons in a given leaf. If it finds a polygon that uses subset 5 for example, it will call the GetRenderData method passing in an attribute ID of 5. If a valid pointer is returned, then it means we have already processed triangles in this leaf for the same subset and as such, its RenderData structure has already been allocated. When this is the case, we can just increment the primitive count of the RenderData structure and continue on to the next polygon in the leaf. If a NULL pointer is returned, it tells the BuildRenderData method that we are currently processing a polygon in a leaf that belongs to a subset we have not yet found in that leaf. This

means that there will not currently be a RenderData structure allocated for it. When this happens, the BuildRenderData method can call the CBaseLeaf::AddRenderData method to add a new RenderData structure to the leaf's array. The current index start and primitive count of this polygon (and any future ones we find in this leaf which share the same subset as this polygon) can then be appropriately stored.

The key for the search is the subset ID (attribute ID) of the RenderData structure you are looking for within this leaf. The function loops through the leaf's array of RenderData structures searching for one with a matching attribute ID. If one is found, its pointer is returned. Otherwise, the loop plays out to its conclusion and we return NULL. This indicates that no RenderData item currently exists in the leaf which matches the passed attribute ID.

```
CBaseLeaf::RenderData * CBaseLeaf::GetRenderData( unsigned long nAttribID )
{
    ULONG i;

    // Search for the correct render data item
    for ( i = 0; i < m_nRenderDataCount; ++i )
    {
        if ( m_pRenderData[i].AttributeID == nAttribID ) return &m_pRenderData[i];
    } // Next RenderData Item

    // We didn't find anything
    return NULL;
}
```

You will see many of these methods being used when we cover the CBaseTree::BuildRenderData method later in the lesson.

AddRenderElement - CBaseLeaf

This method is another method that will never be called by the application but will be used by the CBaseTree::BuildRenderData method while constructing the RenderData structures at each leaf.

As discussed previously, each RenderData structure stored in a leaf will represent that leaf's polygon contribution for a single subset. Each RenderData structure is used to describe a block of triangles in the associated leaf bin's index buffer(s). Usually, each RenderData structure will store a single Element where each element represents the block of triangles in a given leaf bin's index buffer. However, if when adding the vertices of a given leaf's subset, the vertex buffer is found to be full, a new vertex buffer will be generated and that leaf's subset will be split over multiple vertex buffers. When this is the case, we must store multiple Elements in the RenderData structure so that we can inform the associated leaf bin during the visibility pass about which vertex/index buffers store all the triangles for this leaf. For example, if this leaf has polygons that belong to subset 10, but they are spread over three different vertex buffers, the leaf's RenderData structure for subset 10 will contain three Elements. Each Element describes the vertex buffer and index buffer this run of triangles is stored in and the location and number of indices in those buffers.

Because we never know before building how many Elements we will need to store in each leaf, we will need a way for the BuildRenderData method to add new Elements to a leaf's RenderData item structure as and when we encounter a situation where one has to be added. The AddRenderElement method simply resizes the Element array of the leaf's RenderData structure that is associated with the passed subset ID making room at the end for a new Element structure. A pointer to this new Element is returned to the calling function so that it can populate the new Element structure with index start and primitive count information for a given vertex buffer. We will see how this function is used later.

The method is passed a subset ID as its only parameter. The Leaf's GetRenderData method is then called to retrieve a pointer to the RenderData structure within the leaf that represents triangles assigned with the passed attribute.

```
CBaseLeaf::RenderData::Element * CBaseLeaf::AddRenderDataElement
                                                ( unsigned long nAttribID )
{
    RenderData::Element * pBuffer, * pElement;
    RenderData * pData = GetRenderData( nAttribID );
    if ( !pData ) return NULL;
```

If the GetRenderData method returned NULL, it means the caller is trying to add an Element to the array of a RenderData structure which has not yet been created. In this case, the function returns NULL. This informs the caller that there currently exists no RenderData structure in the leaf associated with the passed subset ID.

At this point we allocate a new Element array (notice it is within the RenderData namespace) large enough to store any Elements that may already be in the array plus the new one we wish to add. If there are any elements already in the previous array of the RenderData structure, we copy them over into the new array we have just allocated. We then delete the old array previously pointed at by the RenderData::pElements pointer.

```
    // First allocate space for all the element items
    pBuffer = new RenderData::Element[ pData->ElementCount + 1 ];
    if ( !pBuffer ) return NULL;

    // Any old data?
    if ( pData->ElementCount > 0 )
    {
        // Copy over the old data, and release the old array
        memcpy( pBuffer,
                pData->pElements,
                pData->ElementCount * sizeof(RenderData::Element) );

        delete []pData->pElements;

    } // End if any old data
```

At this point we store a pointer to the new Element structure we added at the end of the new array so we can return the structure to the caller.

```
    // Get a pointer to the new element
    pElement = &pBuffer[ pData->ElementCount ];
```

The new Element structure at the end of the array is un-initialized, so we clear its memory.

```
    // Clear the new entry
    ZeroMemory( pElement, sizeof(RenderData::Element) );
```

We then assign the RenderData structure's pElements pointer to point at our new array (as the old one has been deleted) and increase the RenderData::ElementCount member variable to correctly reflect the number of elements in the array. Finally, we return the pointer to the new element at the end of this array which the caller will then use to populate with meaningful data.

```
    // Store the new buffer pointer
    pData->pElements = pBuffer;
    pData->ElementCount++;

    // Return the element we created
    return pElement;
}
```

SetVisible - CBaseLeaf

We have seen a few simplified versions of this function during our initial discussions of the render system, but now we will see the real thing. Before we look at the code, you should be aware of a new member that has been added to CBaseTree.

We will see later that CBaseTree now has an additional LeafList member variable which is declared as shown below:

Excerpt from CBaseTree.h (CBaseTree class)

```
LeafList                    m_VisibleLeaves;
```

Remembering that LeafList is a type definition for an STL list that contains ILeaf pointers, the name of this member should imply what it is used to store.

When the visibility pass is performed on the tree, a traversal method in the derived class will be used to walk through the tree finding visible leaves. At the very start of this visibility traversal (which is performed with each frame update), the m_VisibleLeaves list will be emptied. Once a visible leaf has been found during traversal, the leaf's SetVisible method will be called. This function will set the leaf's visibility Boolean to true. It will also loop through every RenderData structure stored in the leaf and add each one's Elements to their associated leaf bins as we discussed earlier. All of this code has been covered earlier and is shown below.

```
void CBaseLeaf::SetVisible( bool bVisible )
{
```

```
    ULONG                  i, j;
    RenderData::Element * pElement;
    CLeafBin            * pLeafBin;
    RenderData          * pData;

    // Flag this as visible
    m_bVisible = bVisible;

    // If we're being marked as visible, inform the renderer
    if ( m_bVisible && m_nRenderDataCount > 0 )
    {
        // Loop through each renderable set in this leaf.
        for ( i = 0; i < m_nRenderDataCount; ++i )
        {
            pData    = &m_pRenderData[i];
            pLeafBin = pData->pLeafBin;

            // Loop through each element to render
            for ( j = 0; j < pData->ElementCount; ++j )
            {
                pElement = &pData->pElements[j];
                if ( pElement->PrimitiveCount == 0 ) continue;

                // Add this to the leaf bin
                pLeafBin->AddVisibleData( pElement->VBIndex,
                                          pElement->IndexStart,
                                          pElement->PrimitiveCount );
            } // Next Element

        } // Next RenderData Item

    } //  End if visible
```

However, the final part of this function is new. If the visibility status of the tree is set to true, the leaf adds its own pointer to the tree's m_VisibleLeaves list using a new method of CBaseTree called AddVisibleLeaf. This is a simple method which just wraps the adding of the passed leaf pointer to the tree's visible leaf list. The remainder of this function is shown below.

```
    // Update tree object's if we're visible
    if ( m_bVisible )
    {
        // // Add this leaf to the tree's visible leaf list
        m_pTree->AddVisibleLeaf( this );

    } // End if we are visible
}
```

After the visibility process has been performed for a given frame update, and the SetVisible method has been called for all visible leaves, the spatial tree's m_VisibleLeaves list will contain pointers for all leaves which are currently visible. The application can fetch this list by calling the spatial tree's GetVisibleLeaves method.

It is very useful for the application to be able to ask the tree for a list of currently visible leaves. For example, the application can loop through these leaves and only bother rendering the dynamic objects contained in those leaves. Any dynamic object which is stored in non-visible leaves will simply be ignored by the rendering loop. After we have discussed the rendering system for the static geometry of the spatial tree, we will discuss how the application can assign its own dynamic objects to leaves within the spatial tree and update their positions as they moves around the world.

We have now discussed all the changes to CBaseLeaf that have been added to facilitate the needs of the rendering system. Most of the methods that we have added are utility methods that will be used by the tree's BuildRenderData method to add and retrieve RenderData structures and Element structures to the leaves as the data is being added to leaf bins.

15.3.3 Leaf Bins

When we cover the rendering enhancements to CBaseTree in a moment, we shall see that one of its new members is an array of CLeafBin structures. A leaf bin is an object that stores the indices of all triangles in the tree that use a specific subset. If multiple vertex buffers are being used by the tree to contain the entire scene, and the subset for a specific leaf bin has geometry spread over those multiple buffers, the leaf bin will contain an index buffer for each vertex buffer being used by that subset. The number of index buffers being used is not necessarily equal to the number of vertex buffers being used by the tree. If the tree's static geometry is contained in five vertex buffers, but subset 6 (for example) had triangles contained in only two of those buffers, the leaf bin for subset 6 will contain only two index buffers. Although the leaf bin need not necessarily use a separate index buffer for each vertex buffer containing triangles of its associated subset, it makes the system cleaner and easier to understand. We know for example that if a leaf bin has triangles in vertex buffers 1 and 3, when the leaf bin is rendered, we will need to set vertex buffer 1 first and its associated index buffer and execute the render batches stored for that buffer combination. Then we will then have to set the second index/vertex buffer pair and execute the render batches relative to that buffer set.

In our earlier discussions, we also discovered that a leaf bin is not just a place where all the static index buffers used by a given subset of polygons reside; it also has methods and structures used during the visibility pass to construct a list of render batches for each buffer combination. These render batches describe which triangles in that leaf bin are currently considered visible by the system and should be rendered when the application wishes to render that subset of the tree.

Each render batch structure represents a block of continuous visible triangles in one of the leaf bin's index buffers, and as such describes a block of triangles in that leaf bin that can be rendered with a single draw call. Because the currently visible triangles stored in a leaf bin may not all be arranged in consecutive order in the leaf bin, many render batches will typically be created representing all the visible sections of the index buffer that need to be rendered. Furthermore, because a leaf bin may have to manage multiple index buffers due to the fact that its triangle data is spread over multiple vertex buffers, a render batch list will need to be constructed for each buffer combination. The render batch lists are destroyed and rebuilt for each leaf bin every time a visibility pass of the tree is performed. We can just

think of a render batch list as simply being a list of drawing instructions for a given buffer pair inside the leaf bin.

CBaseTree will now manage a list (actually an STL map, but more on this in a moment) of leaf bins. The number of leaf bins allocated for the tree will be equal to the number of subsets used by the static polygon data stored in the tree. That is, if the polygon data in the tree belongs to a combination of 15 subsets, the BuildRenderData method will create 15 leaf bins, one for each subset. The BuildRenderData method will then proceed to fill those leaf bins with the indices of the triangles that belong in each leaf bin.

We have already seen the CLeafBin::AddVisibleData method being used by the CBaseLeaf::SetVisible method and we will see many of its other methods being used later during the building of the render data. For now though, we will examine the CLeafBin object, look at the structures and support objects it uses, the methods it exposes and the code to those methods.

15.3.4 The RenderBatch Structure

During the visibility pass, the leaf bin will build a list of RenderBatch structures for each buffer combination used by the leaf bin's triangles. Each RenderBatch structure simply describes a block of triangles in one of the leaf bin's index buffers that can be rendered with a single draw call.

```
struct RenderBatch
{
    unsigned long IndexStart;
    unsigned long PrimitiveCount;
};
```

There will be a RenderBatch list constructed during the visibility pass for each index buffer in use by the leaf bin.

unsigned long IndexStart
This value will contain the position in the associated index buffer of the first index in this run of visible triangles.

unsigned long PrimtiveCount
This describes how many triangles starting at IndexStart are contained in this visible continuous section of the index buffer.

15.3.5 CLeafBinData – The Source Code

A CLeafBin object contains an array of CLeafBinData structures. Each CLeafBinData structure houses a vertex/index buffer combination, information about those buffers, and the RenderBatch list for that vertex and index buffer pair. Rendering a leaf bin involves looping through its CLeafBinData array and setting the vertex and index buffers stored in the current CLeafBinData element being processed before looping through the CLeafBinData's render batch list calling DrawIndexedPrimitive for each one.

If the spatial tree is using five vertex buffers, every leaf bin will contain an array of five CLeafBinData objects as this is the maximum number of vertex/index buffers that could ever be needed by a leaf bin. However, not all the elements in the CLeafBinData array are necessarily used by the leaf bin. If the leaf bin represents geometry that is spread over only two of the five vertex buffers in use by the tree, that leaf bin will only use the first two elements in its CLeafBinData array. Each element in that array would contain the index buffer and vertex buffer to set on the device in order to render the batches for that buffer combination.

The CLeafBinData class is really just a structure with a constructor that initializes its members to zero. Although it has a fair number of members, they really just describe a vertex buffer and an index buffer and information about those buffers (e.g., the amount of data that is contained in them).

This object is declared in CBaseTree.h and is shown below followed by a description of its members.

```
class CLeafBinData
{
public:

    // Constructors & Destructors for This Class.
    virtual ~CLeafBinData( );
             CLeafBinData( );

    // Public Variables for This Class.
    LPDIRECT3DVERTEXBUFFER9 m_pVertexBuffer;
    LPDIRECT3DINDEXBUFFER9  m_pIndexBuffer;

    unsigned long           m_nFaceCount;
    unsigned long           m_nVertexCount;
    unsigned char           m_nVBIndex;
    bool                    m_b32BitIndices;
    unsigned long           m_nLastIndexStart;
    unsigned long           m_nLastPrimitiveCount;
    RenderBatch            *m_pRenderBatches;
    unsigned long           m_nBatchCount;
};
```

LPDIRECT3DVERTEXBUFFER9 m_pVertexBuffer
This member stores a pointer to the tree's vertex buffer for which this object is applicable. The tree is responsible for allocating and releasing this vertex buffer; this is just a pointer to it so that we can easily

bind it to the device before rendering the RenderBatch instructions stored here. The vertex buffer is not specific to any one leaf bin and may be shared by many leaf bins. All leaf bins that have geometry in one of the tree vertex buffers will all have a CLeafBinData structure that has a pointer to that buffer.

LPDIRECT3DINDEXBUFFER9 m_pIndexBuffer
This is a pointer to an index buffer that contains all the triangles in the above vertex buffer that use the subset associated with the parent leaf bin. This index buffer is not shared by any other leaf bins or even any other CLeafBinData structures within the same leaf bin. This is a static index buffer that is built at leaf bin creation time and it contains all geometry (not just visible geometry) that uses the applicable subset of the leaf bin.

unsigned long m_nFaceCount
Describes how many triangles are in the above index buffer.

unsigned long m_nVertexCount
Describes how many vertices are contained in the vertex buffer pointed to by the first member of this structure.

unsigned char m_nVBIndex
This member describes the vertex buffer pointed to by the first member of this structure as a numerical index in the spatial tree's vertex buffer array. For example, if the spatial tree has stored its geometry in five vertex buffers, but this CLeafBinData structure was representing triangle data stored in the second vertex buffer, this value would be set to 1 (the index of the second vertex buffer in the spatial tree's vertex buffer array).

bool m_b32BitIndices
This member is set to true or false when building the leaf bins to determine whether the index buffer stored here uses 32-bit indices (rather than 16-bit indices). This is certainly useful information to have if we ever wish to lock the index buffer and access the data.

unsigned long m_nLastIndexStart
We saw this member being used when we looked at a simplified version of the leaf bin's AddVisibleData method. It records the first index in a batch of adjacent triangles currently being collected. This value is first set when the AddVisibleData method is called and must start collecting for a new render batch. Every time the function is called after that, if the passed run of adjacent triangles follows on from the ones added to the batch in the previous function call, this value remains unaltered. When we do finally get passed some render data which does not form a continuous block with all the triangles we have collected so far (starting at m_nLastIndexStart), we have collected all we can for that batch and the triangles are committed to a new RenderBatch structure. m_nLastIndexStart is then set to the location of the new run of triangles we are starting to collect.

In short, this value is used as temporary storage during the visibility pass by the leaf bin to record the start of the current batch of adjacent indices collected so far.

unsigned long m_nLastPrimitiveCount
This member is also used as temporary storage during the visibility pass by the CLeafBin::AddVisibleData method. It is used to record, with each function call, the number of adjacent triangles we have collected so far for the current batch being compiled. We discussed this process in some detail earlier when we examined the construction of the RenderBatch lists.

RenderBatch *m_pRenderBatches
This member is an array of RenderBatch structures that will be flushed and filled every time a visibility pass is executed on the tree. This array is allocated (when the CLeafBinData item is first created) to be large enough to hold the maximum number of render batches that we could ever need to create. Although this admittedly wastes some memory, it does allow us to forego any array resizing overhead when building and storing the render batches. As this should be a critically fast process, we want to do everything we can to eliminate such overhead.

This array describes a list of draw instructions for the vertex and index buffers referenced by this structure. Each element in this array represents one DrawIndexedPrimitive call using the above vertex and index buffers.

unsigned long m_nBatchCount
The member stores the number of *valid* RenderBatch structures contained in the above array. Remember, the size of the above array never changes, as discussed above. It is allocated once when the leaf bin first creates this CLeafBinData item and is made large enough to contain the maximum number of render batches that could possibly be created (more on this in a moment). Therefore, this member really describes the number of elements in the above array that are currently considered valid with respect to the last visibility pass. Whenever a new visibility pass is performed, this member is initially set to zero and then incremented every time we add new RenderBatch information. Therefore, this value describes not only the number of batches in the above array that will need to be executed to draw all the visible data in the associated index buffer, but it will also describe the number of DrawIndexedPrimitive calls that will need to be performed to render that data.

15.3.6 CLeafBin – The Source Code

The object that binds this whole system together is CLeafBin. This class has very few member variables as it is really just a wrapper around an array of CLeafBinData structures for a given subset ID. It also has methods that allow you to retrieve the subset/attribute ID of the leaf bin, add and retrieve CLeafBinData structures from its array, and a method that renders the bin. The leaf bin also has the now familiar AddVisibleData method that is called by the CBaseLeaf::SetVisible method to add a leaf's polygon contribution to a render batch. The leaf bins themselves will be created by CBaseTree during the BuildRenderData method.

Below we show the class declaration for CLeafBin which is contained in CBaseTree.h. This is followed by an explanation of its member variables.

```
class CLeafBin
{
public:

    // Constructors & Destructors for This Class.
    virtual ~CLeafBin();
    CLeafBin( unsigned long nAttribID, unsigned long nLeafCount );

    // Public Functions for This Class.
    unsigned long   GetAttributeID      ( ) const;
    CLeafBinData  * GetBinData          ( unsigned long Index ) const;
    bool            AddLeafBinData      ( CLeafBinData * pData );
    void            AddVisibleData      ( unsigned char VBIndex,
                                          unsigned long IndexStart,
                                          unsigned long PrimitiveCount );
    void            Render              ( LPDIRECT3DDEVICE9 pDevice );

private:

    // Private Variables for This Class.
    unsigned long  m_nAttribID;     // The attribute ID of the faces stored here
    unsigned long  m_nLeafCount;    // Total number of leaves in the tree
    CLeafBinData **m_ppBinData;     // An array containing all the information
                                    // we need to render all the data in this bin
                                    // for each vertex bubber (one per primary VB).
    unsigned char  m_nVBCount;      // Number of vertex buffers in use by system
};
```

unsigned long m_nAttribID
This value of this member will be passed into the constructor when the leaf bin is first created by the tree. It contains the subset ID assigned to this leaf bin. That is, all the triangles in the tree that have a matching attribute ID will have their indices stored in this leaf bin.

unsigned long m_nLeafCount
The value of this member is also passed into the constructor when the leaf bin is first created by the tree. It contains the number of leaves in the tree. You will see why we need this value in a moment when we look at the remaining code.

CLeafBinData **m_ppBinData
This is a pointer to an array of CLeafBinData pointers. The size of this array will be equal to the number of vertex buffers being used by the tree. That is, it will hold enough pointers in each leaf bin for the possibility that the leaf bin might have triangles contained in every one of the vertex buffers and would therefore need to represent these triangles with a CLeafBinData structure for each.

Of course, this does not mean that we always allocate a CLeafBinData object for every vertex buffer for each leaf bin, since a given leaf bin might only use two of the vertex buffers and would therefore only need to have two CLeafBinData structures allocated for it. If a leaf bin does not have geometry in one or more of the tree's vertex buffers, the elements in this array that correspond to that vertex buffer will simply be set to NULL. For example, if the tree uses five vertex buffers to store its geometry, the m_ppBinData array in each leaf bin would be allocated large enough to store five pointers. However, if

a leaf bin only has geometry in the first and third vertex buffer, it would have only two CLeafBinData objects allocated for it and have their pointers stored in elements [0] and [2] in this array. The rest of the elements would be set to NULL for the other vertex buffers.

unsigned char m_nVBCount
This value describes the number of vertex buffers in use by the parent tree. This is useful because it also describes the size of the above array. We need this value so that when we render the leaf bin, we know how many element we have to loop through in the above array testing for valid pointers.

Let us now take a look at the methods for this class, which are for the most part, all rather small and straightforward. We will start with the constructor.

Constructor - CLeafBin

The constructor is called by the tree during the generation of its renderable data. The application should never want to allocate a leaf bin. The constructor takes two parameters; the attribute ID of the subset this leaf bin will contain indices for, and the total leaf count of the tree for which the leaf bin is being created. These are stored in the corresponding member variables.

```
CLeafBin::CLeafBin( unsigned long nAttribID, unsigned long LeafCount )
{
    // Store passed values
    m_nAttribID  = nAttribID;
    m_nLeafCount = LeafCount;
    m_ppBinData  = NULL;
    m_nVBCount   = 0;
}
```

Notice that when the leaf bin is first created, the CLeafBinData pointer array is set to NULL and the vertex buffer count member is set to zero. The CLeafBinData structures will be added to the leaf bin (via the CLeafBin::AddLeafBinData method) once the leaf bin has been constructed.

GetAttributeID – CLeafBin

This is a simple accessor function that allows the caller to query the attribute ID of the leaf bin to determine which subset of polygons it contains.

```
unsigned long CLeafBin::GetAttributeID( ) const
{
    return m_nAttribID;
}
```

AddLeafBinData - CLeafBin

This method is called by the BuildRenderData method when it wishes to add a CLeafBinData object to the leaf bin's internal array. You will see in a moment when we discuss the CBaseTree::BuildRenderData method that it essentially loops through each leaf and then through each polygon in those leaves to build an array of vertices and an array of indices into those vertices for each leaf bin. Once the number of vertices we have collected exceeds the number supported in the single vertex buffer by the hardware, we will create the vertex buffer and fill it with the vertices we have collected so far. We will then create index buffers for each leaf bin that index into that vertex buffer. It is at this point that we will inform each leaf bin that we would like to add a new CLeafBinData item to its array which we will populate with the new vertex buffer and index buffer pointers.

The method itself is fairly routine. We pass in a pointer to a pre-allocated CLeafBinData object and the function will resize the leaf bin's array to make room for this pointer at the end. The first part of the function is like every other array resizing method we have discussed, so this should need no explanation.

```
bool CLeafBin::AddLeafBinData( CLeafBinData * pData )
{
    CLeafBinData ** ppBuffer;

    // First allocate space for all the data items
    ppBuffer = new CLeafBinData*[ m_nVBCount + 1 ];
    if ( !ppBuffer ) return false;

    // Any old data?
    if ( m_nVBCount > 0 )
    {
        // Copy over the old data, and release the old array
        memcpy( ppBuffer, m_ppBinData, m_nVBCount * sizeof(CLeafBinData*) );
        delete []m_ppBinData;

    } // End if any old data

    // Set the new entry
    ppBuffer[ m_nVBCount ] = pData;

    // Store the new buffer pointer
    m_ppBinData = ppBuffer;
    m_nVBCount++;
```

At this point we have resized the array and added the passed CLeafBinData pointer to the end of the array. However, what this function will also be responsible for is allocating the passed CLeafBinData structure's RenderBatch array. You will recall from our coverage of the CLeafBinData structure that the RenderBatch array will be allocated just once when the CLeafBinData structure is first added to the leaf bin. It will be made large enough to store the maximum possible number of render batches that could ever be generated for a leaf bin. This way, we will not have to suffer array resizes and flushes as the number of visible leaves fluctuates with each visibility update.

Because the indices of our triangles will be added to the leaf bin index buffers in tree traversal order to help minimize the number of render batches needed, the worst case is that our queue will contain batches where one leaf is visible and the next is invisible, repeating over the entire set. In such a scenario we would need to create a RenderBatch structure for every visible leaf, which in this scenario would half of them. This means that the highest number of batches we will ever need to store in a leaf bin is simply the total number of leaves divided by two. However, as we are performing a division using integer math, we will add one to the total leaf count prior to performing the division. This is to ensure that the result is rounding up and not down. We want 5/3=1.666 to be rounded up to 2 not down to 1. This will make sure the render batch array in each CLeafBinData structure is large enough to cope with the worst case visibility scenario.

Here is the remaining code that allocates the RenderBatch array for the passed CLeafBinData structure before returning.

```
    // Note: We add '1' to ensure that we don't have any rounding issues.
    pData->m_pRenderBatches = new CLeafBinData::RenderBatch[(m_nLeafCount+1) / 2 ];

    if ( !pData->m_pRenderBatches ) return false;

    // Success!
    return true;
}
```

GetBinData - CLeafBin

This method is a simple function that allows the caller to retrieve one of the leaf bin's CLeafBinData pointers. The caller simply passes the index of the element in the array it would like to retrieve the CLeafBinData item for. This may be NULL if the leaf bin does not contain data for the tree's vertex buffer with the same index.

This function essentially allows the tree to say to the leaf bin, "Give me your index data and render batches for a specific vertex buffer index".

```
CLeafBinData * CLeafBin::GetBinData( unsigned long nIndex ) const
{
    // Validate parameters
    if ( nIndex >= m_nVBCount ) return NULL;

    // Retrieve the item
    return m_ppBinData[ nIndex ];
}
```

As you can see, as long as the passed index is within the bounds of the array (i.e., less than m_nVBCount), the pointer contained in the passed index of the CLeafBinData array is returned.

AddVisibleData – CLeafBin

This method should be familiar since we looked at various versions of this type of function as a means to initially understand the render batch system.

We saw earlier that it is called from the CBaseLeaf::SetVisible method. When a leaf is deemed to be visible during the update pass, a loop is made through the RenderData items stored in that leaf (one exists for each subset in the leaf). An inner loop was then used to iterate through the (possible) multiple Elements stored in that RenderData item. There was an Element in RenderData structure for each vertex buffer that contains geometry from that leaf for the given subset. Each Element describes a run of triangles in that leaf that use the subset along with the index of the vertex buffer in which the run of triangles is contained. The AddVisibleData method of CLeafBin is then called and passed the Element information: the vertex buffer index in which the run is stored, the start index in the leaf bin's index buffer associated with that vertex buffer, and the number of triangles in the run.

```
void CLeafBin::AddVisibleData( unsigned char VBIndex,
                               unsigned long IndexStart,
                               unsigned long PrimitiveCount )
{
```

The vertex buffer index of the render element information passed in also describes the index of the CLeafBinData structure in the leaf bin's array of the index buffer and render batch list associated with this vertex buffer. Therefore, we fetch the pointer to the relevant CLeafBinData structure from the bin's array.

```
    CLeafBinData * pData = m_ppBinData[ VBIndex ];
    if ( !pData ) return;
```

We then fetch the values of the CLeafBinData item's m_nLastIndexStart and m_nLastPrimitiveCount members into local variables. m_nLastIndexStart will currently contain the first index of the first triangle in the current render batch we are trying to build for this index buffer. The m_nLastPrimitiveCount member will contain the number of adjacent triangles we have been able to pack into the batch so far. Hopefully, the range of triangles passed in will follow on exactly where m_nLastPrimitiveCount ends in the index buffer, allowing us to add the new triangle range to the current batch being compiled.

```
    ULONG LastIndexStart      = pData->m_nLastIndexStart,
          LastPrimitiveCount  = pData->m_nLastPrimitiveCount;
```

If LastPrimitiveCount equals zero, it means that we have not yet collected any triangles for the current batch and therefore the triangle range passed in should be used to start the beginning of a new render batch. When this is the case, we simply copy the passed IndexStart and PrimitiveCount into the LastIndexStart and LastPrimitiveCount variables. Hopefully, the next time this function is called for another visible leaf, we can add the passed triangle range to the end of this batch we have just started.

```
    // Build up batch lists
```

```
    if ( LastPrimitiveCount == 0 )
    {
        // We don't have any data yet so just store initial values
        LastIndexStart     = IndexStart;
        LastPrimitiveCount = PrimitiveCount;

    } // End if no data
```

If this is not the case then we must be currently in the middle of compiling a batch of adjacent triangles for the CLeafBinData's index buffer. Therefore, we test to see if the start index passed into the function follows on immediately after the current batch we are compiling ends (LastIndexStart+(LastPrimitiveCount*3)). If it does, then the passed triangles continue the adjacent run of triangles we have already recorded and we can just add them to the current batch by increasing the primitive count to compensate for the number of primitives passed into the function.

```
    else if ( IndexStart == (LastIndexStart + (LastPrimitiveCount * 3)) )
    {
        // Just grow the primitive count
        LastPrimitiveCount += PrimitiveCount;

    } // End if consecutive primitives
```

If none of the above cases are true then it means that we are in the middle of compiling a render batch but the triangle(s) we have just been passed do not follow on continuously from the current batch we are compiling. This essentially ends the current batch we are compiling and the new triangles we have just been passed will be used to start a new batch collection process.

```
   else
   {
   // Store any previous data for rendering
   pData->m_pRenderBatches[pData->m_nBatchCount].IndexStart= LastIndexStart;
   pData->m_pRenderBatches[pData->m_nBatchCount].PrimitiveCount=LastPrimitiveCount;
   pData->m_nBatchCount++;

   // Start the new list
   LastIndexStart     = IndexStart;
   LastPrimitiveCount = PrimitiveCount;

   } // End if new batch
```

As you can see, because LastIndexStart and LastPrimitiveCount describe the block of adjacent triangles we managed to collect until this function was called, we store them in the CLeafBinData object's render batch array and increase its render batch count. This render batch is now finished and we need to start a new collection process. We do this by assigning the start index and primitive count of the range of triangles passed in to the LastIndexStart and LastPrimitiveCount local variables which will be used from this point on. Finally we store the local LastIndexStart and LastPrimitiveCount values in the CLeafBinData member variables so that they are available the next time this method is called.

```
    // Store the updated values
    pData->m_nLastIndexStart     = LastIndexStart;
```

```
    pData->m_nLastPrimitiveCount = LastPrimitiveCount;
}
```

Render - CLeafBin

The CLeafBin::Render method is called by the tree to render all the triangles contained in the leaf bin. This method will not typically be called by the application, as it will use the CBaseTree::DrawSubset method for each subset that it wishes to render instead. DrawSubset simply issues the render call to the leaf bin with the matching attribute.

The Render function is shown below. It essentially loops through each pointer in the leaf bin's CLeafBinData array to process and render the data contained in each.

```
void CLeafBin::Render( LPDIRECT3DDEVICE9 pDevice )
{
    ULONG i, j;

    // Loop through each vertex buffer
    for ( i = 0; i < m_nVBCount; ++i )
    {
        CLeafBinData * pData = m_ppBinData[ i ];
        if ( !pData ) continue;
```

As you can see in the above code, the current iteration of the loop is skipped if this leaf bin does not have a CLeafBinData item for a given vertex buffer.

The next function call requires some explanation. You will recall that in the AddVisibleData method we used the m_nLastIndexStart and m_nLastPrimitiveCount members of the CLeafBinData item to record the start and triangle count of the batch of triangles being compiled. Only when we are passed triangles that do not continue the current batch is the batch data copied into a RenderBatch data structure. This means that at the end of the visibility process, we may be in the middle of compiling a batch of triangles that have not yet been committed to the render batch list. For example, consider the last leaf processed for a given subset. Even if it starts a branch new batch, because no further triangles are passed, the AddVisibleData function is never passed triangles that break the batch, and therefore it is never aware that the batch ever ended. This means that the m_nLastIndexStart and m_nLastPrimitiveCount members of each CLeafBinData structure describe their final batches, but they are not yet committed to a render batch structure. Therefore, before we draw the CLeafBinData render batches, we must call AddVisibleData for this item one last time, passing in both an index start and primitive count of zero.

```
        // Commit any last piece of data to the render queue and reset "Last"
        // values back to 0
        AddVisibleData( (unsigned char)i, 0, 0 );
```

As the first parameter, we pass the current vertex buffer index we are processing which describes (to the AddVisibleData method) which CLeafBinData object we are adding triangles for. Also, because we pass 0 in as the IndexStart parameter, which could not possibly continue any batch that has been compiled,

the function will recognize that the last batch has ended and will store it in the CLeafBinData object's render batch list. Finally, this will cause the function to start a new batch to be compiled with an index start and primitive count set to the values passed in. Since we pass zero for both of these values, this essentially resets the CLeafBinData's m_nLastIndexStart and m_nLastPrimitiveCount members back to zero for the next visibility pass.

At this point, we have the CLeafBinData pointer, so we send its vertex and index buffers to the device and set the FVF for the vertex type being used.

```
        // Set the stream sources to the device
        pDevice->SetStreamSource( 0, pData->m_pVertexBuffer, 0, sizeof(CVertex) );
        pDevice->SetIndices( pData->m_pIndexBuffer );

        // Set the FVF
        pDevice->SetFVF( VERTEX_FVF );
```

Finally, we loop through every RenderBatch structure stored in the CLeafBinData's render batch list and render the triangles described by each.

```
        // Render the leaves
        for ( j = 0; j < pData->m_nBatchCount; ++j )
        {
            CLeafBinData::RenderBatch & Batch = pData->m_pRenderBatches[j];

            // Render any data
            pDevice->DrawIndexedPrimitive( D3DPT_TRIANGLELIST,
                                           0,
                                           0,
                                           pData->m_nVertexCount,
                                           Batch.IndexStart,
                                           Batch.PrimitiveCount );
        } // Next element
    } // Next Vertex Buffer
}
```

We have now covered all of the rendering code for CBaseLeaf, CLeafBin, and CLeafBinData and you should have a fairly good understanding of how these components work. We will now cover the new rendering code in the top level object (CBaseTree) that brings all of these components together under one system.

15.4 CBaseTree – Adding Rendering Support

Adding the code that actually performs the visibility pass and renders the data in the tree is relatively trivial. The CBaseTree methods that perform these tasks will be small and simple as they just pass the requests on to the leaf bins. As we have seen, it is the leaf bins that contain the triangles and have knowledge of how to render them.

The majority of work we will have to do in CBaseTree is the implementation of the BuildRenderData method. As you will soon see, this method is responsible for building all the vertex buffers used by the tree, allocating the leaf bins for each attribute used by the tree, building the index buffers for each leaf bin, and a host of other tasks. Most of our discussion of CBaseTree will be spent describing how this function works. If you have already looked at the source code to this function, you might have noted that it seems a little intimidating. Do not worry though; we will break this function down (and the functions it calls) piece by piece so that we understand everything that is going on when building the render data.

15.4.1 CBaseTree – The Source Code

Surprisingly few methods and members have to be added to CBaseTree in order to implement the rendering system. The upgraded class declaration is shown below. The new methods and members that pertain to the rendering system are highlighted in bold. This declaration will be followed by a detailed description of the new members and an examination of each new method.

```
class CBaseTree : public ISpatialTree
{
public:

    // Friend list for CBaseTree
    friend void CBaseLeaf::SetVisible( bool bVisible );

    // Constructors & Destructors for This Class.
    virtual ~CBaseTree( );
             CBaseTree( LPDIRECT3DDEVICE9 pDevice, bool bHardwareTnL );

    // Public Virtual Functions for This Class (from base).
    virtual bool            AddPolygon        ( CPolygon * pPolygon );
    virtual bool            AddDetailArea     ( const TreeDetailArea &DetailArea );

    virtual bool            Repair              ( );

    virtual PolygonList    &GetPolygonList      ( );
    virtual DetailAreaList &GetDetailAreaList   ( );
    virtual LeafList       &GetLeafList         ( );
    virtual LeafList       &GetVisibleLeafList  ( );

    virtual void            DrawSubset          ( unsigned long nAttribID );
    virtual void            ProcessVisibility   ( CCamera & Camera );

    // Public Functions for This Class
    CLeafBin *              GetLeafBin          ( unsigned long nAttribID );
    bool                    AddLeaf             ( CBaseLeaf * pLeaf );
    bool                    AddVisibleLeaf      ( CBaseLeaf * pLeaf );
    bool                    BuildRenderData     ( );

protected:
```

```
    // STL Typedefs
    typedef std::map<ULONG,CLeafBin*>       LeafBinMap;

    // Protected Functions for This Class.
public:
    void   DrawBoundingBox     ( const D3DXVECTOR3 & Min,
                                 const D3DXVECTOR3 & Max,
                                       ULONG Color,
                                       bool bZEnable = false );

protected:
    void   DrawScreenTint      ( ULONG Color );
    void                    CalculatePolyBounds ( );

    void                    RepairTJunctions    ( CPolygon * pPoly1,
                                                  CPolygon * pPoly2 );

    ULONG                   WeldBuffers ( ULONG VertexCount,
                                          CVertex * pVertices,
                                          std::map<ULONG,ULONG*> & BinIndexData,
                                          std::map<ULONG,ULONG> & BinSizes,
                                          ULONG * pFirstVertex = NULL,
                                          ULONG * pPreviousVertex = NULL );

    bool                    CommitBuffers( ULONG VertexCount,
                                           CVertex * pVertices,
                                           std::map<ULONG,ULONG*> & BinIndexData,
                                           std::map<ULONG,ULONG> & BinSizes,
                                           bool b32BitIndices );

    bool                    PostBuild           (  );

    // Protected Variables for This Class.
    LPDIRECT3DDEVICE9           m_pD3DDevice;
    LPDIRECT3DVERTEXBUFFER9    *m_ppVertexBuffer;
    unsigned char               m_nVBCount;
    bool                        m_bHardwareTnL;

    LeafBinMap                  m_LeafBins;

    LeafList                    m_Leaves;
    PolygonList                 m_Polygons;
    DetailAreaList              m_DetailAreas;

    LeafList                    m_VisibleLeaves;
};
```

Let us discuss a new type definition we have in this namespace:

```
// STL Typedefs
   typedef std::map<ULONG,CLeafBin*>  LeafBinMap;
```

We will store the tree's leaf bins in an STL map. You will recall from our C++ programming course (Module II) that an STL map is basically a hash table that allows us to store key/value pairs in a manner that makes it very efficient to look up that value by specifying the key. We type define LeafBinMap to be an STL map that stores a ULONG as the key and a CLeafBin pointer as the value paired with that key. The key will by the attribute ID of the leaf bin pointed to by the value assigned to that key. Therefore, the tree would be able to very efficiently fetch the leaf bin for subset 6's triangles (for example) by doing something like this:

```
CLeafBin = LeafBinMap [ 6 ];
```

This looks like a simple array look up, so why do we not just use an array to store the leaf bin pointers where the attribute ID is the index into the array where the associated leaf bin is stored?

What we must remember is that our scene uses global attribute IDs and that the static geometry compiled in the tree may only use some of these. For example, assume that after loading our scene and all of our dynamic objects that the scene has created 120 attributes. Imagine however, that the static polygons in the spatial tree only use subsets 6, 40, and 120 out of the 120 possible scene attributes. The leaf bin array would need to be 120 elements in size when only 3 of the elements would contain valid pointers to leaf bins. That is a waste of memory. Alternatively, the map would only have three rows in its hash table. Of course, you could use an array that is the exact size of the number of attributes used by the tree but that would mean the array indices no longer match the attribute IDs of the leaf bins stored there. In this case, whenever you need to fetch the leaf bin pointer for a given subset, you would have to loop through the array searching for the leaf bin with the attribute ID you are looking for. This will hamper performance when the tree contains a lot of attributes (which would have to be searched through every time the DrawSubset method is called). This is especially true if the tree data requires multiple render passes. A map is definitely a better choice of data structure here since it conserves memory and performs efficient value lookups.

Let is now take a look at the new member variables in CBaseTree that have been added to support the render system.

LPDIRECT3DDEVICE9 m_pD3DDevice
This pointer is passed into the constructor of CBaseTree (called by the constructor of the derived classes) and represents the device which the tree will use to render. If this is set to NULL, the BuildRenderData method will perform no action and will return immediately. This is very useful if you intend to use the tree only for collision queries. Passing NULL in as this parameter to the constructor of a derived class allows you to prevent the render system from being activated and avoid the unnecessary memory consumption. No vertex buffers, index buffers, or leaf bins will be generated in this instance. By setting this to point at a valid device, we inform CBaseTree that we intend to use its render system.

LPDIRECT3DVERTEXBUFFER9 *m_ppVertexBuffer
This will be set to NULL until CBaseTree::BuildRenderData executes. At the end of the renderable data building process is will point to an array of vertex buffer pointers. That is, if it was determined during the building of the render data that the static scene needs to be contained in three vertex buffers, this will point to an array of three vertex buffer pointers currently containing the vertex data of the tree's static geometry.

unsigned char m_nVBCount
After the render data building process has been completed, this member will contain the number of vertex buffers being used by the render system and the number of elements in the above vertex buffer pointer array.

bool m_bHardwareTnL
This Boolean is also passed into the constructor of CBaseTree (called from the derived classes) and tells the render system whether the graphics hardware on the current system on which the application is running supports transformation and lighting of vertices in hardware. This Boolean will ultimately determine the vertex buffer creation flags that need to be passed to DirectX when the tree needs to create a new vertex buffer.

LeafBinMap m_LeafBins
This is an STL map containing the leaf bin pointers used by the tree. This map will be empty until CBaseTree::BuildRenderData is called. As the leaf bins are created, their pointers are added to this map. The key for each row in the table is the attribute ID of the leaf bin. The value assigned to that key will be the leaf bin pointer.

LeafList m_VisibleLeaves
We discussed this new leaf list when we discussed the CBaseLeaf source code. This leaf list is emptied just before a new visibility determination pass is performed on the tree. As each visible leaf is encountered, its pointer is added to this list. We saw the code that added the leaf pointers to this list in the CBaseLeaf::SetVisible method earlier in the lesson. At the end of each ISpatialTree::ProcessVisibility call, this list will contain the pointers for all the leaves that are currently deemed visible by the render system (i.e., leaves that are currently inside the camera frustum).

We will now discuss the new methods in CBaseTree that pertain to the rendering system.

AddVisibleLeaf – CBaseTree

We saw this method being called earlier in the lesson when we examined the code to CBaseLeaf::SetVisible. It is passed the pointer of a leaf which it then adds to the tree's visible leaf list. Remembering that LeafList is just an STL list, we can see that this function simply adds the passed pointer to the end of the list.

```
bool CBaseTree::AddVisibleLeaf( CBaseLeaf * pLeaf )
{
    try
    {
        // Add to the leaf list
        m_VisibleLeaves.push_back( pLeaf );

    } // End Try Block

    catch ( ... )
```

```
    {
        return false;

    } // End Catch Block

    // Success!
    return true;
}
```

The application should never call this function; it should be left to the tree's visibility system to build this list with each visibility pass. In particular, it is only the CBaseLeaf::SetVisible method that ever calls this function to add its own pointer to the list.

GetVisibleLeafList - CBaseTree

This method is exposed purely for the application's benefit. The application can call this method to get returned the list of currently visible leaves. This is the leaf list that was compiled the last time the application called the ISpatialTree::ProcessVisibility method.

```
CBaseTree::LeafList & CBaseTree::GetVisibleLeafList()
{
    return m_VisibleLeaves;
}
```

While it might not seem apparent just yet why the application may want to know which leaves are visible (especially when the tree takes care of rendering its visible polygon data), we will see later how this information will be important for the efficient rendering of dynamic objects. The application is going to be responsible for rendering these objects (not the tree) and thus, retrieving the list of currently visible leaves from the tree and then retrieving the dynamic object pointers stored in those leaves, provides the application with the list of currently visible dynamic objects that need to be rendered.

GetLeafBin - CBaseTree

The GetLeafBin method will generally never be called by the application. It is used by the tree during the building of the render data to fetch a leaf bin pointer from the map. For example, if the build process finds a polygon with an attribute of 7 it knows that it has to add its indices to leaf bin 7. As this leaf bin might have already been created (when processing another polygon with the same attribute ID), this method will quickly retrieve the pointer to that leaf bin and return it to the building process. If there is currently no key in the leaf bin map that matches the passed attribute ID the function returns NULL. This informs the calling function that the leaf bin associated with subset 7 has not yet been created, so it should do so now.

```
CLeafBin * CBaseTree::GetLeafBin( unsigned long nAttribID )
{
    LeafBinMap::iterator Item = m_LeafBins.find( nAttribID );
```

```
    // We don't store this attrib ID
    if ( Item == m_LeafBins.end() ) return NULL;

    // Return the actual item
    return Item->second;
}
```

Although it might seem strange that we have not just indexed into the map using the attribute ID (using an array style approach), if we do this and the key/value pair does not exist in the table, this new row will be added with a value of NULL. However, we want this function to return the pointer only if it does exists and not create the row in the hash table if it does not. For this reason, we use the STL map's find method.

The find method does not perform a search through the entire table row by row as its name would perhaps imply. It efficiently jumps straight to the row in the table with the matching key and returns the iterator to that item in the table. If the key (attribute ID) did not exist in the map, then the iterator will point to the end of the map (like a hash table's equivalent of a NULL return). If this is the case, we return NULL from the function. Otherwise we fetch the leaf bin pointer stored in the returned iterator's 'second' member and return it (the key itself is stored in the 'first' member of the iterator).

We have now looked at the small utility functions in CBaseTree which we will need during the render data building process. In the next section, we will discuss the new methods in CBaseTree that are executed once, just after the tree has been built, to compile the tree's static polygon data into vertex and index buffers, and leaf bins.

15.4.2 The Building Phase – Compiling the Render Data

The entire building phase is invoked from the CBaseTree::PostBuild method introduced in the previous lesson. This method is called by the derived classes just after the tree has been built (at the very bottom of their Build functions). We discussed how and why this function calls the CalculatePolyBounds function in the previous lesson to build and store the AABBs for each CPolygon in the tree. What we have not yet seen are the contents of the second method that it calls. The BuildRenderData method is the method that compiles the data into a renderable format. It creates all the vertex and index buffers used by the tree and creates and populates the leaf bins.

```
bool CBaseTree::PostBuild(  )
{
    // Calculate the polygon bounding boxes
    CalculatePolyBounds( );

    // Build the render data
    return BuildRenderData( );
}
```

BuildRenderData - CBaseTree

This function is a very large and seemingly complex function. The function could be made shorter by moving multiple processes into a single loop (instead of doing a separate loop for each process), but this would have made the function must harder to break into components for the purpose of explanation. Before we dive into the code, we will discuss what purpose of this function is, the tasks it must perform, and the way those tasks will be implemented. We will then find that this code is not nearly as intimidating as it first seems.

When the function is first called, no vertex buffers or index buffers will have been created. The function will allocate a temporary array of vertices that will be used to collect the vertices of each polygon it processes. We can think of this array initially as collecting the vertices for the first (and possibly only) vertex buffer that will be created. Likewise, the function will also allocate an array of temporary buffers to create the indices for each leaf bin. That is, if the scene contains polygon data for 15 subsets, we will create an array to store 15 sets of indices, one for each leaf bin. We can think of these initial index arrays as being used to collect the indices that are associated with the first vertex buffer.

The thing the function will do is call the CBaseTree::Repair method. We discussed this function in the previous lesson and saw how removes T-junctions in the polygon dataset. We call this automatically in the case of this particular function because we know this data is being used for rendering and we certainly do not want any T-junctions in our renderable data (they cause lighting artifacts and generate sparklies). After the Repair function returns, we have our data ready to be compiled for rendering with all T-junctions removed.

The next step will be to call the CollectLeavesAABB method passing in the bounding box of the root node. This will collect all the leaves of the tree into a leaf list in the exact order in which the tree would be traversed if every leaf was visible. This is very important as it allows us to add the triangles from each leaf into the leaf bin index buffers in the order in which they will be traversed. This greatly increases our changes of creating large render batches during the visibility pass.

Once we have the leaf list, we will loop through and process each leaf. For each leaf we will process the polygons in that leaf. For each polygon we will retrieve its attribute ID and fetch the associated leaf bin for that subset. If a leaf bin has not yet been created for that subset, we will create a new leaf bin for it. The whole point of this process is to make sure that at the end of the loop we have a leaf bin created and stored in the tree for every subset used by the tree. As we process each polygon, we will also calculate the number of indices that should be generated for it and add it to the temporary index array for that leaf bin. Therefore, at the end of the leaf loop we will have made sure that a leaf bin has been created for every subset used by the tree, and we will have recorded exactly how many indices we will need to allocate the temporary index arrays (for each leaf bin) to hold.

Before we go any further, let us cover the first sections of the code that perform these steps. First we will look at the local variables allocated at the top of the function as some of them are extremely significant.

```
bool CBaseTree::BuildRenderData(  )
{
```

```
    LeafList::iterator LeafIterator;
    map<ULONG,ULONG>   BinSizes;
    map<ULONG,ULONG*>  BinIndexData;
    LeafList           Leaves;
    ULONG              nMaxVertexCount, nPolygonCount, nTotalVertices;
    ULONG              nVertexCount, i, j;
    D3DCAPS9           Caps;
    CBaseLeaf        * pLeaf;
    CLeafBin         * pLeafBin;
    CVertex          * pVertices = NULL;
    bool               b32BitIndices = false;
    D3DXVECTOR3        Min, Max;

    CBaseLeaf::RenderData          * pRenderData;
    CBaseLeaf::RenderData::Element * pElement;
```

Notice the two local variables that are highlighted in bold in the above code. These two STL maps are vital to the building process. The first stores ULONGs as both its keys and values and will be used in the initial loop (just described) to record the number of indices we found for each subset/leaf bin. The key of each row in the hash table will be the attribute ID and the value will be the number of indices we recorded that will need to be generated for it. The second STL map is the partner of the previous one and will be used to store the temporary index arrays being collected for each leaf bin. The key is a ULONG which once again stores the attribute ID that its value is relative to. The value is a ULONG pointer that will be allocated to store as many indices as is described by the row in the BinSizes map with the matching key (attribute ID).

For example, imagine that after looping through the leaf list and processing however many indices will be generated by all the polygons, we find that the tree uses subsets 3, 6, and 9. Let us also assume that the number of indices recorded for each subset was 100, 200, and 300, respectively. At the end of the first loop, the following key/value pairs will be stored in the BinSizes map.

BinSizes [3] = 100
BinSizes [6] = 200
BinSizes [9] = 300

The three rows in the map now tell us that we will need to create a temporary index array to collect the 100 indices for the first leaf bin (subset 3), an array to collect 200 indices for the second leaf bin (subset 6) and an array of 300 to collect the indices for the third leaf bin (subset 9).

After the loop, we can then allocate these temporary arrays in the BinIndexData map with code like the following:

```
// Allocate temporary buffers for each of the bin items
map<ULONG,ULONG>::iterator BinSizeIterator = BinSizes.begin();
for ( ; BinSizeIterator != BinSizes.end(); ++BinSizeIterator )
{
    ULONG AttribID = BinSizeIterator->first;
    ULONG Size     = BinSizeIterator->second;

    if ( Size > 0 )
```

```
            BinIndexData[ AttribID ] = new ULONG[ Size ];
        else
            BinIndexData[ AttribID ] = NULL;

        // Reset sizes back to 0, we're going to tally as we go
        BinSizes[ AttribID ] = 0;

    } // Next Bin
```

As you can see, we loop through each row in the BinSizes table (one per subset used by the tree) and extract the key (attribute ID) and the indices size. We then use this size to allocate an array of indices which is assigned to the row in the BinIndexData map with a matching attribute. The function would then proceed to fill up these index arrays with the indices intended for each leaf bin.

Now that we know how these two maps will be used in tandem to represent the index arrays being compiled for each leaf bin, let us examine the first section of the function that creates the leaf bins and records the number of indices that will be needed for each subset.

The first thing we do is test to see if the device pointer is valid. If not, there is no point in initializing the render system and we simply return. Also, if the tree has no leaves we also have no polygon data so we return false. Provided the device and the leaf array are valid, we then call the CBaseTree::Repair method to remove any T-junctions that may exist in the polygon data.

```
    // Instructed not to build data?
    if ( !m_pD3DDevice ) return true;

    // Anything to do ?
    if ( m_Leaves.size() == 0 ) return false;

    // First thing we need to do is repair any T-Junctions created during the build
    Repair( );
```

We will now need to fetch the list of leaves contained in the tree. However, as this leaf list will be iterated through in order and each leaf's polygons added to the leaf bins, we want this leaf list ordered in the same way that the leaves will be encountered when the visibility traversal is performed. This will ensure that we get the most optimal render batches during visibility traversal. To do this we simply fetch the bounding box of the scene (i.e., the root node's bounding box) and feed this box into the CollectLeavesAABB method. When the function returns, the local leaf list passed in as the first parameter will be filled with all the leaves contained in the tree in traversal order.

```
    // Retrieve the leaf list in TRAVERSAL order to ensure that the
    // render batching works as efficiently as possible
    GetSceneBounds( Min, Max );
    CollectLeavesAABB( Leaves, Min, Max );
```

We will now set up a loop that will loop through each leaf and record the total number of indices that will be generated for each subset. We will also allocate the leaf bins for each subset.

For each leaf we fetch its polygon count and then loop through each polygon in the leaf. Notice also that at the top of the next section of code, we set the local variable nTotalVertices to zero. This will be used to also record the total number of vertices stored in the tree (from all polygons).

```
    // Iterate through all of the polygons in the tree and allocate/add to
    // leaf bins.  In addition, total up the index counts required for each bin.
    nTotalVertices = 0;

    for ( LeafIterator = Leaves.begin();
          LeafIterator != Leaves.end();
          ++LeafIterator )
    {
        // Retrieve leaf
        pLeaf = (CBaseLeaf*)(*LeafIterator);
        if ( !pLeaf ) continue;

        // Loop through each of the polygons stored in this leaf
        nPolygonCount = pLeaf->GetPolygonCount();

        for ( i = 0; i < nPolygonCount; ++i )
        {
```

In this loop we fetch a pointer to each polygon in the leaf. If for some reason its vertex count is smaller than 3, then this is an invalid triangle and we skip it. We also skip the polygon if its m_bVisible Boolean is set to false. The application can set a CPolygon's visibility status to false prior to registering it with the tree. This will allow the application to register polygons that will still be used for collision detection queries but will not be rendered. You will see later when we discuss the changes to our application that we set this flag to false for transparent polygons before they are registered with the tree. Transparent polygons will be rendered by our BSP tree (discussed in the next chapter) so that we can get perfect back to front ordering. However, we still want to register such polygons with the spatial tree so that a 'Glass' polygon for example is still considered a solid polygon by the collision system. Therefore, this flag allows our application to say to the tree, "Here is a static polygon for collision purposes, but do not render it as I will render it on my own using a different methodology."

```
            CPolygon * pPoly = pLeaf->GetPolygon( i );

            // Skip if it's invalid
            if ( !pPoly || pPoly->m_nVertexCount < 3 ) continue;

            // Skip if it's not visible
            if ( !pPoly->m_bVisible ) continue;

            // Retrieve the leaf bin for this attribute
            pLeafBin = GetLeafBin( pPoly->m_nAttribID );
```

In the code above, we see that once we have a pointer to a valid renderable CPolygon, we pass its attribute ID into the CBaseTree::GetLeafBin function. If a leaf bin has already been created for this subset, a pointer to the leaf bin will be returned and stored in the pLeafBin local variable pointer. If we have encountered a polygon which belongs to a subset that we have not yet encountered and created a

leaf bin for, the GetLeafBin method will find no such leaf bin and the returned value of NULL will be stored in pLeafBin.

If pLeafBin is NULL then it means we have found a polygon that a leaf bin does not yet exist for, so we had better create one. In the next section of code, we allocate a new leaf bin (passing in the attribute ID the leaf bin is intended to store triangles for and the total leaf size of the tree) and store the leaf bin's pointer in the CBaseTree's m_LeafBins map with a key equal to the attribute ID.

```
            // Determine if there is a matching bin already in existance
            if ( !pLeafBin )
            {
                try
                {
                    // Allocate a new leaf bin
                    pLeafBin = new CLeafBin( pPoly->m_nAttribID, m_Leaves.size() );
                    if ( !pLeafBin ) throw std::bad_alloc(); // VC++ Compat

                    // Add to the leaf bin list
                    m_LeafBins[ pPoly->m_nAttribID ] = pLeafBin;

                } // End Try Block

                catch ( ... )
                {
                    // Clean up and fail
                    if ( pLeafBin ) delete pLeafBin;
                    return false;

                } // End Catch Block

            } // End if no bin existing
```

At this point we have either confirmed that a bin exists that will accept this polygon or we have created a new one that will collect polygons of this type. We will now increment the value stored in the row of the BinSizes map that has a key equal to the current polygon's subset. This allows us to record the indices for each subset in the BinSizes map as we go. We will need to break our clockwise winding polygons into a series of triangles to store in a triangle list (for the index buffer), and we have previously discovered that the number of triangles produced will be equal to the number of vertices in the polygon minus 2 (see Figure 15.3).

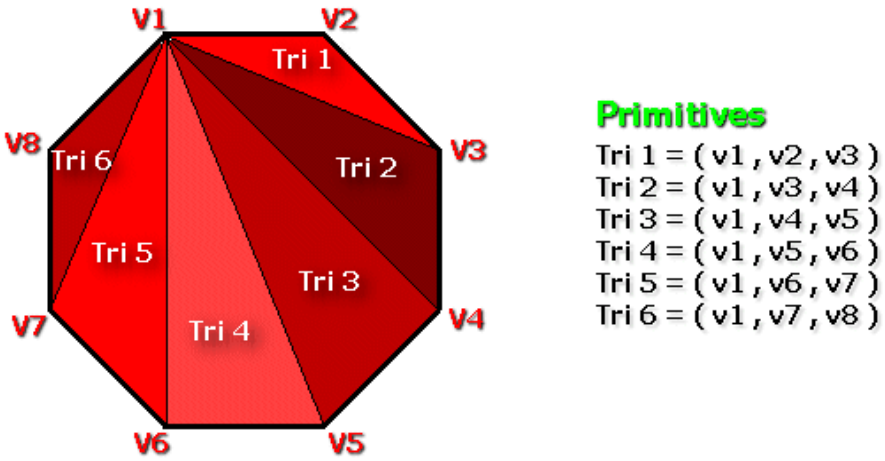

Figure 15.3

In this example we can see that the 8 vertices describe 6 triangles (vertex count - 2). Therefore, as each triangle will be described by three indices in the index buffer, the total number of indices that will be generated by the current polygon will be (VertexCount - 2) * 3.

In the following code you can see that we perform this calculation and add the resulting index count to the value of the row in the map with a key that matches the attribute ID of the polygon. We also add the vertex count of the polygon to the nTotalVertices local variable so that we record the total number of vertices in the entire tree after the entire leaf loop completes.

```
            // Add each of the triangles to the total index count.
            BinSizes[ pPoly->m_nAttribID ] += (pPoly->m_nVertexCount - 2) * 3;

            // Total up vertices
            nTotalVertices += pPoly->m_nVertexCount;

        } // Next Polygon
    } // Next Leaf
```

At this point we are no longer in any loops and we have created the leaf bins for every subset in the tree. We have also recorded the total number of vertices stored in the tree in the nTotalVertices variable. Finally, we have recorded, for each subset, the total number of indices that will be generated for that subset. These index counts are stored in the BinSizes map, keyed by subset/attribute ID. At this point we have collected no vertices or indices and we have not yet added any data to any leaf bins.

What we know is how many vertices we are going to need to store, which allows us to find out two things. First, if the vertex count is larger than the maximum number of vertices the device allows to be stored in one vertex buffer, we know we will need multiple vertex buffers. Second, if the number of vertices we have exceeds 65,535 (0xffff), we know that we will need 32-bit indices to reference them as we cannot fit values greater than this size into a 16-bit index.

First we get the capabilities of the device and retrieve the value of the maximum vertex index capability. This is stored in the D3DCAPS9::MaxVertexIndex member. As the maximum vertex index tells us the maximum index of a vertex that is allowed on the current device, adding one to this amount (remembering that indices are zero based) tells us the total number of vertices that can be placed in a single vertex buffer on this device. We store this value in the nMaxVertexCount local variable.

```
    // Calculate the maximum vertex count the card is capable of storing
    m_pD3DDevice->GetDeviceCaps( &Caps );
    nMaxVertexCount = Caps.MaxVertexIndex + 1;
```

Now that we know the maximum number of vertices that can be stored in a vertex buffer, we should test to see if this is smaller than the total number of vertices used by our tree's static geometry. If it is not, then it means the current device can handle all the vertices we have in a single vertex buffer. When this is the case we simply modify the value of nMaxVertexCount to equal the total number of vertices in the scene. We can think of the nMaxVertexCount member as containing the vertex count at which we will have to create a new vertex buffer during the vertex collection process.

```
    // If it's more than capable, just clamp it to the scene vert count
    if ( nMaxVertexCount > nTotalVertices ) nMaxVertexCount = nTotalVertices;
```

At this point, nMaxVertexCount will contain either the total number of vertices in our tree (if the hardware can handle them all) or the maximum number of vertices that can fit in a single vertex buffer on this device. If this is larger than 65,535 (0xffff) then we will need to create 32-bit index buffers, so we set the local b32BitIndices Boolean to true so we will know this when creating leaf bin index buffers later.

```
    // Determine if we need to use 32 bit indices or not
    b32BitIndices = ((nMaxVertexCount - 1) > 0xFFFF) ? true : false;
```

Since nMaxVertexCount describes the maximum size that the vertex buffers we create will be, we only create a vertex buffer once we have collected this many vertices. Therefore, we create a temporary vertex array of this size that will be used to collect the vertices for each vertex buffer. Once this buffer is full, a hardware vertex buffer will be created, the data copied over, and the array's count set back to zero again. The array will then be reused to collect vertices for the next vertex buffer, and so on.

```
    // Allocate temporary vertex array
    pVertices = new CVertex[nMaxVertexCount];
    if ( !pVertices ) return false;

    nVertexCount = 0;
```

The BinSizes map contains the total number of indices that will be generated for each leaf bin's index buffers. Just as with the temporary vertex array, we will use the BinIndexData map to store pointers to temporary index buffers that will be used to collect the indices for each leaf bin for the current vertex buffer. Once the pVertices array is full and the vertices are committed to a vertex buffer, index buffers will be created for each subset that we collected indices for and the contents of these temporary index arrays will be copied into the index buffers. Each new index buffer will then be added to a leaf bin and

the temporary index arrays stored in the BinIndexData map will be reused to collect the indices for each subset for the next vertex buffer, and so on.

The next section of code loops through every row in the BinSizes map and fetches each key/value pair into the AttribID and Size local variables. If the size of a given row is greater than zero then it means that there are some indices that will be generated for this leaf bin during the index collection process (shown in a moment). Therefore, we allocate an array of indices for each leaf bin used by the scene that is large enough in size to store all the indices recorded for that leaf bin in the above code. After this loop is finished, the LeafIndexData map will store a pointer to an index array for each leaf bin.

```
    // Allocate temporary buffers for each of the bin items
    map<ULONG,ULONG>::iterator BinSizeIterator = BinSizes.begin();
    for ( ; BinSizeIterator != BinSizes.end(); ++BinSizeIterator )
    {
        ULONG AttribID = BinSizeIterator->first;
        ULONG Size     = BinSizeIterator->second;

        if ( Size > 0 )
            BinIndexData[ AttribID ] = new ULONG[ Size ];
        else
            BinIndexData[ AttribID ] = NULL;

        // Reset sizes back to 0, we're going to tally as we go
        BinSizes[ AttribID ] = 0;

    } // Next Bin
```

Notice that the BinSizes map which had its values recorded in the first loop has only been used for the allocation of the temporary index arrays for each subset. As we allocate the index array for each leaf bin, we reset its associated BinSize value to zero. That is because we will use the BinSize map later to record how many indices we have currently added to each leaf bin, which will be used in the generation of the leaf RenderData structures (more on this in a moment).

In the next section of code we will loop through the leaf list again, and through each leaf's polygon list and actually collect the indices and vertices of the polygons into their respective arrays. We will also create and populate the RenderData structures at each leaf (one for each subset contained in that leaf) and create the Elements for each RenderData structure. Remember, each Element in a RenderData structure contains a triangle range (index start and primitive count) for the current vertex buffer being compiled. If all the vertices fit in a single buffer, this loop will only ever create one render element in each leaf's RenderData structure(s). We shall also see two calls to CBaseTree member functions we have not yet covered. The first is called CBaseTree::CommitBuffers and is called once the vertex buffers are filled. It is this function which takes the vertices collected in the temporary vertex array and copies them into a newly allocated vertex buffer. It is also this function that copies the data stored in the index arrays for each subset and copies them into newly allocated index buffers. These index buffers are then stored in newly allocated CLeafBinData structures and added to the leaf bins. We will look at the code to this function in a moment. For now just know that this function is called when we have collected enough vertices and need to create actual Direct3D vertex and index buffers. It is called CommitBuffers because it is this function that takes the data stored in the temporary vertex and index arrays and commits them to static vertex and index buffers. After the CommitBuffers function returns, the data in

the temporary vertex and index arrays are discarded and the current vertex buffer count will have been increased from zero to one. If there are still more leaves or polygons left to the process, the cycle repeats and vertex and index data continues to get collected for the next round of vertex and index buffers that will be created the next time CommitBuffers is called. The code to this function will be covered after we have finished discussing the BuildRenderData method.

The second new CBaseTree method called inside this loop is the WeldBuffers method. This function will be called whenever we fill up the temporary vertex array in an effort to compact the data and get rid of duplicated vertices. We have discussed welding many times throughout this course and understand that it will collapse multiple vertices that share identical properties into a single vertex. This potentially reduces the vertex count and will allow us to fit more vertices in the buffer. Of course, if the vertices are altered or compacted, the weld operation will also need to update the indices so that triangles that indexed vertices that have been removed are now mapped to the vertex they were collapsed onto. Once we find that we cannot add any more polygon vertices to the temporary vertex array without exceeding the maximum vertex count of the hardware, we will call the weld function to try to compact the vertex data in this array and make room for some more vertices. This function will need to be passed not only the temporary vertex array that will be compacted, but also the map of index buffers containing the indices currently collected for each subset that index into this vertex array. These index arrays will also have to be updated so that they correctly index into the compacted vertex array. The contents of this function will also be discussed shortly.

Continuing where we left off, we are now at the point where we have allocated an array to hold the vertices we are going to collect for the vertex buffer we are about to build. We have also allocated an array of indices to record the indices generated for each leaf bin (stored in the BinIndexData map).

We will now loop through each leaf and through each polygon in that leaf. If the current polygon being processed is either invalid or invisible, we skip it and continue to the next iteration of the polygon loop.

```
    // Now we actually build the renderable data for the TRAVERSAL ordered
    // leaf list.
    for ( LeafIterator = Leaves.begin();
          LeafIterator != Leaves.end();
          ++LeafIterator )
    {
        // Retrieve leaf
        pLeaf = (CBaseLeaf*)(*LeafIterator);
        if ( !pLeaf ) continue;

        // Loop through each of the polygons stored in this leaf
        nPolygonCount = pLeaf->GetPolygonCount();

        for ( i = 0; i < nPolygonCount; ++i )
        {
            CPolygon * pPoly = pLeaf->GetPolygon( i );

            // Skip if it's invalid
            if ( !pPoly || pPoly->m_nVertexCount < 3 ) continue;

            // Skip if it's not visible
            if ( !pPoly->m_bVisible ) continue;
```

At this point we have a pointer to the current polygon we are going to process. First we will assign a ULONG pointer to point at the index array in the BinIndexData map for the polygon's subset. We will also assign a pointer to point at the BinSizes value for this subset. This will be set to 0 if this is the first polygon with the current subset we have found so far in the loop.

```
            ULONG * pIndexData = BinIndexData[ pPoly->m_nAttribID ];
            ULONG * pBinSize   = &BinSizes[ pPoly->m_nAttribID ];
```

Just so we understand these variables, pIndexData points to the index buffer we allocated earlier for the leaf bin with the same attribute ID as the current polygon. This pointer will be used to store the indices of the polygon in the array. pBinSize will point to the value in the size map for this polygon's subset so that we can increment the size as we add indices to the index array. This means, with each polygon we add, pBinSize will always tell us how many indices we have currently collected in this subset's index array and therefore, at what location to place the new indices.

Our next task is to fetch the leaf bin that the polygon will be assigned to. We pass the polygon's attribute ID into the GetLeafBin method to retrieve a pointer to the leaf bin that is assigned to the polygon's subset and will ultimately receive its indices.

```
            // Retrieve the render data item for this leaf / attrib ID
            pLeafBin    = GetLeafBin( pPoly->m_nAttribID );
            pRenderData = pLeaf->GetRenderData( pPoly->m_nAttribID );
```

Notice in the above code how we also call the leaf's GetRenderData method to fetch the RenderData structure in the leaf for the current subset. Remember, there will ultimately be a RenderData structure stored in the leaf for every subset contained in that leaf as it is inside the RenderData structure that the leaf's triangle range (for that subset) is stored. Of course, at this point, the leaf may not have a RenderData structure allocated for it if this is the first polygon we have encountered in the current leaf that has this subset. Therefore, if a RenderData structure exists in the leaf for the passed subset, its pointer will be stored in pRenderData. If not, pRenderData will be assigned a value of NULL, which means we had better allocate one.

```
            // If we were unable to find a render data item yet built for this
            // leaf / attribute combination, add one.
            if ( !pRenderData )
            {
                pRenderData = pLeaf->AddRenderData( pPoly->m_nAttribID );
                if ( !pRenderData ) return false;

                // Store the leaf bin for later use
                pRenderData->pLeafBin = pLeafBin;

            } // End if no render data
```

As you can see in the above code, if the current leaf being processed does not yet have a RenderData structure allocated for it for the subset of the current polygon being processed, we allocate a new one in that leaf by using the CBaseLeaf::AddRenderData method and passing in the subset ID/leaf bin we would like it associated with. The function will return a pointer to a new RenderData structure which we

will store in the pRenderData local pointer. We will then use this pointer to assign the RenderData's pLeafBin member to point at the leaf bin that will contain its indices (which was fetched above)

At this point we have the polygon we are currently processing and we also have the RenderData structure associated with its subset for the current leaf we are processing. The m_nVBCount local variable describes the index of the vertex buffer we are currently collecting vertices and indices for. This will obviously be 0 at the start of the function since we are collecting vertices for vertex buffer[0] in the tree's vertex buffer array. Every time the vertex array is filled up and the CommitBuffers method is called to create the vertex and index buffers, this value will be incremented. For example, after the first set of buffers has been created, it will contain an index of 1 and we will know that any vertices we collect are going to be assigned to the tree's second vertex buffer. We also know that the next set of index buffers we create for the leaf bins will index into this second buffer.

Each RenderData structure in a leaf (remember, there will be one for each subset stored in that leaf), will contain an array of one or more Element structures. For example, if a leaf has a series of polygons belonging to the same set that ultimately ends up getting spread over two vertex buffers, the RenderData structure for that subset (in that leaf) will have two Element structures. Each Element contains the run of triangles for one of those vertex buffers.

So now that we know which RenderData item this polygon's triangles need to be added to, we have to get the Element structure within it for the current vertex buffer being compiled. In the next section of code we loop through each Element in the RenderData's element array to search for the one that has a vertex buffer index assigned to it that is equal to the vertex buffer we are currently compiling data for (m_nVBCount). When we find the correct element to add the polygon's triangles to, we break from the loop as shown below.

```
            // Search for element associated with the current vertex buffer
            for ( j = 0; j < pRenderData->ElementCount; ++j )
            {
                pElement = &pRenderData->pElements[j];
                if ( pElement->VBIndex == m_nVBCount ) break;

            } // Next Element
```

If, at the end of the above loop, the loop variable *j* is equal to the RenderData's current element count, it means the loop did not break early. This tells us that the RenderData structure does not currently have an Element for the vertex array currently being compiled. This also means the current polygon is the first we have found in this leaf that uses this subset since collecting data for the current vertex buffer. Thus we will have to add a new Element to the RenderData's element array.

The following code adds a new Element structure to the leaf's RenderData structure that matches the attribute ID of the polygon currently being processed. This is all handled in the CBaseLeaf::AddRenderDataElement function. It finds the RenderData structure in its array with an attribute that matches the polygon's and adds a new Element structure to the end of its element array. It then returns a pointer to this new element.

```
            // If we reached the end, then we found no element
```

```
            if ( j == pRenderData->ElementCount )
            {
                // Add a render data element for this vertex buffer
                pElement = pLeaf->AddRenderDataElement( pPoly->m_nAttribID );
                pElement->IndexStart     = *pBinSize;
                pElement->PrimitiveCount = 0;
                pElement->VBIndex        = m_nVBCount;

            } // End if no element for this VB
```

Notice in the above code how once we get back the new Element for the current vertex buffer, we set its primitive count to 0 as no triangles have been added to it yet. We also set its VBIndex member to the current value stored in m_nVBCount. This tells us the number of vertex buffers we have created so far and therefore, the index of the current vertex buffer we are collecting data for.

What requires a little explanation is why we set the IndexStart value of this element to the value currently contained in pBinSize. We saw just inside the polygon loop that this is used to point at the value in the row of the BinSizes map that records the current number of indices that have been collected so far for this attribute. This was set to zero for every subset at the beginning of the leaf loop and will be incremented every time we add indices to the corresponding index array. Therefore, the value pointed at by this pointer will always contain the number of indices we have added to that subset's temporary index array so far. Therefore, we know that the indices we are about to add for the current polygon we are processing will begin at that location in the buffer. To clarify, if the pBinSize pointer points to a value of 6 and the polygon we are currently processing belongs to subset 20, it means we have current added 6 indices to the temporary index array stored at BinIndexData[20]. When we add the current polygon's indices to this same array, and because we only enter the above section of code if we have just created a new element, this triangle must be the first triangle we have found in the leaf so far for the current vertex buffer being compiled. Thus, its first index will be the start index for the run of triangles that use this subset and may exist in this leaf.

At this point we have the polygon itself, the leaf bin in which it is contained, the RenderData structure within that leaf that pertains to the subset of the polygon, and the Element structure in that RenderData structure that references the current vertex buffer being compiled. We are now ready to start adding the vertices and indices in this polygon to their respective buffers.

Before we can add the vertices of any of the polygon's triangles to the vertex array (pVertices), we first make sure that there is room enough to do so. If the current number of vertices we have collected in the vertex array so far (nVertexCount) is greater than the maximum number of vertices we will be able to store in a single vertex buffer (nMaxVertexCount) minus 3 (we need at least three spare slots to add the next triangle), it is time to commit the vertex array and all the index arrays we have compiled for each leaf bin to Direct3D vertex and index buffers.

However, before we do, we will perform a weld on the vertex array just to make sure that we cannot compact the vertex data and make some more room in there. Therefore, in the next section of code, once we realize there is no more room left in the vertex array for another triangle, we call the CBaseTree::WeldBuffers method. As the job of this method is to remove duplicated vertices (and remap the indices accordingly), the function returns the new vertex count describing how many vertices are in

the passed vertex array after the weld has been performed. Since the function will also have the job of remapping all the index arrays that reference vertices that get collapsed in the weld process, we must also pass this function the map of index arrays (for each leaf bin).

```
            if ( nMaxVertexCount != nTotalVertices &&
                 nVertexCount > nMaxVertexCount - 3 )
            {
                // Weld the data built so far
                nVertexCount = WeldBuffers( nVertexCount,
                                            pVertices,
                                            BinIndexData,
                                            BinSizes );
```

We will look at the code to this function later, so for now just know that when it returns, the pVertices array may have had vertices removed. The return value (which we store in nVertexCount) describes the new number of vertices in this array. On function return, any index arrays stored in the BinIndexData map will have had some of their indices remapped to new vertex positions in the array if these indices referenced vertices that were collapsed during the weld operation.

After the weld has been performed it is entirely possible that we may have made more space in the vertex buffer and may now have enough space to add the triangles in this polygon. However, if the vertex count of the pVertices array is still too large and we cannot add another triangle, we must commit the buffers using the CBaseTree::CommitBuffers method as shown below.

```
                // If there is still not enough room commit buffers
                if ( nVertexCount > nMaxVertexCount - 3 )
                {
                    CommitBuffers( nVertexCount,
                                   pVertices,
                                   BinIndexData,
                                   BinSizes,
                                   b32BitIndices );

                   nVertexCount = 0;

                    // Add a new render data element and prepare it
                    pElement = pLeaf->AddRenderDataElement( pPoly->m_nAttribID );
                    pElement->IndexStart     = 0;
                    pElement->PrimitiveCount = 0;
                    pElement->VBIndex        = m_nVBCount;

                } // End if start a clean buffer.

            } // End if not enough room for even a single triangle.
```

The CommitBuffers method is passed the vertex array that we have compiled so far and the map containing all the index arrays we have compiled for this vertex array so far. It is also passed the size of the vertex array and the map describing the size of the index arrays contained in the BinIndexData map. Note that we also pass the Boolean that describes to this function whether or not it should create 32-bit or 16-bit index buffers.

The CommitBuffers method is not a large method, but it has a very important job. For starters, it creates a new vertex buffer and populates it with the data in the passed vertex array and then adds this vertex buffer to the tree's vertex buffer array. It will also loop through every row in the BinIndexData map and extract the index arrays compiled for each leaf bin (for the current vertex buffer). For each index array, it will create a new index buffer and populate it. Then it will add each index buffer to the correct leaf bin which should own it. After the index buffer for each leaf bin has been created, its corresponding size value in the BinSizes map will be reset to zero so that we can start collecting new indices for the next vertex buffer. This function will also increase the tree's m_nVBCount variable so that it reflects the new number of vertex buffers stored in the tree.

When the function returns, we wish to start the collection process all over again (the index array counters have already been reset back to zero in the BinSizes map by the CommitBuffers function). Therefore, we set the current vertex count back to zero so that the vertex array can be used again to collect vertices for the next vertex buffer. This means that any Elements we create from this point on (in the RenderData structures of each leaf) will describe triangle runs in the new vertex buffer we are about to build.

Finally, notice in the above code that once we have committed the buffers, we have essentially deduced that the polygon being processed will be added to a new Element in the leaf's RenderData structure (describing triangle runs in the new vertex buffer we are just about to compile). Therefore, we add a new Element to the RenderData structure that is linked to the new vertex buffer we are about to create. Remember, the CommitBuffers method would have incremented the value of m_nVBCount so that it now contains the index of the next vertex buffer we will create the next time CommitBuffers is called. We still have not added the polygon's indices to this Element yet, so we set the primitive count of this new structure to 0. Further, because we have just committed the buffers, we know this polygon's triangles will be positioned at the start of the index buffer that will be created for the new vertex buffer (for the leaf bin associated with the polygon attribute). Therefore, we can set the index start to zero as well.

As discussed many times before, we will add the polygon triangles to the index buffer by stepping around each vertex in the polygon. For each vertex we will add it to the vertex array and for every vertex beyond the second one, we will create indices for the first vertex in the polygon, the previous vertex in the edge, and the current vertex. These three indices will be added to the index array associated with this leaf bin and the pBinSize pointer will have the value it points at (the number of indices in the array) incremented each time an index is added.

In the first section you will see us setting up a loop to step through each vertex in the edge. Notice just above the loop that we store the number of vertices currently in the vertex array in the FirstVertex local variable. This is important because we will need to keep track of where this polygon's vertices are being added from so that we can construct the right indices that index them.

```
            // Store triangle pre-requisites
            ULONG FirstVertex    = nVertexCount;
            ULONG PreviousVertex = 0;

            // For each triangle in the set
            for ( j = 0; j < pPoly->m_nVertexCount; ++j )
```

```
            {
                // Add this vertex to the buffer
                pVertices[ nVertexCount++ ] = pPoly->m_pVertex[ j ];
```

If the current loop variable *j* is greater then or equal to 2, it means we have added at least three vertices from this polygon so far and we can start generating indices to describe its triangles. As Figure 15.4 illustrates, at vertex 3 we will add the indices for vertices 1, 2, and 3. At vertex 4 we will increment the previous vertex and the current vertex so that the next triangle indexes vertices 1, 3, and 4, and so on around the edges of the polygon.

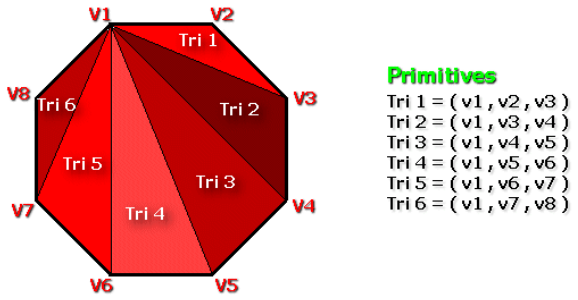

Figure 15.4

For every three indices we add to the index buffer we also know that we have just added a triangle (primitive) to the current element, so we increment the primitive count for that element. We then adjust the previous vertex by 1 so that it now points at the current vertex so that in the next iteration of the loop, we will have the next pair of vertices in the edge.

```
                // Enough vertices added to start building triangle data?
                if ( j >= 2 )
                {
                    // Add the index data
                    pIndexData[ (*pBinSize)++ ] = FirstVertex;
                    pIndexData[ (*pBinSize)++ ] = PreviousVertex;
                    pIndexData[ (*pBinSize)++ ] = nVertexCount - 1;

                    // Update leaf element, we've added a primitive
                    pElement->PrimitiveCount++;

                } // End if add triangle data

                // Update previous vertex
                PreviousVertex = nVertexCount - 1;
```

Because we are adding the polygons to our index buffers one triangle at a time, we may find that we might be only part of the way through adding its triangles when we fill up the vertex buffer. Looking at Figure 15.4 for example, we can see how the first vertex might be v1, the previous vertex might be v4 and the current vertex might be v5, which collectively describe triangle 3. However, after adding triangle 3, we might find that the vertex buffer is full and we have to switch buffers. If this is the case, we will first call the weld function to try compacting the vertex array, hopefully making enough room to add all the vertices in this polygon to the vertex array. Notice this time that we pass in two additional parameters to the WeldBuffers function.

```
                if ( nMaxVertexCount != nTotalVertices &&
                     nVertexCount == nMaxVertexCount )
                {
                    // Weld the data built so far
                    nVertexCount = WeldBuffers( nVertexCount,
                                                pVertices,
```

```
                                                BinIndexData,
                                                BinSizes,
                                                &FirstVertex,
                                                &PreviousVertex );
```

Because we are in the middle of stepping around the vertices of a triangle when we perform the weld, we will need to know where the position of the first vertex and the previous vertex in the edge got moved to during the weld. This tells us which vertices to use for the next triangle. For example, imagine we have just added triangle 3 in Figure 15.4 where the first vertex (v1) was at position 20 in the vertex buffer and the previous vertex (which was v4 when the triangle was added and was then increased to v5) was set to 24. We know that if the weld had not been performed, the next triangle added would consist of vertices 20, 24, and 25. However, after the weld, vertices 20 and 24 might get repositioned in the buffer to locations 10 and 14, in which case we will need to update the values stored in FirstVertex and PreviousVertex to these values so that the next triangle added will use vertices 10 and 14 and the next vertex in the edge. That is what the last two values to the weld function are for. The weld function will return the new positions of these vertices using these output parameters. That is, FirstVertex and PreviousVertex tell the weld function the two vertices we wish to track the changes for. After the weld is complete, these values will be updated with the new vertex positions.

Of course, if the weld function did not successfully make enough room in the vertex array for the next vertex in the polygon, we will need to commit the buffers and start collecting vertices and indices for the next vertex buffer.

```
                    // If there is still not enough room, commit the changes
                    if ( nVertexCount == nMaxVertexCount )
                    {
                        // Commit the changes
                        CommitBuffers( nVertexCount,
                                       pVertices,
                                       BinIndexData,
                                       BinSizes,
                                       b32BitIndices );

                        nVertexCount = 0;
```

What we have to remember is that if a polygon spans multiple buffers, we will need to also add the first vertex and previous vertex to the new buffer as well. For example, imagine in Figure 15.4 we have added triangle 1 and then we start a new buffer. The next vertex in the polygon to be processed would be v4 and the triangle that should be added to the new buffer would be <v1, v3, v4>. However, v1 and v3 exist in the previous vertex buffer so they cannot possibly be indexed by the new index buffers we are about to create. Therefore, we must make sure that these vertices exist in the new buffer as well.

In the next section of code we can see that if we do change buffers mid-polygon, we add a new element for that vertex buffer in the RenderData structure associated with the polygon's subset. We also assign its VBIndex member so that it describes the next vertex buffer that will be created the next time CommitBuffers is called. As we have not added any primitives yet, we will set its index start and primitive count to zero.

```
                        // If the polygon spans multiple VB's,
                        // then we need a new element
                        if ( (signed)j < pPoly->m_nVertexCount - 1 )
                        {
                            // Add a new render data element and prepare it
                          pElement=pLeaf->AddRenderDataElement(pPoly->m_nAttribID);
                          pElement->IndexStart     = 0;
                          pElement->PrimitiveCount = 0;
                          pElement->VBIndex        = m_nVBCount;
```

We will now add the first vertex in the polygon and the current vertex (which will become the previous vertex in the next iteration) to the first element of the new vertex array. We will then set this vertex array's count to 2 since we have only collected two vertices for this vertex array so far. We then assign the FirstVertex and PreviousVertex variables to contain the indices of the first and second vertices in the new vertex array so that in the next loop, the vertices we just duplicated in the new buffer are used to construct the next triangle. The remainder of the entire process is shown below.

```
                            // Since this polygon data is now split over multiple
                            // vertex buffers, we're going to need to re-add the
                            // first and previous vertices to the
                            // new buffer as well. This is so that we can form a
                            // valid triangle next time assuming there is any
                            // triangle data left to be processed for this polygon,

                            pVertices[0]   = pPoly->m_pVertex[ 0 ];
                            pVertices[1]   = pPoly->m_pVertex[ j ];
                            nVertexCount   = 2;
                            FirstVertex    = 0;
                            PreviousVertex = 1;

                        } // End if more triangles to come

                    } // End if not enough room.

                } // End if buffer full

            } // Next Triangle

        } // Next Polygon

    } // Next Leaf
```

At this point in the function we have processed every leaf and every polygon in the tree. We will have constructed vertex buffers and added them to the tree and we will have added (potentially) multiple index buffers to each leaf bin. Every leaf will contain a RenderData structure for each subset it contains, which in turn will contain an array of elements for every vertex buffer that subset (within that leaf) is contained within.

Of course, as the buffers are only committed once they are full, unless the very last vertex we added caused the buffers to be committed, there will still be vertices in the pVertices array and index arrays in the BinIndexData map that have not yet been committed. Therefore, as our final step, we weld any

vertices we have not yet committed before committing them too, creating one last vertex buffer and one last set of index buffers (one per leaf bin which has indices in the index arrays for this vertex buffer).

```
    // Build any remaining data
    if ( nVertexCount > 2 )
    {
        // Weld any remaining data and commit it
        nVertexCount = WeldBuffers( nVertexCount,
                                    pVertices,
                                    BinIndexData,
                                    BinSizes );

        CommitBuffers( nVertexCount,
                       pVertices,
                       BinIndexData,
                       BinSizes,
                       b32BitIndices );

    } // End if any data left to commit
```

With our render data constructed we must release all temporary memory that was not allocated on the stack. So we will iterate through each row in the BinSize map (one for each leaf bin) and extract its attribute ID and index array size. If this size if greater then zero, it means there is a corresponding index array in the BinIndexData map that needs to be deleted from memory. Thus we fetch the index array from the BinIndexData map with the matching attribute ID and call delete on its pointer.

```
    // Release temporary index buffer arrays
    BinSizeIterator = BinSizes.begin();
    for ( ; BinSizeIterator != BinSizes.end(); ++BinSizeIterator )
    {
        ULONG AttribID = BinSizeIterator->first;
        ULONG Size     = BinSizeIterator->second;
        if ( Size > 0 && BinIndexData[ AttribID ] )
            delete []BinIndexData[ AttribID ];

    } // Next Bin
```

We now delete the vertex array that was used to collect the vertices for each vertex buffer before returning a successful build indicator.

```
    // Release temp vertex array.
    if ( pVertices ) delete []pVertices;

    // Success!
    return true;
}
```

This was some very complicated code to try to absorb in one read, so fully expect to have to make a few passes over the source code to this function (and the explanations included here) to fully understand the relationships between the various components.

One of the major processes in the above function that we have yet to cover is the call to the CommitBuffers method. The code to this method will be discussed next.

CommitBuffers - CBaseTree

The function is passed an array of vertices which must be used to create a new vertex buffer for the render system. It will also be passed two STL maps. The first map's rows will contain an index array for each leaf bin. The number of rows in this map will be equal to the number of leaf bins used by the tree. This function will create an index buffer for each of these index arrays and store each index buffer in the relevant leaf bin. The second map that is passed (parameter four) describes the number of indices contained in each of the index arrays. The final parameter is a Boolean which tells the function whether the index buffer it creates for each leaf bin should use 16 or 32-bit indices.

The first thing the function does is grow the tree's vertex buffer array making room for an extra vertex buffer pointer at the end of the array. If there are current vertex buffer pointers in this array, this involves the allocation of a new array large enough to hold all the old buffer pointers plus the space at the end for the new buffer. The buffer pointers are then copied over from the old array into the new one and the old array is released. The tree's pointer to its vertex buffer array is then updated to point at this new array and the vertex buffer count is then increased.

```
bool CBaseTree::CommitBuffers( ULONG VertexCount,
                               CVertex * pVertices,
                               map<ULONG, ULONG*> & BinIndexData,
                               map<ULONG, ULONG> & BinSizes,
                               bool b32BitIndices )
{
    ULONG                      ulUsage = D3DUSAGE_WRITEONLY;
    LPDIRECT3DVERTEXBUFFER9 * ppVBBuffer, pVB;
    CVertex                 * pDestVertices;
    UCHAR                   * pDestIndices;
    ULONG                   * pIndices;
    HRESULT                    hRet;
    ULONG                      i;

    // First allocate space for a new vertex buffer
    ppVBBuffer = new LPDIRECT3DVERTEXBUFFER9[ m_nVBCount + 1 ];
    if ( !ppVBBuffer ) return false;

    // Any old data?
    if ( m_nVBCount > 0 )
    {
        // Copy over the old data, and release the old array
        memcpy( ppVBBuffer,
                m_ppVertexBuffer,
                m_nVBCount * sizeof(LPDIRECT3DVERTEXBUFFER9) );

        delete []m_ppVertexBuffer;

    } // End if any old data
```

```
    // Set the new entry to NULL
    ppVBBuffer[ m_nVBCount ] = NULL;

    // Store the new buffer pointer
    m_ppVertexBuffer = ppVBBuffer;
    m_nVBCount++;
```

Notice in the above code that we assign the ulUsage variable the value of D3DUSAGE_WRITEONLY. This variable will be used for the vertex buffer creation flags. We will inform Direct3D to create the vertex buffer in write only mode so that memory placement of the vertex buffer is chosen based on the best performance. If the current device is a software device (which will be stored in the tree's m_bHardwareTnL member passed into its constructor), the D3DUSAGE_SOFTWAREPROCESSING flag will need to be combined with ulUsage so that the vertex buffer is created in system memory (for efficient CPU transformation and lighting).

Next we allocate a new vertex buffer large enough to hold the number of vertices contained in the passed array. Allocation will be in the managed resource pool. We then store the newly create vertex buffer's pointer in the tree's vertex buffer array, as shown below.

```
    // Should we use software vertex processing ?
    if ( !m_bHardwareTnL ) ulUsage |= D3DUSAGE_SOFTWAREPROCESSING;

    // Create the actual vertex buffer ready to store the data
    hRet = m_pD3DDevice->CreateVertexBuffer( VertexCount * sizeof(CVertex),
                                             ulUsage,
                                             VERTEX_FVF,
                                             D3DPOOL_MANAGED,
                                             &pVB,
                                             NULL );
    if ( FAILED(hRet) ) return false;

    // Store the vertex buffer in the array
    // (so that it's released if anything goes wrong)
    m_ppVertexBuffer[ m_nVBCount - 1 ] = pVB;
```

With the new vertex buffer allocated and added to the tree's vertex buffer array, we then lock the vertex buffer and copy in all the vertices in the input vertex array before unlocking it.

```
    // Lock the vertex buffer ready to copy
    hRet = pVB->Lock( 0, 0, (void**)&pDestVertices, 0 );
    if ( FAILED(hRet) ) return false;

    // Copy over the data that we were passed
    memcpy( pDestVertices, pVertices, VertexCount * sizeof(CVertex) );

    // Unlock the buffer, we're done with VB creation
    pVB->Unlock();
```

The vertex buffer has now been dealt with. Next we have to create the index buffers for each leaf bin. First we set up a loop to iterate though each row in the BinIndexData map (one row for each leaf bin)

and extract the attribute ID for that row. This tells us what leaf bin the index array should be assigned to. We also extract the size of the index array (stored in the BinSizes map with the same key) and fetch a pointer to the leaf bin assigned to that attribute using the CBaseTree::GetLeafBin function.

```
    // Now that we've built the VB, we need to propogate the index data
    map<ULONG, ULONG*>::iterator DataIterator = BinIndexData.begin();
    for ( ; DataIterator != BinIndexData.end(); ++DataIterator )
    {
        ULONG AttribID = DataIterator->first;
        ULONG Size     = BinSizes[ AttribID ];

        // Retrieve the leaf bin
        CLeafBin * pLeafBin = GetLeafBin( AttribID );
        if ( !pLeafBin ) { BinSizes[AttribID] = 0; continue; }
```

Every index buffer added to a leaf bin is contained inside its own CLeafBinData structure inside the leaf bin's internal array of these structures. Thus, we allocate a new CLeafBinData structure.

```
        // Allocate a new LeafBinData structure
        CLeafBinData * pData = new CLeafBinData;
        if ( !pData ) return false;
```

We now instruct the leaf bin to add this CLeafBinData pointer to its internal array of CLeafBinData pointers.

```
        // Add to leaf bin, so that the data is released if something goes wrong
        if ( !pLeafBin->AddLeafBinData( pData ) ) { delete pData; return false; }
```

It is time to fill out the information for the CLeafBinData structure, including whether or not it uses 32-bit indices, the number of triangles that will be in the index buffer assigned to this CLeafBinData structure, and the index of the vertex buffer in the tree's vertex buffer array that this index buffer will index into. We also store the number of vertices in that vertex buffer in the structure.

```
        // Fill out the data items for this leaf bin.
        pData->m_b32BitIndices = b32BitIndices;
        pData->m_nFaceCount    = Size / 3;
        pData->m_nVBIndex      = m_nVBCount - 1;
        pData->m_nVertexCount  = VertexCount;
```

If the index array inside the BinIndexData map for this leaf bin has no indices, we will just skip generating an index buffer for this leaf bin (for this vertex buffer) and continue on to process the next leaf bin.

```
        // If there is no data here,
        // we'll just continue (but we must have allocated the leaf bin data)
        if ( Size == 0 ) continue;
```

If we get this far, it indicates that there are indices for the current leaf bin, so we will need to create an index buffer.

```
        // Create the index buffer ready to store the data
        UCHAR     IndexStride = ( b32BitIndices ) ? 4 : 2;
        D3DFORMAT Format      = (b32BitIndices) ? D3DFMT_INDEX32 : D3DFMT_INDEX16;

        hRet = m_pD3DDevice->CreateIndexBuffer( Size * IndexStride,
                                                ulUsage,
                                                Format,
                                                D3DPOOL_MANAGED,
                                                &pData->m_pIndexBuffer,
                                                NULL );
        if ( FAILED(hRet) ) return false;
```

With the index buffer for this leaf bin/vertex buffer combination allocated, we will now lock it and copy over all the index data from the index array for this leaf bin contained in the BinIndexData map.

```
        // Lock the index buffer ready to copy
        hRet = pData->m_pIndexBuffer->Lock( 0, 0, (void**)&pDestIndices, 0 );
        if ( FAILED(hRet) ) return false;

        // Copy over the buffer data
        if ( b32BitIndices )
        {
            // We can do a straight copy if it's a 32 bit index buffer
            pIndices = DataIterator->second;
            memcpy( pDestIndices, pIndices, Size * IndexStride );

        } // End if 32bit
        else
        {
            pIndices = DataIterator->second;
            for ( i = 0; i < Size; ++i )
            {
                // Cast everything down to 16 bit
                ((USHORT*)pDestIndices)[i] = (USHORT)pIndices[i];

            } // Next Index

        } // End if 16bit

        // Unlock the buffer, we're done with IB creation

        pData->m_pIndexBuffer->Unlock();
```

Notice in the above code that when we create the index buffer, we store the returned pointer in the leaf bin's CLeafBinData structure.

Next we assign the address of the vertex buffer we have just created to the CLeafBinData's vertex buffer pointer so that this structure now contains pointers to both the vertex buffer and the index buffer that should be bound to the device in order to draw its render batches. Since we are making a copy of the vertex buffer pointer, we also increase its reference count.

```
        // Store a reference to the VB in the data area to make it easy to process
        pData->m_pVertexBuffer = pVB;
```

```
        pVB->AddRef();
```

Finally, having committed the index array for the current leaf bin to an index buffer, we set the size of this array back to zero so that when the function returns we can start collecting indices from the beginning of this array for the next vertex buffer. That ends the loop that is performed for each leaf bin.

```
        // Reset bin size to 0, we've commited the data
        BinSizes[ AttribID ] = 0;

    } // Next set of index data

    // Success!
    return true;
}
```

When the loop ends, every leaf bin that had indices collected for it for the current vertex buffer will have had an index buffer created for it and assigned to it. With the job done, the function then returns a success flag.

WeldBuffers - CBaseTree

We saw this method being called from the BuildRenderData method discussed previously. It is used to perform a weld on the passed vertex array to (hopefully) compact the data and make some more room in the buffer for additional vertices. We call this function whenever the buffer is found to be full so that we are able to squeeze as many triangles into a single vertex buffer as possible. Fewer vertex buffers results in reduced vertex T&L and a smaller number of index and vertex buffer changes during rendering.

The function accepts six parameters. The first two parameters describe the size and contents of the passed vertex array that is going to be welded by this function. The second two parameters are maps that contain the index arrays collected for each leaf bin which indexed into the vertex array and the size of each leaf bin's index array. We must pass the index arrays collected for each leaf bin because they index into the passed vertex array. If the vertex array is going to be compacted and have duplicated vertices collapsed into a single vertex, the index arrays must also be updated so that any indices in any leaf bins' array that reference these deleted vertices are properly updated to reference the new vertices that the original vertices were collapsed onto. The final two parameters are optional. They allow us to pass the address of two vertex indices that will have their values tracked and remapped by the weld and returned to the caller. For example, if we passed in variables that held the values 12 and 24 respectively, this tells the weld function that we would like to know where the 12^{th} and 24^{th} vertex were repositioned in the vertex array after the weld. If these two vertices were relocated to slots 5 and 6 in the vertex buffer after the weld, on function return, the variable passed as the fifth parameter would contain 5 and the variable passed as the sixth parameter would contain the value 6. We saw why we needed to track the remapping of certain vertices during the BuildRenderData function. If a weld was performed partway through adding the triangles of a polygon to the vertex buffer, we needed to track where the two vertices used in the last triangle (that will also be used in the next triangle) will be positioned after the weld. This allows us to reference these vertices as we add the rest of the triangles in the polygon using their new vertex

buffer positions. All other times that a weld is performed in the BuildRenderData method, NULL is passed for the final two parameters since we only need to track the vertex positions when the weld happens mid-way through adding a single polygon.

Performing a weld seems like it would involve a good amount of code as you can imagine the various conditional tests that would be needed and we would certainly want a fast way of determining which vertices are candidates for collapse. While it would not be very difficult to code from scratch, fortunately D3DX includes a welding function that works with D3DX meshes and it is quite fast. All we will have to do is temporarily build a D3DX mesh using the vertex and index data passed in, and perform a weld on the mesh and extract the vertex and index data back out again into their original arrays which can then be returned to the caller. The mesh can then be released since it was only used temporarily so that we would get access to the D3DX weld functionality. Because the vertex array will be welded and all the index arrays (one for each leaf bin) describe triangles in that vertex array, we can think of the vertex array and all the index arrays combined as describing a single mesh. Therefore, what we will do is create a mesh into which we will copy all the vertex data in the vertex array into its vertex buffer and all the indices from all the index arrays (collected for each leaf bin in the BinIndexData map) into its index buffer. This means we will need to know how large and allocation we will for the temporary mesh's index buffer so that we can inform the mesh creation function of how many triangles it will need to store.

The first thing we do in this function is loop through all the rows in the BinSize map and sum up the sizes of each index array (one per leaf bin). We divide the total size by three (# indices per triangle) so that at the end of the loop we know the total number of triangles we will need to store in the mesh. Remember, this mesh will contain all of the triangles contained in all of the index arrays we have collected for each leaf bin/subset that reference the passed vertex buffer.

```
ULONG CBaseTree::WeldBuffers( ULONG VertexCount,
                              CVertex * pVertices,
                              map<ULONG,ULONG*> & BinIndexData,
                              map<ULONG,ULONG> & BinSizes,
                              ULONG * pFirstVertex /* = NULL */,
                              ULONG * pPreviousVertex /* = NULL */ )
{
    ULONG       i;
    HRESULT     hRet;
    LPD3DXMESH  pMesh;
    ULONG       TotalTriangles = 0;
    ULONG       nFirstIndex = 0xFFFFFFFF, nPreviousIndex = 0xFFFFFFFF, Counter = 0;

    // Total the full amount of triangles in the bin data so far
    map<ULONG,ULONG>::iterator SizeIterator = BinSizes.begin();
    for ( ; SizeIterator != BinSizes.end(); ++SizeIterator )
    {
        TotalTriangles += (SizeIterator->second / 3);

    } // Next Index Buffer
```

At this point the TotalTriangles local variable will contain all the triangles described by every index array. We now create a D3DXMesh that is large enough to store the correct number of vertices and triangles.

```
    hRet = D3DXCreateMeshFVF( TotalTriangles,
                              VertexCount,
                              D3DXMESH_SYSTEMMEM |
                              D3DXMESH_SOFTWAREPROCESSING | D3DXMESH_32BIT,
                              VERTEX_FVF,
                              m_pD3DDevice,
                              &pMesh );

    if ( FAILED( hRet ) ) return false;
```

Notice that since we are using this mesh for CPU bound operations (we do not intend to render it) we pass in the D3DXMESH_SYSTEMMEM and D3DXMESH_SOFTWAREPROCESSING flags so that we have a mesh created in system memory.

Next, we lock its vertex buffer, its index buffer, and its attribute buffer because we will need to fill the mesh with the data from our vertex and index arrays.

```
    ULONG   *pDestIndices, *pAttributes;
    CVertex *pDestVertices;

    // Lock the vertex, index and attribute buffers ready for population
    if ( FAILED( pMesh->LockIndexBuffer( 0, (void**)&pDestIndices ) ))
         { pMesh->Release(); return VertexCount; }

    if ( FAILED( pMesh->LockVertexBuffer( 0, (void**)&pDestVertices ) ))
         { pMesh->Release(); return VertexCount; };

    if ( FAILED( pMesh->LockAttributeBuffer( 0, &pAttributes ) ))
         { pMesh->Release(); return VertexCount; }
```

We copy the vertices in the passed array into the mesh's vertex buffer and then set every entry in the mesh's attribute buffer to zero.

```
    // Copy over the vertices
    memcpy( pDestVertices, pVertices, VertexCount * sizeof(CVertex) );

    // Zero out the attribute buffer
    memset( pAttributes, 0, TotalTriangles * sizeof(ULONG) );
```

Why do we fill the attribute buffer with zeros? We do this because the D3DX weld function may perform operations on the indices that cause them to be moved around in the index buffer. For example, triangles may be shuffled around so that they are grouped by subset. The problem is, although we wish the vertex data to be compacted and the indices to have their values updated to correctly use these vertices, we must be absolutely sure that the weld function never changes the location of the triangles within the mesh's index buffer. We need to know that the triangles stay exactly where they are so that we can extract them out again into the index arrays for each leaf bin. Imagine for example that we added

10 triangles from leaf bin 1 followed by 10 triangles from leaf bin 2 to the mesh's index buffer. Provided the triangles never have their positions within the index buffer changed, we know that after the weld we can extract the first 10 triangles back out into leaf bin 1's array and the second 10 back out into leaf bin 2's index array. However, if these triangles were repositioned, we would lose all knowledge of which triangles in the welded index buffer need to be copied back out into their original index array. By placing all zeros in the mesh's attribute buffer, we trick the mesh into thinking that all the triangles belong to a single subset (subset zero) and therefore, the optimization that moves triangles for better subset batching will not be performed.

Our next task is to loop through every row in the BinIndexData map and extract the index pointer for each subset/leaf bin. We then copy the indices stored in each index array into the mesh's index buffer. The next section of code starts the beginning of this loop.

```
    // Now we need to update the indices
    map<ULONG,ULONG*>::iterator BinIterator = BinIndexData.begin();
    for ( ; BinIterator != BinIndexData.end(); ++BinIterator )
    {
        ULONG AttribID = BinIterator->first;
        ULONG Size     = BinSizes[ AttribID ];

        // Skip if there is no data
        if ( Size == 0 ) continue;

        // Copy over the indices
        ULONG * pIndices = BinIterator->second;
        memcpy( pDestIndices, pIndices, Size * sizeof(ULONG) );
```

At this point in the current iteration of the loop we have copied over all the indices of the current index array we are processing into the mesh's index buffer (pDestIndices).

The next section of the loop code may look a little strange, so let us quickly explain why it is needed. As the final two input parameters, the caller can pass the address of two unsigned longs that describe vertex indices into the original vertex array passed. We know that the weld function will automatically update all the indices in the index buffer so that the triangles correctly index the updated vertices in the post-weld vertex buffer (even if many of the original vertices were deleted/collapsed). However, if we call the weld function partway though adding the triangles of a single polygon to the vertex array (which we might do in the BuildRenderData method), we will need to track the position changes made to two of the polygons vertices. This way, when the weld function returns, we can continue to add another triangle using the two vertices used in the previous triangle that was added before the weld function was called. We explained where and why we need this functionality when we covered the BuildRenderData method earlier, so refer back to that discussion if you are fuzzy on the details.

If either pFirstVertex or pPreviousVertex are not NULL, it means they point to variables assigned by the caller that contain the indices of two vertices. It also means that the caller would like to know where these two vertices end up in the vertex array after the weld. Unfortunately, the weld function does not give us this information, so we will have to do a little work beforehand. Essentially, as we add each index array to the index buffer, we will loop through those indices searching for an index that references the vertex we are interested in tracking the position changes for. For example, if *pFirstVertex=10 it

means the caller would like to know the new index for vertex 10 if it got moved in the vertex array during the weld. In order to do this, we test each index array as we add it and search for the first index we find that references this vertex. We then record the location of this index. After the weld, the vertices may have changed, but the index we recorded will still be in the same location in the index buffer, so we can read back the value it now contains. This will tell us the vertex that index has been updated to use and the new position of the original vertex 10 in the new vertex buffer.

Let us just step through an example so that the logic is clear. Let us say that the caller would like to know the post-weld positions of vertex 10 and vertex 12. They would pass in as the pFirstVertex and pPreviousVertex parameters pointers to two variables that contain the values 10 and 12, respectively. In this next section, we will search for the first index in any index buffer that currently indexes vertices 10 and 12 in the vertex array and we will record the locations of these indices in the index buffer. Let us imagine that we found that the first index that references vertex 10 is in leaf bin 2's index array at location 100 in the mesh's main index buffer. We will record this index location. Let us also assume that we find the first reference to vertex 12 in leaf bin 5 and record the location where it has been added to the mesh's index buffer as well. Assume that it has been placed at index 500 in the mesh's index buffer. So we have the following.

*pFirstVertex = 10
*pPreviousVertex = 12

nFirstIndex = 100
nPreviousIndex = 500

Just to be clear, we have determined that there is an index that references vertex 10 stored at location 100 in the mesh's index array and an index that references vertex 12 at location 500 in the mesh's index array. Once we have recorded these values, we no longer need to search for it anymore; we are just interested in finding the first occurrence of these two vertices in the index buffer. After the weld is performed, vertices 10 and 12 may be in completely different locations. However, the triangles (and thus their indices) in the mesh index buffer will not have changed position at all, but they will have had their values updated by the weld function so that they correctly reference the updated vertex buffer. Therefore, all we have to do is read back the values now stored in the index buffer at locations 100 and 500 and we will have the new locations of vertex 10 and 12 in the vertex buffer. We can then return this information to the caller.

Let us look at the code in this loop that searches and records the index locations prior to the weld being performed. Notice that we only perform the search if we have not already found the first index that references each vertex.

```
        if ( (pFirstVertex && nFirstIndex == 0xFFFFFFFF) ||
             (pPreviousVertex && nPreviousIndex == 0xFFFFFFFF) )
        {
            // Loop through the indices
            for ( i = 0; i < Size; ++i )
            {
                if ( (pFirstVertex &&
                      nFirstIndex == 0xFFFFFFFF)
                      && pIndices[i] == *pFirstVertex ) nFirstIndex = Counter + i;
```

```
                if ( (pPreviousVertex &&
                      nPreviousIndex == 0xFFFFFFFF)
                      && pIndices[i] == *pPreviousVertex) nPreviousIndex=Counter+i;

            } // Next Index

        } // End if search for remap
```

At the start of the code, nFirstIndex and nPreviousVertex are set to 0xFFFFFFFF which means we have not yet found the location of an index that references the vertex. Notice we only step into this code block if we have not yet found both nFirstVertex and nSecondVertex and if the application did not pass NULL as the pFirstVertex and pPreviousVertex parameters. Inside the code block we loop through every index in the index array we are about to add and test to see if its value is equal to pFirstVertex. If it is, then we have found an index that references the first vertex we are interested in tracking, so we record the location of that index in the nFirstIndex variable. As this variable will no longer be set to 0xFFFFFFFF, the search for this index will not be performed again when adding any other vertex arrays. We do exactly the same thing for the pPreviousVertex and record the location of the first index we find that references it in nPreviousVertex. Notice above that the Counter variable starts at zero and is incremented at the bottom of the loop by the size of the index array we just added to the mesh's index buffer. Therefore, at the beginning of each loop iteration, it contains the location of first index in the index buffer of the index array we just added. Thus, Counter + i describes exactly where the index we have just found will be located in the mesh's index buffer (pre- and post-weld).

Finally, at this point in the loop we have added the current index array to the index buffer and have performed a search through those indices for the tracked vertices, so we increment the index buffer pointer past the new indices we just added so that it points at the location where the next index array that we process in the next iteration of the loop should be added. We also increment the Counter variable by the size of the index array so that it always describes (at the beginning of each loop iteration) the location in the index buffer where the index array that has just been added begins.

```
        // Move the destination index array on for the next batch
        pDestIndices += Size;
        Counter      += Size;

    } // Next Index Buffer
```

Once this has been done, we unlock all the buffers in the mesh since it now contains all the vertex and index data needed to perform the weld.

```
    // Unlock the buffers
    pMesh->UnlockIndexBuffer();
    pMesh->UnlockVertexBuffer();
    pMesh->UnlockAttributeBuffer();
```

You will recall from Chapter 8 that the D3DXWeld function must be passed a D3DXWELDEPSILONS structure that allows us to control how fuzzy the comparison is between two vertices. This allows us some control over what are considered duplicate vertices. We can assign the various vertex components

different epsilons so that two vertices that are almost the identical, but have positions that vary by as little as 0.01 (for example) are considered to be the same and are collapsed into a single vertex. Another example would be two vertices that share the exact same location and have normals that are similar enough to warrant welding them into a single vertex.

The D3DXWELDEPSILONS structure is shown below as a reminder. The larger the epsilon we assign to a vertex component, the more fuzzy the compare will be when determining whether two vertices are the same for that component.

```
typedef struct _D3DXWELDEPSILONS
 {
    FLOAT Position;
    FLOAT BlendWeights;
    FLOAT Normal;
    FLOAT PSize;
    FLOAT Specular;
    FLOAT Diffuse;
    FLOAT Texcoord[8];
    FLOAT Tangent;
    FLOAT Binormal;
    FLOAT Tess Factor;
} D3DXWELDEPSILONS;
```

We will set all the members of this structure to a standard epsilon of 0.001. Rather than assign each value of the structure to 0.001 individually, we know that it really is just a block of memory representing 10 floats, so we will just instantiate the structure, access it via a float pointer, and loop through the 10 floats assigning each location a value of 0.001 (1e-3).

```
    // Set all epsilons to 0.001;
    D3DXWELDEPSILONS WeldEpsilons;
    float * pFloats = (float*)&WeldEpsilons;
    for ( i = 0; i < sizeof(D3DXWELDEPSILONS) / sizeof(float); i++ )
         *pFloats++ = 1e-3f;
```

Now we pass this structure, along with the mesh pointer itself, into the D3DXWeldVertices method to perform the weld.

```
    // Weld the vertex data
    hRet = D3DXWeldVertices( pMesh,
                             D3DXWELDEPSILONS_WELDPARTIALMATCHES |
                             D3DXWELDEPSILONS_DONOTSPLIT,
                             &WeldEpsilons, NULL, NULL, NULL, NULL );

    if ( FAILED(hRet) ) { pMesh->Release(); return VertexCount; }
```

The D3DXWELDEPSILONS_WELDPARTIALMATCHES flag instructs the function that we would like duplicated vertices removed. The D3DXWELDEPSILONS_DONOTSPLIT flag instructs the function to never split (i.e., duplicate) vertices that are in separate attribute groups. This is passed just to be safe, since splits should never happen because we have zeroed out the attribute buffer. As far as the mesh is concerned, it only has a single subset.

With the weld performed, we now need to exact the mesh data back out into the vertex and index arrays that were passed into the function so that the modified data is returned to the caller. The first step is to lock the mesh vertex and index buffers and update the VertexCount parameter so that it now reflects the number of vertices in the welded mesh.

```
    // Lock the vertex and index buffers ready for extraction
    if ( FAILED( pMesh->LockIndexBuffer( 0, (void**)&pDestIndices ) ))
         { pMesh->Release(); return VertexCount; }

    if ( FAILED( pMesh->LockVertexBuffer( 0, (void**)&pDestVertices ) ))
         { pMesh->Release(); return VertexCount; };

    // Store updated vertex count
    VertexCount = pMesh->GetNumVertices();
```

In the next section we copy the vertices from the mesh's vertex buffer into the passed pVertices array. This overwrites the old vertex data contained there. We then access the indices in the index buffer at locations nFirstIndex and nPreviousIndex to retrieve the new locations of vertices described by the pFirstVertex and pPreviousVertex parameters. The variables addressed by these two pointers have their values updated to contain the new post-weld position of these vertices, which will be accessible to the caller on function return.

```
    // Copy over the vertices
    memcpy( pVertices, pDestVertices, VertexCount * sizeof(CVertex) );

    // Update remap information if it was requested
    if ( pFirstVertex    ) *pFirstVertex    = pDestIndices[ nFirstIndex ];
    if ( pPreviousVertex ) *pPreviousVertex = pDestIndices[ nPreviousIndex ];
```

Finally, all that is left to do is iterate through each index array in the BinIndexData map and overwrite their indices with the modified mesh indices.

```
    // Now we need to copy back the index buffers
    BinIterator = BinIndexData.begin();
    for ( ; BinIterator != BinIndexData.end(); ++BinIterator )
    {
        ULONG AttribID = BinIterator->first;
        ULONG Size     = BinSizes[ AttribID ];

        // Skip if empty
        if ( Size == 0 ) continue;

        // Copy over the indices
        memcpy( BinIterator->second, pDestIndices, Size * sizeof(ULONG) );

        // Move the destination index array on for the next batch
        pDestIndices += Size;

    } // Next Index Buffer

    // Unlock the buffers and release the mesh
    pMesh->UnlockIndexBuffer();
```

```
    pMesh->UnlockVertexBuffer();
    pMesh->Release();

    // Return new vertex count.
    return VertexCount;
}
```

At the end of this process, we unlock the mesh's buffers and release the mesh before returning the new modified vertex count of the passed vertex array back to the caller.

We have now covered all the code involved in preparing the data for rendering and all of the processes invoked by the CBaseTree::BuildRenderData function. When the BuildRenderData method returns, all the tree's vertex buffers and leaf bins will have been constructed and are ready for use. In the next section we will examine the code that manages the visibility pass on the tree and the code for rendering that visible data.

15.4.3 Processing Tree Visibility / Rendering the Static Data

Before the application instructs the spatial tree to draw any of its subsets, it should first tell it to perform a visibility pass by calling the ISpatialTree::ProcessVisibility method. Because this method is a traversal method that is dependant on node type and the number of children each node has, it must be implemented in the derived classes. That is, the quad-tree's version of this method will step into four children at each node while the oct-tree's version will step into eight.

Although this method must be implemented in the derived class, all that is really in the derived class is the traversal logic that determines whether a given node is within the frustum or not and therefore, whether the children should be traversed. For each leaf that is found to have its bounding box inside the camera's frustum, the ProcessVisibility method will issue a call to the leaf's SetVisible method. As we have seen, it is this method that adds the leaf's triangles to render batches in their respective leaf bins. Thus, we have already done the hard work. All that is left to do in the derived class is the tree traversal and frustum tests at each node.

Because the CBaseTree object must make sure that the render batch lists for each leaf bin are reset prior to the visibility traversal taking place, the derived class's ProcessVisibility method must call the CBaseTree::ProcessVisibility method before starting the visibility pass. Below we show the code to the CQuadTree::ProcessVisibility method.

```
void CQuadTree::ProcessVisibility( CCamera & Camera )
{
    CBaseTree::ProcessVisibility( Camera );

    // Start the traversal.
    UpdateTreeVisibility( m_pRootNode, Camera );
}
```

As you can see it is passed (by the application) the CCamera object whose frustum will be used for the visibility pass. It first calls the base class version of the function prior to calling its own UpdateTreeVisibility method. The UpdateTreeVisibility method is the recursive function that traverses the tree and performs the frustum tests at each node. The ProcessVisibility method in the derived classes is really just a wrapper. In fact, the ProcessVisibility method in all derived classes will look identical to this one so we will not show them all. Each derived class's version of this method will first call the CBaseTree::ProcessVisibility method to reset the batch lists in each leaf bin. Then it will call its version of the UpdateTreeVisibility method to perform the visibility traversal starting at the root node. Throughout this section we will only discuss the implementation in the CQuadTree derived class and you can check the source code for the implementations in the other cases.

ProcessVisibility – CBaseTree

This function is called from the derived class's version of the function to reset the batch lists in each leaf bin. The batch lists are compiled in the CLeafBinData structures in each leaf bin and represent a vertex/index buffer pair. The function loops through each leaf bin and then loops through each CLeafBinData pointer in its internal array. It then resets the CLeafBinData::m_nBatchCount member of each CLeafBinData structure in the leaf bin to zero.

```
void CBaseTree::ProcessVisibility( CCamera & Camera )
{
    LeafBinMap::iterator        BinIterator  = m_LeafBins.begin();
    ULONG                       i;

    // Iterate through the leaf bins and destroy them
    for ( ; BinIterator != m_LeafBins.end(); ++BinIterator )
    {
        CLeafBin * pBin = BinIterator->second;
        if ( !pBin ) continue;

        // For each buffer
        for ( i = 0; i < m_nVBCount; ++i )
        {
            CLeafBinData * pData = pBin->GetBinData( i );
            if ( !pData ) continue;

            // Reset the batch count
            pData->m_nBatchCount = 0;

        } // Next Buffer

    } // Next Leaf Bin

    // Clear the visible leaf list.
    m_VisibleLeaves.clear();
}
```

15.4.4 Traversing the Tree to Ascertain Leaf Visibility

It is clear from the previous discussion that the visibility traversal will be performed in the derived class's UpdateTreeVisibility method. In theory, this method could be extremely simple and just traverse through all the nodes in the tree calling the CCamera::BoundsInFrustum method to test if the current node's bounding volume is within the frustum. If it is not, then it calls the node's SetVisible method to traverse down the rest of that tree and set the visible status all leaves below it to false. If the node is inside the frustum (or partially inside the frustum) we can traverse into its children and test their volumes against the frustum in the same manner. Eventually, we will traverse to all leaves that are inside the frustum, at which point the leaf's SetVisible method will be called. As we have seen, this will cause the triangles in those leaves to be added to the render batches in the leaf bins in which they are contained.

While there is certainly nothing wrong with such a strategy, it does not take full advantage of the hierarchical nature of the tree to reduce the number of plane tests that will need to be performed at each node. Furthermore, it does not take into account the fact that if node was found to be outside a frustum plane in the previous visibility update (outside the frustum), because the movement of the camera will typically be very small between frame updates, the node will probably still be outside that frustum plane in the next update. Therefore, when testing the bounding box of a node against the frustum, we should test the plane it failed on in the last update first in the hopes of rejecting the node immediately without having to perform tests for the rest of the frustum planes. This is referred to as frame coherence. It is essentially the concept of using information collected on a previous frame update to optimize the process in the current one. Let us discuss the frame coherence optimization first.

15.4.5 Frustum Culling with Frame to Frame Coherence

Figure 15.5 depicts a 2D representation of a node's AABB and the current world space position of the camera's frustum planes. As this is a 2D representation, the frustum has four planes instead of the usual six. We can clearly see that the node is not visible because its bounding box is outside the frustum. This obviously means the node's children are also invisible and there is no need to test them against the frustum. Thus, we can immediately mark this node and all its children as invisible.

The planes of the frustum are labeled 1 through 4 and describe the order in which the frustum planes will be tested against the bounding box.

> **Note:** Frustum culling AABBs was discussed in Module I and will not be discussed again here.

If we walk though the frustum test, we will see that it is only when the polygon box is tested against the fourth plane that we know it is outside the frustum.

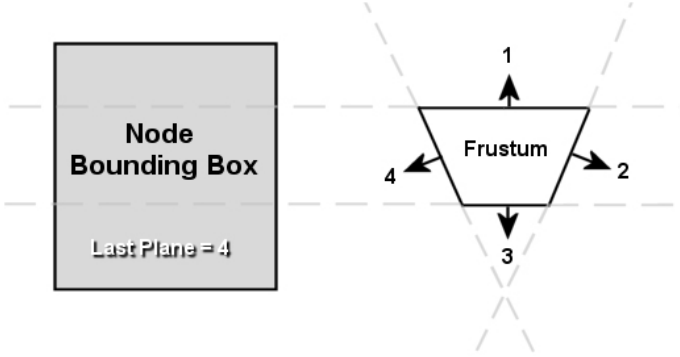

Figure 15.5

For example, we can see that when plane 1 is tested, the box is not totally in front of the plane. Since it spans this plane, the box could very well be in the frustum at this point. Next we test the box against frustum plane 2 where we once again discover the box is totally in its backspace and therefore may still be within the frustum. Remember, we only know that an AABB is inside the frustum if the box is behind all planes (plane normals are assumed to be facing outwards in this example). So far we have tested two planes and have not found a plane the box is totally in front of, so next we move on to plane 3. Once again, the box is not totally in front of this plane, so we know at this point that the box is at least partially contained behind the three planes tested and may well be in the frustum. Finally, we test frustum plane 4 where we discover that the box is totally in its front space and therefore could not possibly be visible. At this point we set the visibility status of all leaves underneath that node to false.

Although this works fine, it took us four plane tests to determine that the box was outside. However, if we knew in advance that we would fail against plane 4, we could have rejected the node with one plane test. Although this might sound like a minimal savings at the node level, just remember that your spatial tree might have thousands of nodes, and the 3D frustum will have six planes. In the worst cases, you could end up having to perform six frustum plane tests at a great many nodes.

If we examine Figure 15.5 again we can imagine that during the next frame update, where the camera will likely only be moved by a very small amount (say, vertically), it would fail on the same plane again. So if we know the plane that we failed on last time, which in this case was frustum plane 4, we could store the index of that plane in the node and make sure that when this node is encountered in the next visibility pass, we test plane 4 first. Although our first visibility pass would require that we test all four planes to learn that the fourth plane was the one that caused the rejection, the next visibility pass (next iteration of the game loop) can be potentially optimized when we visit that node, by reading back the index of the plane we failed on last time and making sure that the CCamera::BoundsInFrustum function test this plane first. In a great many cases, this will lead to immediate rejection of large portions of the tree using a single plane test. Again, if a node was outside a certain frustum plane during one frame update, it will probably be outside that same frustum plane during the next frame update (camera changes are generally minimal between frames when an application is running at 30+ frames per second).

We will implement this frame-to-frame coherency in our visibility system. You now know why each of the node classes we developed in the previous lesson stored that signed char member variable called LastFrustumPlane. As a reminder, we show the CQuadTree node class declaration below.

```
class CQuadTreeNode
{
public:

    // Constructors & Destructors for This Class.
     CQuadTreeNode( );
    ~CQuadTreeNode( );

    // Public Functions for This Class
    void SetVisible( bool bVisible );

    // Public Variables for This Class
```

```
    CQuadTreeNode * Children[4];        // The four child nodes
    CBaseLeaf     * Leaf;               // If this is a leaf, store here.
    D3DXVECTOR3     BoundsMin;          // Minimum bounding box extents
    D3DXVECTOR3     BoundsMax;          // Maximum bounding box extents
    signed char     LastFrustumPlane;   // The frame coherance 'last plane' index.
};
```

When the node is first created, its LastFrustumPlane index will be set to -1 in the constructor. This is because we do not yet have the index of a frustum plane at which this node failed. It will also be set back to -1 for any node that was found to be visible in the previous visibility update. However, for nodes that are currently outside the frustum, or were found to be outside the frustum in the previous visibility update, this member will store a value between 0 and 5, describing the index of the first frustum plane that generated the outside the frustum result. When this node is visited in the next visibility update, and the CCamera::BoundsInFrustum method is called to test the bounding box of the node against the frustum planes, we will pass this plane index into that function to instruct it to test this plane first. Hopefully, the BoundsInFrustum method will immediately determine that the node is still outside this plane and will return the invisible status. If the camera has been moved from the previous position and the node is no longer totally in front of this plane, we will just perform a test on the rest of the planes as normal. If one of the other planes is found to have the AABB totally in its front space, the node's LastFrustumPlane member is updated to store the index of that plane. If the box is not in front of any planes and is therefore inside (or partially inside) the frustum, the node's LastFrustumPlane member is set to -1 and a visible status is returned for the node. The next time this node is encountered in the next visibility process, it will have -1 in its LastFrustumPlane member which means the BoundsInFrustum test will just loop through and test all 6 planes in the usual way.

In a moment we will see how the CCamera::BoundsInFrustum method has been updated to test against the chosen frustum plane first if such a plane index is passed into the function. We will also see how it will update the value of the node's LastFrustumPlane member if a new 'first' rejection plane is found. But before we discuss the code for the frame-to-frame coherence optimization, we will talk about a second optimization that can be introduced to make use of the spatial hierarchy and further reduce the number of frustum plane tests that have to be performed at each node.

15.4.6 Hierarchical Frustum Culling

In the previous chapter we discussed hierarchical frustum culling as the process of stepping through the nodes of the tree and rejecting any node (and all its children) that is outside the frustum from our rendering pipeline without further testing. However, we can further exploit the parent/child relationship of nodes in the tree to introduce another means for frustum plane test reduction in the typical case.

This technique is used to speed up the case where the node is not totally inside or outside the frustum, but is intersecting in such a way that the node's volume is totally behind/inside one or more of the frustum planes. Although we know that in the intersecting case, the children of the node must also be tested against the frustum, we also know (because of the child/parent relationship) that if the parent node is totally behind/inside one of the frustum planes, all of its child nodes/leaves will be as well. Therefore,

when testing the children, we no longer need to test this plane against their volumes because we know that they will always be found to be in the plane's back space.

Figure 15.6 demonstrates this idea in two dimensions by showing a parent node's AABB and the AABBs of its four immediate children.

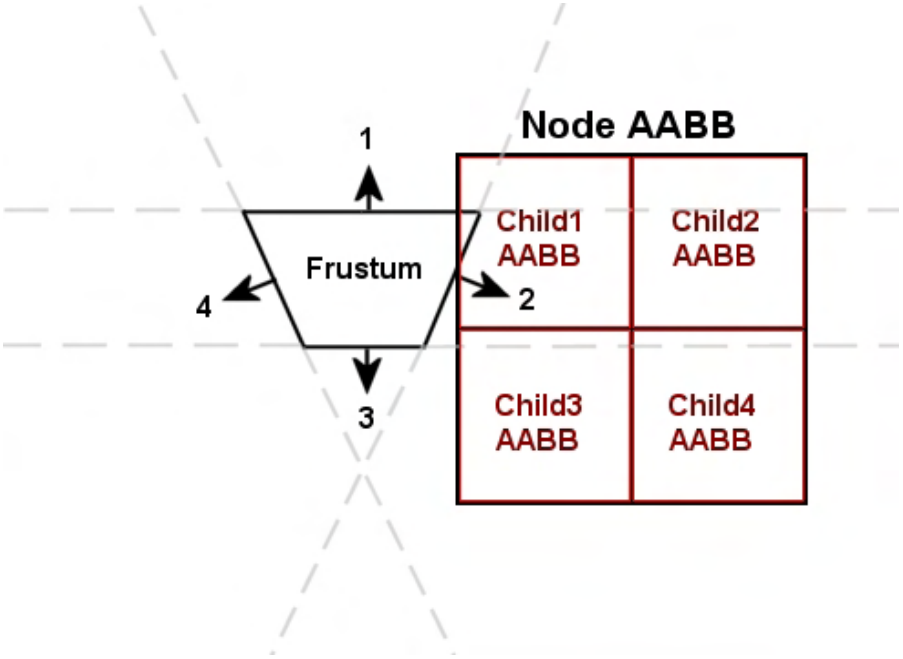

Figure 15.6

The important frustum plane to look at in this example is frustum plane 4. We can see that the parent node's volume intersects frustum planes 1, 2, and 3 and is totally behind frustum plane 4. This tells us that part of the parent node is behind all frustum planes so the node is visible. As the node is not completely inside the frustum, this does not mean that we should set all child nodes to visible automatically. We can see for example, that although the parent node intersects the frustum, three of its children do not. Indeed they are fully outside the frustum. Therefore, if the frustum is intersecting the node, the child nodes must also be tested to determine their visibility status. This means that in a worst case scenario, we have to do six frustum plane tests against the node's volume and perform the same six tests for each of its children, and so on.

If we look at frustum plane 4 in Figure 15.6 we can see that the parent node is completely behind (inside) this plane. But because the parent node is behind plane 4, so are all of its children. This is clear from just looking at the diagram. So we recognize that there is no need to test this plane against the children. The parent can essentially say to the child nodes, "I am behind this plane, so all of you are too. Do not bother performing a test against this plane; just assume that you are behind it and test the other planes instead".

The recursive visibility process will pass an array of bits from parent to child as it traverses the tree. Each bit will represent one of the six frustum planes. The CCamera::BoundsInFrustum function will be updated to take an unsigned char whose first six bits will be used to represent the status of the frustum planes. This unsigned char will be set to zero at the beginning of the traversal.

When a node is reached, its bounding box will be passed into the CCamera::BoundsInFrustum function along with this unsigned char. When this function finds any plane that the AABB of the node is completely behind, it will set the bit to 1 in the unsigned char corresponding to that plane. When the function returns back to the node, the node flag will have the corresponding bits set to 1 for any planes the node's volumes is totally behind. This unsigned char is then passed down to the children. The child

nodes will then pass this unsigned char of frustum plane bits into their CCamera::BoundsInFrustum calls so that that any planes at this node which result in the fully behind case can also have their bits set to 1. The important point here however, is that the CCamera::BoundsInFrustum test will only test planes which have not had their bits set to 1 in the passed unsigned char.

Now that we know the two optimizations we will apply during the frustum culling traversal of the tree, we are ready to look at an example of the UpdateTreeVisibility method. Since these methods are the same in all derived classes (with the exception of having to step into a varying number of children), we will only show the CQuadTree::UpdateTreeVisibility method here.

UpdateTreeVisibility - CQuadTree

This method is called from the CQuadTree::ProcessVisibility function to start the recursive process for the root node. It repeatedly calls itself until all leaves in the tree which intersect the camera's frustum have there visible status set. The function is very simple as nearly all the optimizations are performed inside the modified CCamera::BoundsInFrustum method, which we will discuss in a moment.

The function is passed three parameters. The first is the node currently being visited by the function. This will be the root node of the tree when this function is first called from the CQuadTree::ProcessVisibility method. The second parameter is the camera whose frustum will be used for the visibility test. The third parameter is the function's means of passing the array of 'Totally Inside' frustum bits from one node to the next. Since this parameter is not passed for the root node, the value of the FrustumBits unsigned char will be set to 0 when tree traversal begins at the root.

The first thing the function does is call the CCamera::BoundsInFrustum method, passing in the node's bounding box extents, the unsigned char of frustum plane bits, and the node's LastFrustumPlane member.

```
void CQuadTree::UpdateTreeVisibility( CQuadTreeNode * pNode,
                                      CCamera & Camera,
                                      UCHAR FrustumBits /* = 0x0 */ )
{
    unsigned long i;
    CCamera::FRUSTUM_COLLIDE Result=Camera.BoundsInFrustum( pNode->BoundsMin,
                                                            pNode->BoundsMax,
                                                            NULL,
                                                            &FrustumBits,
                                                          &pNode->LastFrustumPlane);
```

The third parameter to this function is an optional world matrix that can be used to transform the input bounding box into world space prior to performing the test. As our node's bounding box is already in world space, no transformation is required so we set the matrix pointer to NULL.

Before examining the rest of this function, let us just make sure we understand what may have happened when the above function has returned. Any bits set to 1 in the passed FrustumBits char will not be tested

against the frustum. Instead, the function will assume that the node's box is totally behind these planes and will progress to the next plane that needs to be tested. If any of the planes that did require testing (their bits were set to 0) are found to contain the bounding box completely in its back space, that plane will have its bit set to 1 in the FrustumBits char and will also not need to be tested again for any children of this node. Finally, if the BoundsInFrustum method did determine that the node is outside the frustum, the LastFrustumPlane member of the node will have its value altered such that it contains the index of the first plane it failed on. This will be the first plane that is tested by this function the next time the BoundsInFrustum function is called for this node.

The BoundsInFrustum method will return one of three values which are members of the FRUSTUM_COLLIDE enumerated type defined inside the CCamera namespace. This enumerated type is shown below with an explanation of its members.

```
enum FRUSTUM_COLLIDE
{
        FRUSTUM_OUTSIDE     = 0,
        FRUSTUM_INSIDE      = 1,
        FRUSTUM_INTERSECT   = 2,
        FRUSTUM_FORCE_32BIT  = 0x7FFFFFFF
};
```

FRUSTUM_OUTSIDE
The node's bounding volume is totally outside the frustum (the node is not visible). This means we will not perform any more frustum tests down this branch of the tree and we can immediately set the visibility status of any leaves stored under this node to false. If the parent node is completely outside the frustum, so too must be all of its children.

FRUSTUM_INSIDE
The node's bounding volume is contained completely within the frustum (the node is visible). This also means that we do not have to perform any more frustum tests down that branch of the tree and we can immediately set the visibility status of all leaves stored under that node to true. If the parent node is fully contained within the frustum, so too must be all of its children.

FRUSTUM_INTERSECT
The node's bounding volume is partially contained within the frustum (the node is visible). This means we must traverse into the children and continue to perform frustum tests for each child. If the parent node is partially intersecting the frustum, one of more of its children will be visible.

Now that we know what the results mean, let us see the code that processes them in a switch statement.

```
    // Test result of frustum collide
    switch ( Result )
    {
    case CCamera::FRUSTUM_OUTSIDE:
        // Node is not at all visible
        pNode->SetVisible( false );
        return;
```

If the frustum test returned FRUSTUM_OUTSIDE then the node's bounding volume is completely outside the frustum, so the node is not visible and neither are any of its children. When this is the case we simply call the node's SetVisible method passing a visibility parameter of false. This method performs no frustum tests and simply traverses the rest of the branch setting the visible status of any leaves found there to false. The function then returns so that the rest of this branch of the tree avoids further frustum testing.

If the frustum test returned FRUSTUM_INSIDE then the node's bounding volume is entirely contained inside the frustum and therefore, this node and all child nodes are visible and no further frustum tests need to be done down this branch of the tree. Instead we just call the node's SetVisible method passing a visibility status of true. This function will quickly traverse to find all the leaf nodes underneath this current node and will set their visibility status to true. We then return from the function so that we do not perform any more frustum tests down this branch of the tree.

```
    case CCamera::FRUSTUM_INSIDE:
        // Node is totally visible
        pNode->SetVisible( true );
        return;
```

Finally, if the frustum test returned FRUSTUM_INTERSECT it means that the current node is visible but some of its children might not be, so we will need to perform further frustum tests along this branch of the tree. If the current node is a leaf, we set its visible status to true (which we know will cause its triangles to be added to their leaf bin's render batch lists).

```
    case CCamera::FRUSTUM_INTERSECT:
        // We need to resolve this further, unless this is a leaf
        if ( pNode->Leaf )
        {
            pNode->SetVisible( true );
            return;
        } // End if leaf
        break;

    } // End Switch
```

Remembering that the function will have returned already in any case other than FRUSTUM_INTERSECT, this last section of code is also only executed in the intersection case. It simply loops through each child node and recurs into it.

```
    // The remaining case (FRUSTUM_INTERSECT) means we need to test further
    for ( i = 0; i < 4; ++i )
    {
        if ( pNode->Children[i] ) UpdateTreeVisibility( pNode->Children[i],
                                                        Camera,
                                                        FrustumBits );

    } // Next Child
}
```

You will find that the UpdateTreeVisibility method in all the derived classes will be identical to the code shown above, with the exception of the number of children traversed.

SetVisible - CQuadTreeNode

Although we took a brief look at this method in the previous lesson, we will take a quick look at it again now that we have seen it being called in the FRUSTUM_INSIDE and FRUSTUM_OUTSIDE cases in the above function.

```
void CQuadTreeNode::SetVisible( bool bVisible )
{
    unsigned long i;

    // Set leaf property
    if ( Leaf  ) { Leaf->SetVisible( bVisible ); return; }

    // Recurse down if applicable
    for ( i = 0; i < 4; ++i )
    {
        if ( Children[i] ) Children[i]->SetVisible(bVisible);

    } // Next Child
}
```

As you can see, if the node is a leaf it calls its SetVisible method to instruct it to add its polygon data to the render batches in each leaf bin. As we now know, this will also instruct the leaf to add its ‘this’ pointer to the tree’s visible leaf list.

Of course, the final piece of the puzzle is the CCamera::BoundsInFrustum method. Although this method has been in use since Module I in this series, we have now modified it to accept some additional parameters that optimize the frustum rejection for a spatial tree. After we have look at the code to that function, we will have covered all of the code that is executed when the application calls the ISpatialTree::ProcessVisibility method. Thus we will have completely explored how the visibility pass on the tree is performed.

BoundsInFrustum - CCamera

The frustum culling of AABBs and the extraction of the frustum planes in world space was explained in detail in Module I. This function has been with us for quite some time now and we have seen it used in nearly all our lab projects since its inception. Therefore we will not be covering how frustum culling works when discussing this code. If you do not remember how the frustum culling of AABBs can be done, please refer back to Chapter 4 in Module I for the details.

The first thing this function does is call the CCamera::CalcFrustumPlanes method to extract the world space planes for the view frustum and store them in the camera object’s m_Frustum planes array (which

contains 6 elements). We then make a copy of the passed FrustumBits unsigned char into the nBits local variable for ease and speed of access. We also copy the value stored in the passed LastOutside char which will contain the index of the plane which the node that called this function failed on the last time this function was called.

```
CCamera::FRUSTUM_COLLIDE CCamera::BoundsInFrustum( const D3DXVECTOR3 & vecMin,
                                                   const D3DXVECTOR3 & vecMax,
                                                   const D3DXMATRIX * mtxWorld ,
                                                   UCHAR * FrustumBits ,
                                                   signed char * LastOutside )
{
    // First calculate the frustum planes
    CalcFrustumPlanes();

    ULONG           i;
    D3DXVECTOR3     NearPoint, FarPoint, Normal, Min = vecMin, Max = vecMax;
    FRUSTUM_COLLIDE Result  = FRUSTUM_INSIDE;
    UCHAR           nBits = 0;
    signed char     nLastOutside = -1;

    // Make a copy of the bits passed in if provided
    if (FrustumBits) nBits = *FrustumBits;

    // Make a copy of the 'last outside' value to prevent us having to dereference
    if ( LastOutside ) nLastOutside = *LastOutside;
```

If the caller passed a matrix into the function, then it means we were passed a model space bounding box which should be transformed into world space using this matrix before the frustum planes are tested. That is no problem because we wrote a function in the previous lesson that did exactly that.

```
    // Transform bounds if matrix provided
    if ( mtxWorld ) MathUtility::TransformAABB( Min, Max, *mtxWorld );
```

If the node's LastFrustumPlane value (now stored in nLastOutside) is not set to -1, it contains a valid index for a frustum plane and we will test that plane first. However, we will only test it if that plane does not have its bit set to 1 in the nBits array. If it does, then regardless of the fact that the node was found to be outside the plane in the previous visibility pass, it must be inside it now, because one of its parent nodes higher in the tree was found to be completely inside it and set this bit to 1. Alternatively, if a valid last plane index is passed which does not currently have its bit set, we will perform the test.

As the nLastOutside variable contains the index of the plane we want to test first, we will extract the plane normal from the camera's m_Frustum array. This array stores the planes in <a,b,c,d> format so we know that the normal is contained in members a, b, and c.

```
    // If the 'last outside plane' index was specified, test it first!
    if ( nLastOutside >= 0 && ( ((nBits >> nLastOutside) & 0x1) == 0x0 ) )
    {
        // Store the plane normal
        Normal = D3DXVECTOR3( m_Frustum[nLastOutside].a,
                              m_Frustum[nLastOutside].b,
                              m_Frustum[nLastOutside].c );
```

We then use the plane normal to calculate the near and far points on the bounding box with respect to the plane.

> **Note:** Remember from our Plane/AABB intersection discussion that the near point is the point that would intersect the plane first were it located totally in the plane's front space and slowly moved towards the plane until the point of intersection. The far point the last point on the AABB that would cross the plane in the same scenario.

```
        // Calculate near / far extreme points
        if ( Normal.x > 0.0f ) { FarPoint.x  = Max.x; NearPoint.x = Min.x; }
        else                   { FarPoint.x  = Min.x; NearPoint.x = Max.x; }

        if ( Normal.y > 0.0f ) { FarPoint.y  = Max.y; NearPoint.y = Min.y; }
        else                   { FarPoint.y  = Min.y; NearPoint.y = Max.y; }

        if ( Normal.z > 0.0f ) { FarPoint.z  = Max.z; NearPoint.z = Min.z; }
        else                   { FarPoint.z  = Min.z; NearPoint.z = Max.z; }
```

If the near point is found to be in front of the plane, the entire box must be in front of the plane. Consequently, if the box is totally in front of any of the planes, then it must be completely outside the frustum. As soon as such a plane is found, we return FRUSTUM_OUTSIDE

> **Note:** Our frustum planes normals face outwards.

```
        // If near extreme point is outside, then the AABB is totally outside
        if ( D3DXVec3Dot( &Normal, &NearPoint ) + m_Frustum[nLastOutside].d>0.0f )
           return CCamera::FRUSTUM_OUTSIDE;
```

If we have not returned from the function yet, it means the near point is in the backspace of the plane, so we next test to see if the far point is in the front space. If it is, the box is spanning the frustum plane and we return FRUSTUM_INTERSECT.

```
        // If far extreme point is outside, then the AABB is intersecting
        if ( D3DXVec3Dot( &Normal, &FarPoint ) + m_Frustum[nLastOutside].d > 0.0f )
            Result = CCamera::FRUSTUM_INTERSECT;
```

If we have still not returned from the function, it must mean that both the near and far points of the box are behind the frustum plane. This means the box is completely contained in the backspace of the plane and we must test the rest of the frustum planes. However, if the box is completely contained in the backspace of this plane, it also means all of the node's children will be too. Therefore, when this function is called for the child nodes, we should skip testing this plane and assume that they are in the backspace also. To do this, we set the bit for this plane in the nBits char to update the bit set that is passed down to the child nodes. We set the bit that corresponds to this plane by shifting the value 1 by the appropriate number of bits to the right (the number of bits to shift is equal to the index of the plane we are setting the bit for) and OR'ing it with the current bit set.

```
        else
            nBits |= (0x1 << nLastOutside); // We were inside, update our bit set
```

```
    } // End if last outside plane specified
```

If we reach this part of the function, it means that either no valid LastFrustumPlane value for the node was passed or that it was tested first, but the node is now found to be intersecting or behind that plane.

In the next section we simply create a loop from 0 to 6 to loop through the 6 frustum planes so that we can test the rest of them. We will skip a plane if its bit is already set to 1 in the nBits array and also skip the plane that was tested first in the above section of code (whose index is contained in nLastOutside).

```
    // Loop through all the planes
    for ( i = 0; i < 6; i++ )
    {
        // Check the bit in the uchar passed to see if it should be
        // tested (if it's 1, it's already passed)
        if ( ((nBits >> i) & 0x1) == 0x1 ) continue;

        // If 'last outside plane' index was specified,
        // skip if it matches the plane index
        if ( nLastOutside >= 0 && nLastOutside == (signed char)i ) continue;
```

If we get this far in the loop code, it means the current plane being processed has not yet had its bit set to 1 in the frustum bits char and it is not the plane we have already tested. As with the first plane we tested, we extract the normal of the current plane and calculate the near and far points.

```
        // Store the plane normal
        Normal = D3DXVECTOR3( m_Frustum[i].a, m_Frustum[i].b, m_Frustum[i].c );

        // Calculate near / far extreme points
        if ( Normal.x > 0.0f ) { FarPoint.x  = Max.x; NearPoint.x = Min.x; }
        else                   { FarPoint.x  = Min.x; NearPoint.x = Max.x; }

        if ( Normal.y > 0.0f ) { FarPoint.y  = Max.y; NearPoint.y = Min.y; }
        else                   { FarPoint.y  = Min.y; NearPoint.y = Max.y; }

        if ( Normal.z > 0.0f ) { FarPoint.z  = Max.z; NearPoint.z = Min.z; }
        else                   { FarPoint.z  = Min.z; NearPoint.z = Max.z; }
```

Next we calculate the distance from the near point to the plane. If it is found to be in the frontspace of the plane, we know the entire box must be outside the frustum so we can return FRUSTUM_OUTSIDE. However, before we return, we also store the index of this plane in the node's LastFrustumPlane member (pointed to by LastOutside) so that this function will test this plane first when the node is frustum tested again in the next visibility pass. We also copy the contents of the nBits char which currently contains all the frustum planes that the node is totally inside of. This is assigned to the FrustumBits pointer so that it is returned from the function to the node, where it can be passed down to its children.

```
        // If near extreme point is outside, then the AABB is totally outside
        // the frustum
        if ( D3DXVec3Dot( &Normal, &NearPoint ) + m_Frustum[i].d > 0.0f )
```

```
        {
            // Store the 'last outside' index
            if ( LastOutside ) *LastOutside = (signed char)i;

            // Store the frustm bits so far and return
            if (FrustumBits) *FrustumBits = nBits;
            return CCamera::FRUSTUM_OUTSIDE;

        } // End if outside frustum plane
```

If the near point is not in front of the plane but the far point is, it means the box is spanning the plane so we return FRUSTUM_INTERSECT.

```
        // If far extreme point is outside, then the AABB is intersecting
        // the frustum
        if ( D3DXVec3Dot( &Normal, &FarPoint ) + m_Frustum[i].d > 0.0f )
            Result = CCamera::FRUSTUM_INTERSECT;
```

Otherwise, it means the current plane being processed has the box contained totally in its backspace. Since this means that all of the node's children will also share this relationship with the plane, we set the bit that corresponds to this plane so that the children know they do not have to process it.

```
        else
            nBits |= (0x1 << i);
           // We were totally inside this frustum plane, update our bit set

    } // Next Plane
```

If we have not yet returned from the function it means the box is inside the frustum. Since there was no plane that rejected it, we set the node's last plane index (pointed to by LastOutside) to -1. We then copy the nBits array into the FrustumBits parameter so that they are accessible to the caller on function return. We then return a result of FRUSTUM_INSIDE.

```
    // Store none outside
    if ( LastOutside ) *LastOutside = -1;

    // Return the result
    if (FrustumBits) *FrustumBits = nBits;
    return Result;
}
```

We have now seen all of the code involved in the visibility processing procedure for the tree. This is all invoked when the application calls the ISpatialTree::ProcessVisibility function. In the last and final section covering the CBaseTree rendering system, we will examine how the visible data is rendered.

15.4.7 Rendering the Visible Static Polygon Data

After the application has called the ISpatialTree::ProcessVisibility method to flag the visible leaves and build the render batches in each leaf bin, all it has to do is loop through each subset in use by the scene and call the ISpatialTree::DrawSubset method. This method is shown below and is the final function of CBaseTree we will cover that pertains to its internal rendering system.

DrawSubset - CBaseTree

This method is called by the application to draw a particular subset in the tree. The application will typically set the texture and material required to render this subset prior to making this call. This function essentially just calls other functions which we have already covered.

Provided the device is valid, we use the CBaseTree::GetLeafBin method to fetch a pointer to the leaf bin for the associated subset ID. If a leaf bin does not exist for this subset ID, it means the tree contains no polygon data that uses this subset. In such situations, the GetLeafBin function returns NULL and we return from the function without taking any further action.

> **Note:** Since the scene is using global attribute IDs for all objects, it is entirely possible that the tree's polygon data will only use a handful of those attributes. As the application will essentially call DrawSubset for each global attribute, this function may be called many times with an attribute ID for which no polygon data exists in the tree for and for which no leaf bin has been created.

```
void CBaseTree::DrawSubset( unsigned long nAttribID )
{
    // Can draw?
    if ( !m_pD3DDevice ) return;

    // Retrieve the applicable leaf bin for this attribute
    CLeafBin * pLeafBin = GetLeafBin( nAttribID );
    if ( !pLeafBin ) return;

    // Render the leaf bin
    pLeafBin->Render( m_pD3DDevice );
}
```

After a valid leaf bin has been retrieved, its Render method is called. We looked at this function earlier and saw how it rendered all the render batches for each index/vertex buffer combination it contains triangles for.

15.5 Rendering the Tree – Application Perspective

Rendering the tree's static geometry could not be easier. Below we see the CScene::Render method from Lab Project 14.1. Because this function is now getting quite large (given all of the code to set up render states, enables lights and fog, rendering the CObject array, etc.), we have snipped a good amount of the code out to condense the listing.

You will recall that the first part of this function sets up certain render states, renders the sky box and enables lighting and fog. In this lab project we have added a new function call to the ISpatialTree::ProcessVisibility method at the bottom of the next section of code.

```
void CScene::Render( CCamera & Camera )
{
    ULONG i, j;
    long  MaterialIndex, TextureIndex;

    if ( !m_pD3DDevice ) return;

    //……SNIP : Set up Global Render states here

    // Render the skybox first !
    RenderSkyBox( Camera );

    //……SNIP : Set up lights and fog here……

    // Allow the spatial tree to process visibility
    m_pSpatialTree->ProcessVisibility( Camera );
```

Now that the visibility status of the tree has been updated using the camera's current position and orientation, we set the device world matrix to an identity matrix because the static geometry stored in the tree is already in world space.

```
    // Loop through each scene owned attribute
    D3DXMATRIX mtxIdentity;
    D3DXMatrixIdentity( &mtxIdentity );

    m_pD3DDevice->SetTransform( D3DTS_WORLD, &mtxIdentity );
```

Now it is time to render the subsets of the spatial tree. We do this by looping through the array of attributes used by the scene. For each attribute, we set its texture and material on the device and call the ISpatialTree::DrawSubset method, passing in the respective attribute ID. If the tree has any data for this attribute, its associated leaf bin will render its triangles.

```
    for ( j = 0; j < m_nAttribCount; j++ )
    {
        // Retrieve indices
        MaterialIndex = m_pAttribCombo[j].MaterialIndex;
        TextureIndex  = m_pAttribCombo[j].TextureIndex;
```

```
        // Set the states
        if ( MaterialIndex >= 0 )
            m_pD3DDevice->SetMaterial( &m_pMaterialList[ MaterialIndex ] );
        else
            m_pD3DDevice->SetMaterial( &m_DefaultMaterial );

        if ( TextureIndex >= 0 && m_pTextureList[ TextureIndex ] )
            m_pD3DDevice->SetTexture( 0, m_pTextureList[ TextureIndex ]->Texture );
        else
            m_pD3DDevice->SetTexture( 0, NULL );

        // Render all faces with this attribute ID
        m_pSpatialTree->DrawSubset( j );

    } // Next Attribute
```

At this point the tree has been rendered in its entirety, so next we loop though the scene's CObject array (which will now store only the dynamic objects in use by the scene, like CActors) and render each one. We will discuss how this works in the next section. Then we can iterate through our terrain array and render any terrains in use. We do not show the code for this as it has not changed from previous demos (we will cover dynamic object rendering in the next section).

Finally, our CGameApp class now includes a new member called m_bDebugDraw. This is a Boolean that has its state toggled by a 'Debug Draw' menu option. The CGameApp::GetDebugDraw method returns the state of this Boolean. As you can see in the following code, if this function returns true, it means the user would like to enable debug drawing and thus the spatial tree's DebugDraw method is called. We discussed the code to this function in the previous lesson and saw how it traverses the tree and draws the bounding boxes at each node.

```
    // …… SNIP : Render all CObjects here (dynamic actors and tri mehses)

    // …… SNIP : Render any terrains here

    // Draw the spatial tree's debug data if requested
    if ( GetGameApp()->GetDebugDraw() ) m_pSpatialTree->DebugDraw( Camera );

}
```

And there we have it. That is all of the code involved in render our spatial tree from the application's perspective. All it took was two function calls to ISpatialTree member functions.

We have now covered the complete rendering system used by CBaseTree. In the end, we have built ourselves a very useful set of spatial managers that optimize both collision queries and scene rendering. In the final section of this chapter we will examine how our dynamic objects can also benefit from the visibility information in our tree. This will enable us to render only the actors that are currently considered visible by the tree.

15.6 Managing Dynamic Objects

So far we have implemented spatial trees that compile static polygon data and we have examined the methods used to prepare and render that data in an efficient manner. We have also added the concept of linking external objects to the leaves of the tree using the concept of detail areas. You will recall that a detail area is a bounding volume that helps shape the tree as it is being built. It is assigned during the compilation phase to the leaves in which it is fully or partially contained. Because each detail area compiled into the tree can also store a context pointer, they allow us to store any type of external object in the tree. A detail area may represent a series of render states, for example, that must be set on the device when the player enters the same leaves as the detail area. This might be handy if you wanted to use detail areas to represent regions of fog within the level or to represent an area where lights should be enabled/disabled. A detail area might also be used to represent a mesh or an actor that we do not want compiled into the tree at the per-polygon level, although we still want it to use the tree's visibility system to inform the application if that object should be rendered. The tree has no understanding of what a detail area represents internally. It just sees it as a bounding volume that has its pointer stored in the leaves in which it is contained. However, the application will know exactly what that detail area represents as it was responsible for registering it with the tree and assigning its context pointer. This context pointer will likely point to some structure or object that has meaning to the application.

The application is ultimately responsible for when and how to process detail areas. If we think about a detail area that represents an external mesh for example, the application would be responsible for rendering that mesh. However, if the detail area is not in any currently visible leaves, the application then knows it does not need to be rendered. In this situation the application can simply query the tree for a list of visible leaves and process only the detail areas in those leaves.

As useful as detail areas are, they do not provide us with coverage for all situations. Since they are compiled directly into the tree, they are totally static concepts. We can link an external mesh or actor to the tree at compile time by registering it as a detail area, but if the application plans on animating or updating the position of that object, detail areas will not suffice. Therefore, a system will have to be added to our tree that works in a similar manner to the detail area idea, but allows for an entity to have its position within the tree dynamically updated.

We will only need to add a handful of methods to CBaseTree in order for our trees to support dynamic objects. The system we will use to register dynamic objects with the tree will be similar to the system we used to register dynamic objects with the collision system. The ISpatialTree::InsertTreeObject method will be used for this purpose. It will store the object internally in the tree and return an ID (a handle) back to the caller. The caller can then use this handle to query for information about that object (such as what leaves is it currently in).

15.6.1 The TreeObject Structure

When a dynamic object is registered with the tree, a TreeObject structure is used as the transport mechanism to pass information about the object to the InsertTreeObject method. This structure is defined in ISpatialTree.h and is shown below.

Excerpt from ISpatialTree.h

```
typedef struct _TreeObject
{
    void          * pContext;
    bool          * pbVisible;
    long            nTreeObjectIndex;
} TreeObject;
```

When we pass a structure of this type into the InsertTreeObject method, only the first two members are used to describe the object. On function return, the third member (nTreeObjectIndex) will contain the handle assigned to the object by the spatial tree. The application can then store this returned handle in the object and use it for later querying.

void *pContext
This member is a pointer to some object that the application would like associated with the dynamic object in the tree. This could be a pointer to a CActor object for example. In our lab project code, we will pass a pointer to a CObject, which will contain either a dynamic CTriMesh or CActor object.

bool *pbVisible
This member allows the application to store a Boolean pointer that the tree will automatically update if the object is inside a visible leaf. That is, during the visibility pass, if a leaf is encountered that is visible, any tree objects (dynamic objects) that have been assigned to that leaf will have their Booleans set to true. This provides an alternative way for the application to query the visibility status of a dynamic object rather than fetching the visible leaves and searching them for the object currently being processed.

In Lab Project 14.1, we extend our CObject structure to store a Boolean member called m_bVisible. We will pass a pointer to this Boolean in this member of the TreeObject structure when we register the CObject with the spatial tree. Later, when the ProcessVisibility process is performed and a leaf which contains this object is found to be visible, the value of this Boolean will automatically be set to true by the tree even though it is stored in a CObject structure which has nothing to do with the tree. When rendering dynamic objects, the application can just loop through each one and only render it if the tree has set its Boolean visibility status to true (more on this later)

long nTreeObjectIndex
This is not an input parameter to ISpatialTree::InsertTreeObject; it will be set on function return so that the application can retrieve and store this value in the CObject structure. Just like our collision system, this is a unique ID that the tree has given to this pair of context and Boolean pointers inside its internal arrays.

15.6.2 The CObject Structure

Our CObject structure has been updated to include two new members. The new version of this structure is shown below with the new members highlighted in bold.

```
class CObject
{
public:

      // Constructors & Destructors for This Class.
         CObject( CTriMesh * pMesh  );
         CObject( CActor   * pActor );

             CObject( );
    virtual ~CObject( );

    // Public Variables for This Class
    D3DXMATRIX                  m_mtxWorld;
    CTriMesh                   *m_pMesh;
    CActor                     *m_pActor;
    LPD3DXANIMATIONCONTROLLER   m_pAnimController;
    CActionStatus              *m_pActionStatus;
    long                        m_nObjectSetIndex;

    long                        m_nTreeObjectIndex;
    bool                        m_bVisible;            // Is this object visible?
};
```

m_nTreeObjectIndex
This member will contain the handle (unique ID) assigned to the object by the spatial tree in response to the ISpatialTree::InsertTreeObject method being called for this object. Whenever we wish to update the position of the object or remove it from the spatial tree, it is this handle that we pass into the ISpatialTree::UpdateTreeObject and the ISpatialTree::RemoveTreeObject methods so that the tree knows exactly which tree object we are referring to.

m_bVisible
This member is a Boolean that describes the visibility status of the object. The address of this Boolean will be passed into the ISpatialTree::InsertTreeObject method (via the TreeObject structure) when the object is first registered. The spatial tree will automatically set this Boolean to true when the object is found to be in a visible leaf. The scene now has visibility information for the external object automatically with having to intersect with the tree itself. The tree will automatically set the m_bVisible Booleans of any CObjects in use by the application that have been registered with the spatial tree and are currently in visible leaves.

Before we discuss the ISpatialTree management of dynamic objects, we will take a look at how the application registers and updates the positions of dynamic objects using the ISpatialTree member functions. This will give us a better understanding of the system we need to implement and the way our application will expect that system to behave.

15.6.3 Registering a Dynamic Object with the Spatial Tree

As was the case with our collision system, any dynamic object that we create is registered with the spatial tree and returned a unique ID for that object within the system. In Lab Project 14.1 we load our scenes from IWF files and, as we have seen, the static geometry stored in the IWF file is added to the tree as static polygon data inside the CScene::ProcessVertices function. We have also seen in nearly all previous lab projects, that our dynamic objects are usually stored in the IWF file as external references to X files which are loaded into actors and stored in the scene's CObject array. It is the ProcessReference method that has always been the function used to create and load such X files into actors. It is in this function that the newly created CObject structure is registered with our collision system. It is also the function where we will register the object with the spatial tree.

The following snippet of code has been added to the very bottom of the CScene::ProcessReference function. It is responsible for adding the newly created CObject (which at this point may store a pointer to a CActor or a CTriMesh) with the spatial tree. In this code, which is only executed if the scene has a spatial tree, the new CObject which has been created earlier in the function (and populated accordingly) has been assigned to the pNewObject pointer.

```
// Add to the spatial tree's object list if applicable
if ( m_pSpatialTree )
{
  TreeObject Object;
  Object.pbVisible = &pNewObject->m_bVisible;
  Object.pContext  = NULL;

  // Add to the tree
  pNewObject->m_nTreeObjectIndex = m_pSpatialTree->InsertTreeObject( Object );

} // End if has spatial tree
```

As you can see, a new TreeObject structure is instantiated as our means of describing the dynamic object to the tree. The TreeObject's Boolean pointer is assigned to point at the m_bVisible Boolean member in our CObject structure for later updates during visibility testing. Notice how we set the context pointer of the TreeObject structure to NULL as we do not need to use it. You could assign this to point at the CObject structure itself, which would be useful if your means for determining dynamic object visibility was to loop through the currently visible leaves searching for TreeObjects that are then rendered. However, our current application only needs to know whether any of the CObjects in its array need to be rendered. Since we have registered the object's Boolean, this will be adequate for our purposes. All our application will need to know when looping through the CObject array is which ones need to be rendered. How you choose to do it is up to you as both methods suit different situations. Using the Boolean means that the application is not required to perform queries into the tree to determine visibility status.

After we have set up the TreeObject structure we then call ISpatialTree::InsertTreeObject passing in TreeObject structure so that this object can be stored in the tree's dynamic object array. The return value from this function is the handle (ID) of the new dynamic object we have just added which has been assigned by the spatial tree. We store this in the CObject's m_nTreeObjectIndex member so that when

our application alters the position of this object in the scene, it can pass this ID into the ISpatialTree::UpdateTreeObject to inform the tree that the object has been updated and that the leaves in which it is currently contained need to be recalculated.

Note that all we have done here is register a single Boolean pointer with the tree. We have not even assigned the object a bounding volume. So how can the tree know which leaves the object should be assigned to? The answer is that it does not; at least not currently. All the above function does is create an entry in the tree's dynamic object array where the passed Boolean pointer and context data pointer are stored. At this point, it is not assigned to any leaves. This is what the ISpatialTree::UpdateTreeObject method is for.

15.6.4 Updating Dynamic Tree Objects

When the application updates the position of an object (i.e., changes its world matrix), we must inform the tree so that it can remove that object's pointer from any leaves in which it is currently contained and assign it to the appropriate new leaves. This is all done automatically when the application makes a call to the ISpatialTree::UpdateTreeObject function. It is this function that is passed the ID of the object we would like to update and a world space AABB. This function will first remove the object from any leaves in which it is currently assigned. It will then pass the AABB of the object down the tree (using the CollectLeavesAABB method) to collect a list of leaves in which the bounding box is contained. The object then has its pointer added to each leaf in which it is contained. This same list of leaves is then stored inside the tree in a structure that pairs the tree object with its intersected leaf list.

Each leaf in our tree will now potentially store a list of TreeObject pointers and each TreeObject stored in the tree will also be stored alongside a list of leaves in which the object is currently contained. This provides yet more convenient ways to use dynamic objects with the system. As each tree object is stored in an array paired with a list of leaves in which it is currently contained, this means the application can quickly access the leaf list for an object using the ISpatialTree::GetTreeObjectLeaves method. This method is passed the ID of a tree object and will simply look up that object in the tree's internal array and return the leaf list that is stored alongside it. Additionally, because the leaves themselves also store a list of tree object pointers describing the list of dynamic objects contained within them, the application can call the ISpatialTree::GetVisibleLeafList method and then parse the returned visible leaves to see if the object in which it is interested is stored there. These few methods provide the application with choices about the way it would like to work with and query the status of its dynamic objects.

The following section of code is taken from the CScene::AnimateObjects method in Lab Project 14.1. This function is certainly familiar to us at this point, but now a few new lines have been added so that the spatial tree is informed about object position updates so that it can rebuild the leaf lists for that object.

The first section of the function is unchanged from our previous lab projects. It sets up a loop to iterate though every object in the scene's CObject array and fetches the CActor and CTriMesh pointers into

local variables. If the actor pointer is valid, we attach the object's controller to the actor and call the actor's AdvanceTime method to advance the timeline of any animation it may be playing.

```
void CScene::AnimateObjects( CTimer & Timer )
{
    ULONG i;

    // Process each object for coll det
    for ( i = 0; i < m_nObjectCount; ++i )
    {
        CObject * pObject = m_pObject[i];
        if ( !pObject ) continue;

        // Get the pointers
        CActor   * pActor = pObject->m_pActor;
        CTriMesh * pMesh  = pObject->m_pMesh;
        if ( !pActor && !pMesh ) continue;

        // Update actor?
        if ( pActor )
        {
            if ( pObject->m_pAnimController )
                 pActor->AttachController( pObject->m_pAnimController,
                                           false,
                                            pObject->m_pActionStatus );

            // Advance time
            pActor->AdvanceTime( Timer.GetTimeElapsed(), false );

        } // End if actor
```

The next section of code is only executed is the current object being processed has been registered with the collision system or the spatial tree. If so, then we will set the actor's matrix and force its absolute matrices to be updated. This is important because we shall see later that this is used to calculate the world space bounding box for the actor which we will need in order to update its position in the tree.

```
        if ( pObject->m_nObjectSetIndex > -1 || pObject->m_nTreeObjectIndex > -1 )
        {
            // Set world matrix and update combined frame matrices.
            if ( pActor ) pActor->SetWorldMatrix( &pObject->m_mtxWorld, true );
```

If the CObject has a valid collision system handle, we call the collision system's ObjectSetUpdated method to allow it to recalculate information about its dynamic object array.

```
            // Notify the collision system that this set of dynamic objects
            // positions, orientations or scale have been updated.
            if ( pObject->m_nObjectSetIndex > -1 )
                 m_Collision.ObjectSetUpdated( pObject->m_nObjectSetIndex );
```

The next bit is new. If the application is using a spatial tree and the current CObject being processed has a valid spatial tree handle stored in its m_nTreeObjectIndex structure, it means that this object has been

registered with the tree and therefore (as its position may have been updated by the AdvanceTime call) we should inform the spatial tree to recalculate the leaves in which this object is situated.

To instruct the spatial tree that the position of our object might have changed, we have to send the object's spatial ID and its world space bounding box into the ISpatialTree::UpdateTreeObject method. Until now, we have had no methods exposed from either CTriMesh or CActor that return the world space bounding box; we will add them to these classes at the end of this lesson. For now, let us just assume that both CTriMesh and CActor have a method called GetBoundingBox which is passed two vectors that will be filled with the world space extents of the object's bounding box.

```
            // Update the tree information
            if ( m_pSpatialTree && pObject->m_nTreeObjectIndex > -1 )
            {
                D3DXVECTOR3 vecMin, vecMax;

                // Retrieve the bounding box
                if ( pActor )
                    pActor->GetBoundingBox( vecMin, vecMax );
                else
                    pMesh->GetBoundingBox( vecMin, vecMax, &pObject->m_mtxWorld );
```

The CActor::GetBoundingBox method takes only two output parameters for the purposes of retrieving the world space box extents that encompass the entire actor hierarchy. The CTriMesh object (which may alternatively be stored in a CObject) has no way of returning a world space bounding box unassisted. It is typically an object space mesh and has no knowledge of its world space position. Therefore, the CTriMesh object will store a model space bounding box which can be converted into world space by passing a transformation matrix as the third parameter to its GetBoundingBox function. This function will simply use our handy TransformAABB method to convert the mesh's model space AABB into a world space AABB. The extents will then be returned using the first two output parameters.

At this point, whether the CObject contains a mesh or an actor, we have a world space bounding box which we can pass into the tree.

```
                // Update the spatial tree object
                m_pSpatialTree->UpdateTreeObject( pObject->m_nTreeObjectIndex,
                                                  vecMin,
                                                  vecMax );

            } // End if has object index

        } // End if actor exists

    } // Next Object
}
```

As you can see, we pass the UpdateTreeObject method the bounding box of the object and its spatial ID, which was issued at the time of registration. Later in the lesson we will see exactly how the bounding boxes are calculated for meshes and actors and how all these new spatial tree methods work.

15.6.5 Rendering Dynamic Objects

In the following code we see a section of the CScene::Render method. Since this is a large method we will only show the new additions which pertain to the rendering of the scene's objects. Remember that they have all been registered with the spatial tree as dynamic objects,

As we discussed in the previous section, situated near the top of the CScene::Render function, the ISpatialTree::ProcessVisibility function is called to traverse the tree and set the visible leaves based on the input camera's frustum. Earlier in the lesson we also learned that this function also builds the render batches for the static data stored in each leaf bin. We will see in a moment that this method can be updated to handle dynamic objects as well. When any leaf is found to be visible, any TreeObject structures stored in that leaf will have their Boolean pointers set to true. We know that the Boolean pointer in each TreeObject structure is actually a pointer to the CObject::m_bVisible member variable, so when the ProcessVisibility method returns, any CObjects that are in visible leaves will have their m_bVisible members set to true.

In the next section of code we show the call to the ProcessVisibility method followed by the loop that iterates through the CScene's CObject array and renders any that have had their visibility Booleans set to true by the spatial tree.

```
    // Update the leaf visibility  (sets CObject Booleans)
    m_pSpatailTree->ProcessVisibility( pCamera);

     … SNIP : Render spatial tree's static data here

    // Process each object
    for ( i = 0; i < m_nObjectCount; ++i )
    {
        CObject  * pObject = m_pObject[i];
        if ( !pObject ) continue;

        // Skip if this object is listed as not visible
        if ( !pObject->m_bVisible ) continue;

        // Flag this object as *not* visible for the next call to ProcessVisibility
        // but only if it has been registered with the tree
        if ( pObject->m_nTreeObjectIndex >= 0 ) pObject->m_bVisible = false;

        // Retrieve actor and mesh pointers
        CActor   * pActor = pObject->m_pActor;
        CTriMesh * pMesh  = pObject->m_pMesh;
        if ( !pMesh && !pActor ) continue;

        … SNIP : Set Object matrix
        …
        … For Each  Subset
        …
        …    pActor/pMesh -> DrawSubset ( … )
        …
        … End For Each Subset
```

```
    }

    // SNIP : Render any terrains here
```

The important point to notice in the above code snippet is that once we find a CObject that is in a visible leaf, we reset its visibility Boolean back to false prior to rendering it. This is so the Boolean will be returned to its default state when the ISpatialTree::ProcessVisibility method is called during the next frame render.

Now that we have had a high level look at how the spatial tree's dynamic object system will work, it should be clear that, from the application's perspective, things could not be easier. The application really only ever has to call two methods for each dynamic object. The InsertTreeObject method is called once (at load time in our example) to register the object with the tree, and the UpdateTreeObject method is called to update the position of the object inside the spatial tree when required. Let us now have a look at the changes we have had to make to both the ISpatialTree and ILeaf interfaces in order to add support for these concepts.

15.6.6 ILeaf - Adding Dynamic Object Support

The ILeaf abstract base class from which CBaseLeaf is derived only requires one extra method to be implemented in the derived classes so that application can query the list of TreeObjects for a given leaf. This method is called GetTreeObjectList and is highlighted in bold below.

Excerpt from ISpatialTree.h

```
class ILeaf
{
public:

    // Typedefs, Structures and Enumerators.
    typedef std::list<TreeObject*> TreeObjectList;

    // Constructors & Destructors for This Class.
    virtual ~ILeaf() {};     // forces derived classes to have virtual destructors

    // Public Pure Virtual Functions for This Class.
    virtual bool            IsVisible           ( ) const = 0;
    virtual unsigned long   GetPolygonCount     ( ) const = 0;
    virtual CPolygon *      GetPolygon          ( unsigned long nIndex ) = 0;
    virtual unsigned long   GetDetailAreaCount  ( ) const = 0;
    virtual TreeDetailArea *GetDetailArea       ( unsigned long nIndex ) = 0;

    virtual TreeObjectList& GetTreeObjectList   ( ) = 0;

    virtual void            GetBoundingBox      ( D3DXVECTOR3 & Min,
                                                  D3DXVECTOR3 & Max ) const = 0;

};
```

Notice that this method accepts no parameters and will return a list of all the TreeObject structures stored in this leaf. The return type TreeObjectList is a type definition for an STL list which stores TreeObject structure pointers. You can see this typedef at the top of the code shown above.

As you can see, from the application's perspective (which always works with the ISpatialTree interface), only one method has been added that allows it to retrieve the entire list of dynamic objects stored in that leaf. An application might, for example, employ a totally different rendering strategy than the one we have chosen. It might prefer to fetch the list of visible leaves from the tree and then loop through each of them individually. For each leaf, it can use this new method (GetTreeObjectList) to get the list of dynamic objects stored in that leaf and then fetch the context pointer from each TreeObject structure for further processing. This is an alternative to the Boolean pointer method we have chosen to use in Lab Project 14.1.

15.6.7 ISpatialTree - Adding Dynamic Object Support

Four new methods have been added to the ISpatialTree interface to allow the application to add, insert, and remove dynamic objects from the tree. There is also a method that allows the application to retrieve a list of all the leaves a given object is currently contained in.

We will not show the entire ISpatialTree class here since we have only added four methods. These are shown below.

Excerpt from ISpatialTree.h

```
virtual long            InsertTreeObject    ( TreeObject & Object ) = 0;

virtual void            UpdateTreeObject    ( long nObjectIndex,
                                              const D3DXVECTOR3 &BoundsMin,
                                              const D3DXVECTOR3 &BoundsMax)= 0;

virtual void            RemoveTreeObject    ( long nObjectIndex ) = 0;

virtual bool            GetTreeObjectLeaves ( long nObjectIndex,
                                              LeafList & List ) = 0;
```

These are all pure virtual methods which serve to define the functionality that must be implemented in the derived classes.

15.6.8 CBaseTree/CBaseLeaf - Adding Dynamic Object Support

The full implementation for dynamic object support will be contained within CBaseTree and CBaseLeaf. The derived classes will not require any additional code. We will start by examining the members and methods that will need to be added to CBaseLeaf first.

15.6.9 CBaseLeaf – The Source Code

CBaseLeaf will need three new member functions and a single member variable. In the following listing we do not show the entire declaration of CBaseLeaf, only the new members.

```
public:

    // Public Virtual Functions for This Class (from base).
    virtual TreeObjectList& GetTreeObjectList   ( );

    // Public Functions for This Class.
    void                    InsertTreeObject    ( TreeObject * pObject );
    void                    RemoveTreeObject    ( TreeObject * pObject );

protected:

    // Protected Variables for This Class
    TreeObjectList      m_TreeObjects;      // List of objects
```

m_TreeObjects
This member will be used to store a list of TreeObject structures. This list represents all the tree objects that are currently considered to be in this leaf by the CBaseTree. A dynamic object (a TreeObject) will be assigned to a leaf (or multiple leaves) when the application issues a call to the CBaseTree::UpdateTreeObject method. This method will traverse the tree with an input world space bounding box and collect a list of all leaves intersecting that box. The CBaseLeaf::InsertTreeObject method will then be called for each leaf in this list so that the tree object is added to each leaf's tree object list.

InsertTreeObject – CBaseLeaf

This method will never be called by the application. It is used during a tree object update by CBaseTree when it determines that the tree object should be added to a leaf. The tree will issue a call to this method for each leaf in which the tree object is contained. This method is a simple function that just adds the passed TreeObject pointer to the leaf's internal list of tree objects.

```
void CBaseLeaf::InsertTreeObject( TreeObject * pObject )
{
    // Push this context pointer onto the end of the list
    m_TreeObjects.push_back( pObject );
}
```

RemoveTreeObject – CBaseLeaf

This is another method that will never be called by the application, but is called by the tree during the update of a tree object. When the application issues a call to the CBaseTree::UpdateTreeObject method, the first thing this method will do is remove the tree object from any leaves to which it is currently assigned. We will see in a moment that, inside CBaseTree, each tree object is stored along with a list of leaves in which it is currently contained. Therefore, when its position needs to be updated, this leaf list is traversed and the CBaseLeaf::RemoveTreeObject method will be called to unhook the tree object from all its current leaves. The update method will then pass the bounding box of the tree object (in its new world space position) down the tree and collect a new list of leaves in which the object is now considered to be contained. This new leaf list is then traversed and the CBaseTree::InsertTreeObject method called for each. This will add the tree object to each of the new leaves as discussed above. Therefore, updating a tree object will essentially involve removing it from all its current leaves, finding a new list of leaves its bounding box intersects, and then adding the object to this new list of leaves. The code to CBaseLeaf::RemoveTreeObject, which is used in this process, is shown below.

```
void CBaseLeaf::RemoveTreeObject( TreeObject * pObject )
{
    // Remove this context pointer from the list
    m_TreeObjects.remove( pObject );
}
```

As you can see, it simply removes the passed TreeObject pointer from the leaf's tree object list. At that point, the tree object will no longer be considered to be in that leaf.

GetTreeObjectList - CBaseLeaf

This method is required by the base class (ILeaf) and allows the application to retrieve the list of tree objects currently contained in the leaf. This method just returns the leaf's m_TreeObjects list.

```
ILeaf::TreeObjectList& CBaseLeaf::GetTreeObjectList( )
{
    // Just return the list.
    return m_TreeObjects;
}
```

As mentioned, this might prove useful if the application chooses a different rendering strategy than the one we are using.

SetVisible – CBaseLeaf

We have examined this function a few times in this lesson in one form or another. You will recall that it is called by a derived class's UpdateTreeVisibility method every time a visible leaf is found during the visibility traversal. It is called to flag leaves as either invisible or visible.

As we know, this function sets the visible status of the leaf. If the leaf is visible, its triangle runs are added to the relevant leaf bins. After that, the leaf then adds its 'this' pointer to tree's visible leaf list. This is all unchanged from the previous version. All we have added to the bottom of the function is a couple of lines that loop through the list of tree objects stored in this leaf and sets their registered Booleans to true. The new lines of code are highlighted in bold at the bottom of the function listing.

```
void CBaseLeaf::SetVisible( bool bVisible )
{
    ULONG                 i, j;
    RenderData::Element * pElement;
    CLeafBin            * pLeafBin;
    RenderData          * pData;

    // Flag this as visible
    m_bVisible = bVisible;

    // If we're being marked as visible, inform the renderer
    if ( m_bVisible && m_nRenderDataCount > 0 )
    {
        // Loop through each renderable set in this leaf.
        for ( i = 0; i < m_nRenderDataCount; ++i )
        {
            pData    = &m_pRenderData[i];
            pLeafBin = pData->pLeafBin;

            // Loop through each element to render
            for ( j = 0; j < pData->ElementCount; ++j )
            {
                pElement = &pData->pElements[j];
                if ( pElement->PrimitiveCount == 0 ) continue;

                // Add this to the leaf bin
                pLeafBin->AddVisibleData( pElement->VBIndex,
                                          pElement->IndexStart,
                                          pElement->PrimitiveCount );
            } // Next Element
        } // Next RenderData Item
    } //  End if visible

    // Update tree object's if we're visible
    if ( m_bVisible )
    {
        // // Add this leaf to the tree's visible leaf list
        m_pTree->AddVisibleLeaf( this );
```

```
        TreeObjectList::iterator Iterator = m_TreeObjects.begin();
        for ( ; Iterator != m_TreeObjects.end(); ++Iterator )
        {
            TreeObject * pObject = *Iterator;
            if ( pObject->pbVisible ) *pObject->pbVisible = true;

        } // Next tree object

    } // End if we are visible
}
```

As you can see, we iterate through the TreeObject list stored in this leaf only if the leaf is visible. For each tree object, if it has a non-NULL Boolean pointer (pbVisible), then it means that the application would like this Boolean set to true when the object is visible. As we saw earlier, in our application, the Boolean pointer in each tree object will actually point to a CObject's visibility Boolean. This means that although the tree itself has no knowledge that this tree object actually represents a CObject structure, it still has the ability to set its visibility status to true so that the application knows it has to render this CObject during the CScene::Render function.

We have now looked at the minor changes to CBaseLeaf that provide support for the containment of dynamic objects. Next we will discuss the changes to the CBaseTree class where most of our dynamic object support functionality will be contained.

15.6.10 CBaseTree – The Source Code

We have seen that our leaves will maintain a list of TreeObject structures, so every leaf will know which dynamic objects it contains. However, CBaseTree will also store an array (STL vector) of all TreeObjects currently registered with the system, along with a list of leaves that object is currently contained within. This means that each leaf will have immediate access to the objects it contains, and each object will have immediate access to the list of leaves in which it is contained. This allows us to very efficiently return a list of leaves when the application issues a call to the ISpatialTree::GetTreeObjectLeaves method. This method is passed the ID of a tree object and returns its leaf list. The leaf list for each tree object is updated during the call to the CBaseTree::UpdateObject method, which we will see the code for in a moment.

15.6.11 The TreeObjectData Structure

A new structure will be needed so that CBaseTree can maintain a list of TreeObject structures paired with the object leaf lists. This new structure is defined in the CBaseTree namespace but is shown below on its own. It is called TreeObjectData and there will be an array of these structures stored in CBaseTree. Each element in this array will store the information for a tree object that is currently registered with the system.

Excerpt from CBaseTree.h

```
struct TreeObjectData             // Stores the data relating to a tree object
{
        TreeObject   Object;      // The 'context' for the tree object
        LeafList     Leaves;      // List of leaves in which the object exists
        bool         bInUse;      // This element is currently in use?
}
```

TreeObject Object

This member stores the TreeObject structure itself. This is the TreeObject that this TreeObjectData structure represents. Recall that the TreeObject structure has three members: a spatial ID that identifies the object to the system, a Boolean pointer that will be set to true when the object is visible, and a context pointer that can be used by the application to store any arbitrary data.

LeafList Leaves

This is a list of leaves in which the above TreeObject is currently considered contained. This leaf list is used to update the position of a tree object very efficiently. Because we store the list of leaves the object is currently contained in, when we wish to update the position of a tree object (which first involves removing it from all current leaves), we can iterate through this list calling the CBaseLeaf::RemoveTreeObject method before emptying the list. This will allow us to quickly empty this list and remove the object from all the leaves prior to an update. Then, the CBaseTree::UpdateTreeObject method will send the AABB of the tree object down the tree to build a new leaf list which is then stored in this member. We can then iterate through this list and call the CBaseLeaf::InsertTreeObject method for each leaf to add the TreeObject to each new leaf in which it is now contained.

Of course, the other useful thing about this member, beyond speeding up the tree object updates, is that it allows the application to retrieve a list of leaves for a given tree object. As this information is already compiled for every tree object, when the application requests the leaf list for a tree object by passing its spatial ID, the CBaseTree::GetTreeObjectLeaves method can simply search the TreeObjectData array for a TreeObject data structure with the matching ID and, if found, return the leaf list stored there.

bInUse

This is a Boolean that will tell the tree whether this particular TreeObjectData structure currently contains a tree object or whether it is empty and can be reused. This minimizes array resizing every time a tree object is removed. When a tree object is removed from the system (at the application's request), we do not delete its TreeObjectData structure and resize the array; we simply set this Boolean to false so that we know the next time we wish to add a new object, this TreeObjectData element can be used and its current data overwritten.

Below we see the new members and methods in CBaseTree that have been added to manage dynamic objects. As you can see, it implements the four methods required by ISpatialTree to allow the application to add, remove, and update dynamic objects within the tree. It contains only one new member, which is an array of TreeObjectData structures.

Excerpt from CBaseTree.h

```
public:

    virtual long            InsertTreeObject    ( TreeObject & Object );
    virtual void            UpdateTreeObject    ( long nObjectIndex,
                                                  const D3DXVECTOR3 & BoundsMin,
                                                  const D3DXVECTOR3 & BoundsMax );

    virtual void            RemoveTreeObject    ( long nObjectIndex );

    virtual bool            GetTreeObjectLeaves ( long nObjectIndex,
                                                  LeafList & List );

protected:

    // STL Typedefs
    typedef std::vector<TreeObjectData>     TreeObjectVector;

    // Protected Variables for This Class.
    TreeObjectVector            m_TreeObjects;
};
```

TreeObjectVector m_TreeObjects
This is an STL vector that stores TreeObjectData structures. Therefore, this array is basically used to store all of the tree's currently registered dynamic objects.

InsertTreeObject – CBaseTree

This is the method that the application uses to register a dynamic object with the system. The caller fills out a TreeObject structure and passes it in and the function will look for a place to store it in the TreeObjectData array. It first searches though the m_TreeObjects vector to see if there are any TreeObjectData structures that are not currently in use by the system. If one if found, we break from the loop so that the loop variable *i* contains the index of this element.

```
long CBaseTree::InsertTreeObject( TreeObject & Object )
{
    ULONG i;

    // Loop through the vector and determine if there is a free slot
    for ( i = 0; i < m_TreeObjects.size(); ++i )
    {
        // Is this in use?
        if ( m_TreeObjects[i].bInUse == false ) break;

    } // Next Tree Object
```

If we could not find a free slot, then the loop would have run to completion. Either way, loop variable *i* will now contain the new index for where we wish to store the passed tree object. We store this index in the object's nTreeObjectIndex member so that on function return the application will have access to this

ID and can store it. This is a unique ID for this object within the system and the handle the application will use to refer to it when it wants to update its position within the tree.

```
    // Update the object's index to the new slot
    Object.nTreeObjectIndex = i;
```

If *i* equals the current size of the array, then it means that there was no free slot that can be reused, and we will need to instantiate a new TreeObjectData structure, store the passed TreeObject in it, and set its bInUse Boolean to true. We then add it to the end of the array.

```
    // Did we reach the end?
    if ( i == m_TreeObjects.size() )
    {
        TreeObjectData Data;

        // Populate a new data element
        Data.bInUse   = true;
        Data.Object   = Object;

        // Add a new element to the array
        m_TreeObjects.push_back( Data );

    } // End if no free slot
```

If we did find a free slot in the array, we will reuse it by storing the passed TreeObject in it and setting its bInUse Boolean to true. Notice in the following code that because this TreeObjectData structure was used previously by another object that has since be un-registered, the leaf list stored there will need to be emptied as it will not be valid for our new object.

```
    else
    {
        // Just re-use the free slot
        m_TreeObjects[i].bInUse                 = true;
        m_TreeObjects[i].Object                 = Object;
        m_TreeObjects[i].Leaves.clear();

    } // End if free slot found

    // Return the new object's index
    return i;
}
```

Finally, the function returns the ID that was assigned to the new tree object. This ID is just the position of the TreeObjectData structure in the tree's object list.

What is important to remember is that although this function is used to add a new dynamic object to the tree, when the function returns it will have not yet be assigned to any leaves. That is what the UpdateTreeObject method does, which we will examine next.

UpdateTreeObject – CBaseTree

We saw earlier that this function is called by the application in the CScene::AnimateObjects method. It should be called whenever the world matrix of an object has been changed, or in the case of an animated actor, whenever its animation has been advanced. In the case of an animated actor, even if the application never changes its position in the scene, the individual meshes contained in its hierarchy may move or rotate. This would ultimately change the size of the actor's bounding box (the box that bounds all meshes in the actor) and if the bounding box has gotten bigger or smaller with respect to the previous frame update, the actor may now exist in more or less leaves than before.

The function is actually quite straightforward even though it would seem to have a difficult task to perform. It is passed the ID identifying the object that needs its leaves recalculated, and the world space bounding box of that object. The function uses the passed ID to fetch a pointer to the relevant TreeObjectData structure to update.

```
void CBaseTree::UpdateTreeObject( long nObjectIndex,
                                  const D3DXVECTOR3 & BoundsMin,
                                  const D3DXVECTOR3 & BoundsMax )
{
    LeafList::iterator Iterator;
    TreeObjectData *   pData = NULL;

    // Valid the specified data item.
    if ( nObjectIndex < 0 || nObjectIndex >= (signed)m_TreeObjects.size() ) return;
    if ( !m_TreeObjects[ nObjectIndex ].bInUse ) return;

    // Store pointer to object to save lookups
    pData = &m_TreeObjects[ nObjectIndex ];
```

As the object may have moved, we will first remove it from all leaves in which it is currently stored. As each TreeObjectData structure contains the TreeObject and its current leaf list, we just have to loop through that leaf list calling the CBaseLeaf::RemoveTreeObject method for each.

```
    // Loop through the leaves and remove this from the object list
    for ( Iterator = pData->Leaves.begin();
          Iterator != pData->Leaves.end(); ++Iterator )
    {
        CBaseLeaf * pLeaf = (CBaseLeaf*)(*Iterator);
        if ( !pLeaf ) continue;

        // Request that this object is removed from the leaf
        pLeaf->RemoveTreeObject( &pData->Object );

    } // Next Leaf

    // Clear the list
    pData->Leaves.clear();
```

We saw the code to the CBaseLeaf::RemoveTreeObject function a moment ago. It simply removes the passed TreeObject pointer from its list. After this loop ends, we will have visited every leaf that currently contains the object and removed its pointer from those leaves. After that, we empty the leaf list in the TreeObject as well. At this point our object has the same status as a newly registered object; it is not stored in any leaves and it does not have any leaves in its leaf list.

Now it is time to rebuild this information. We start by passing the TreeObject's empty leaf list into the CollectLeavesAABB method, along with the world space bounding box of the object. When this function returns, the object will have an updated leaf list.

```
    // Collect the new leaves
    CollectLeavesAABB( pData->Leaves, BoundsMin, BoundsMax );
```

Of course, our job is not quite done. Although the object now has an updated list of leaves, the leaves in this list still do not know that they contain the object. Therefore, we will loop through the new leaf list and call the CBaseLeaf::InsertTreeObject method to add the object to the object lists for each leaf in which it is currently contained.

```
    // Loop through the leaves and add this back to the newly discovered leaves
    for ( Iterator = pData->Leaves.begin();
          Iterator != pData->Leaves.end(); ++Iterator )
    {
        CBaseLeaf * pLeaf = (CBaseLeaf*)(*Iterator);
        if ( !pLeaf ) continue;

        // Request that this object is removed from the leaf
        pLeaf->InsertTreeObject( &pData->Object );

    } // Next Leaf
}
```

GetTreeObjectLeaves - CBaseTree

This function can be used by the application to fetch the list of leaves (both visible and invisible) in which a tree object is currently contained. The application passes in the ID of the tree object it would like to retrieve a leaf list for and a leaf list to store the results.

```
bool CBaseTree::GetTreeObjectLeaves( long nObjectIndex, LeafList & List )
{
    // Valid the specified data item.
    if ( nObjectIndex < 0 || nObjectIndex >= (signed)m_TreeObjects.size() )
         return false;

    if ( !m_TreeObjects[ nObjectIndex ].bInUse ) return false;

    // Populate the list
    List = m_TreeObjects[ nObjectIndex ].Leaves;
```

```
    // Success!
    return true;
}
```

This method uses the passed ID to fetch the TreeObjectData structure from the array and, provided this element is in use (i.e., it is a valid object), it returns the TreeObjectData's leaf list.

RemoveTreeObject - CBaseTree

This method can be called by the application to remove a dynamic object from the tree. It is the mirror function to the InsertTreeObject method. Its single parameter is the ID of the tree object you would like to unregister from the system.

The first thing the method does is use the passed ID to fetch the corresponding TreeObjectData structure from the tree's object data array.

```
void CBaseTree::RemoveTreeObject( long nObjectIndex )
{
    LeafList::iterator Iterator;
    TreeObjectData *   pData = NULL;

    // Valid index?
    if ( nObjectIndex < 0 || nObjectIndex >= (signed)m_TreeObjects.size() ) return;

    // Store pointer to object to save lookups
    pData = &m_TreeObjects[ nObjectIndex ];
```

Now we loop through this tree object's leaf list and call the CBaseLeaf::RemoveTreeObject method for each one. This removes it from the object list in each leaf currently containing the object.

```
    // Remove it from any leaves it currently exists in
    for ( Iterator = pData->Leaves.begin();
          Iterator != pData->Leaves.end(); ++Iterator )
    {
        CBaseLeaf * pLeaf = (CBaseLeaf*)(*Iterator);
        if ( !pLeaf ) continue;

        // Request that this object is removed from the leaf
        pLeaf->RemoveTreeObject( &pData->Object );

    } // Next Leaf
```

Finally, we set this TreeObjectData structure's bInUse Boolean to false and empty its leaf list.

```
    // Just re-use the free slot next time someone inserts
    pData->bInUse = false;
    pData->Leaves.clear();
}
```

We have now covered all the new methods and code that are involved in adding dynamic object support to CBaseTree.

15.6.12 Conclusion – Dynamic Objects

After an admittedly arduous journey, we have completed the code for our ISpatialTree derived classes. Along the way we have seen that CBaseTree provides nearly all of the core functionality for any tree type we might care to derive from it in the future.

One interesting item we encountered in this last section was that CBaseTree views dynamic objects in a very abstract way. It has no idea what the TreeObject structure represents and does not need to. We do not even use the context pointer of this structure in our lab project, only its Boolean pointer. Therefore, we have discovered that a dynamic object used in this way is really just a Boolean pointer with an assigned ID. It is ultimately attached to some number of leaves every time the UpdateTreeObject method is called, but it remains quite a separate concept. The TreeObject does not even store a bounding volume for the object it represents, as one might suspect. Instead, this bounding volume is passed into the UpdateTreeObject method by the application whenever it wishes to inform the tree that the object has moved and its Boolean pointer should now be assigned to a new set of leaves.

Of course, the dynamic object system we have developed does place a particular burden on the application. In order for the application to update the position of a CObject, it must have access to the world space bounding box of the object it contains (either a CTriMesh or a CActor). Up until this point in the course however, CTriMesh and CActor have never exposed a method for retrieving any world space bounding box, so we will need to add these now before concluding the lesson.

15.7 CTriMesh Revisited – World Space Bounding Boxes

CTriMesh will now have two new members added to it. These will be 3D vectors that describe the *object space* AABB of the mesh. As a mesh is by its very nature an object space concept, there is no way it can know about its world space position or size and therefore, the object space box will be created and stored instead. CTriMesh will then expose a method called GetBoundingBox which allows for a world transformation matrix to be passed. This function will transform the object space bounding box into world space before returning it to the application. We saw CTriMesh::GetBoundingBox being used earlier when we examined the changes to the CScene::AnimateObjects method. This method would fetch the world space bounding box from the CTriMesh (if one was stored in the current CObject structure being updated) and pass it into the ISpatialTree::UpdateTreeObject. When the CTriMesh::GetBoundingBox method was called, it was passed the world matrix of the owner object. This meant we would get back the world space AABB for the mesh.

Here are the new members and methods added to CTriMesh.

```
protected:
D3DXVECTOR3         m_vecBoundsMin;
D3DXVECTOR3         m_vecBoundsMax;

public:

HRESULT UpdateBoundingBox();

void    GetBoundingBox(D3DXVECTOR3 &BoundsMin,
                       D3DXVECTOR3 &BoundsMax,
                       D3DXMATRIX * pMatrix = NULL ) const;
```

UpdateBoundingBox - CTriMesh

Our application will never call this function (although it can if it would like to rebuild the object space bounding box of the mesh for some reason) as it is called automatically by the CTriMesh::LoadMeshFromX function just before returning. The function is like many we have seen before. The first thing it does is query the D3DXMesh managed by the CTriMesh object for an ID3DXBaseMesh interface. This allows us to work with both regular and progressive meshes using the base interface.

```
HRESULT CTriMesh::UpdateBoundingBox( )
{
    HRESULT           hRet;
    UCHAR           * pVertices  = NULL;
    ULONG             nVertexStride, nVertexCount;
    D3DXVECTOR3       vecPos;
    ULONG             i;

    // Retrieve the mesh
    LPD3DXBASEMESH pMesh = NULL;

    // What type of mesh?
    if ( m_pMesh )
    {
        // Query the interface to get back the base mesh.
        hRet = m_pMesh->QueryInterface( IID_ID3DXBaseMesh, (void**)&pMesh );
        if ( FAILED( hRet ) ) return hRet;

    } // End if standard mesh
    else if ( m_pPMesh )
    {
        // Query the interface to get back the progressive mesh
        hRet = m_pPMesh->QueryInterface( IID_ID3DXBaseMesh, (void**)&pMesh );
        if ( FAILED( hRet ) ) return hRet;

    } // End if progressive mesh
    else
    {
        // Just return
```

```
        return D3D_OK;

    } // End if no mesh
```

We initialize the mesh's bounding box to extreme starting values (an inside-out box).

```
    // Reset the bounding box
    m_vecBoundsMin = D3DXVECTOR3(  FLT_MAX,  FLT_MAX,  FLT_MAX );
    m_vecBoundsMax = D3DXVECTOR3( -FLT_MAX, -FLT_MAX, -FLT_MAX );
```

We then get the number of vertices and the number of bytes each vertex consumes in memory before locking the mesh's vertex buffer to get a pointer to its vertex data.

```
    // Retrieve additional info we need for processing
    nVertexStride = pMesh->GetNumBytesPerVertex( );
    nVertexCount  = pMesh->GetNumVertices( );

    // Lock the vertex buffer
    hRet = pMesh->LockVertexBuffer( D3DLOCK_READONLY, (void**)&pVertices );
    if ( FAILED(hRet) ) { pMesh->Release(); return hRet; }
```

Now we will iterate through every vertex in the vertex buffer and copy the positional data into a D3DXVECTOR3 called vecPos.

```
    // Compute this frame's bounding box
    for ( i = 0; i < nVertexCount; ++i, pVertices += nVertexStride )
    {
        // Retrieve the position of this vertex in it's reference pose
        vecPos = *(D3DXVECTOR3*)pVertices;
```

We then test the components of this vertex against the currently recorded maximum and minimum box extents and adjust them accordingly.

```
        // Test it against the frame bounding box and update if necessary
        if ( vecPos.x < m_vecBoundsMin.x ) m_vecBoundsMin.x = vecPos.x;
        if ( vecPos.y < m_vecBoundsMin.y ) m_vecBoundsMin.y = vecPos.y;
        if ( vecPos.z < m_vecBoundsMin.z ) m_vecBoundsMin.z = vecPos.z;
        if ( vecPos.x > m_vecBoundsMax.x ) m_vecBoundsMax.x = vecPos.x;
        if ( vecPos.y > m_vecBoundsMax.y ) m_vecBoundsMax.y = vecPos.y;
        if ( vecPos.z > m_vecBoundsMax.z ) m_vecBoundsMax.z = vecPos.z;

    } // Next Vertex
```

After this loop finishes, the bounding box will fit every vertex in the mesh and our job is complete. All we have to do now is unlock the vertex buffer and return.

```
    // Unlock the vertex buffer
    pMesh->UnlockVertexBuffer();

    // Release the pointer to the mesh we retrieved
```

```
    pMesh->Release();

    // Success!!
    return D3D_OK;
}
```

It should be noted that while this method need never be called if you are populating the CTriMesh using its CTriMesh::LoadMeshFromX method (it calls this method automatically), if you are procedurally building a CTriMesh then you will want to call this method after you have added all the vertex data and built its underlying D3DXMesh. Another time you will want to call this method is if you detach the underlying D3DXMesh and attach a new one.

GetBoundingBox - CTriMesh

Although the CTriMesh object stores its model space bounding box, we want a function that can optionally return the world space bounding box if needed. A CTriMesh object has no information about where the mesh lives in the world, so we will add a matrix pointer parameter to its GetBoundingBox function. This allows the application to pass a world matrix that will be used to transform the model space bounding box into world space before returning it to the caller. Luckily, we have already written the TransformAABB method that performs this very task and as such, the CTriMesh::GetBoundingBox uses it to optionally perform the world space transformation.

```
void CTriMesh::GetBoundingBox( D3DXVECTOR3 & BoundsMin,
                               D3DXVECTOR3 & BoundsMax,
                               D3DXMATRIX * pMatrix /* = NULL */ ) const
{
    BoundsMin = m_vecBoundsMin;
    BoundsMax = m_vecBoundsMax;

    // Transform if a matrix is provided
    if ( pMatrix ) MathUtility::TransformAABB( BoundsMin, BoundsMax, *pMatrix );
}
```

As you can see, the function is passed the 3D vectors that will receive the resulting AABB extents. First we copy the model space bounding box of the mesh into these vectors. If the caller passed a matrix, this bounding box is then transformed by that matrix prior to the function returning.

15.8 CActor Revisited – World Space Bounding Boxes

Adding a function to our actor that will return its world space bounding box will not be quite as simple as it was for our mesh. The bounding box it returns must be large enough to encompass all the meshes contained in its hierarchy. At first we might think that this could be done at actor creation time by traversing the tree to find all mesh containers and then building a box to contain the vertices in those meshes. That would certainly work if the actor was not animated, but as we know, actors can be

animated and this changes things. If we imagine an actor that has been created to store a hierarchy of meshes that all rotate and move, we can see that the size of the actor's bounding box would changed during animation updates. Imagine a skinned character for example. It would have one bounding box when its arms are by its side and a different one when it holds its arms out to each side. An even better example of the drastic size changes that can occur to an actor's bounding box would be an actor that models a space ship on a launching pad (like our lab project in Chapter 9). At the start of the animation, the craft would be on the launch pad with a small bounding box encompassing the launch pad and the spaceship. As the animation plays, the spaceship takes off and flies off into the distance. As both the launch pad and the actor are mesh containers within the same actor in this example, the bounding box of the actor would have to dynamically grow to contain the craft as it flies off into the distance.

Traversing the actor hierarchy whenever its animation is updated and calculating a new world space bounding box at the per-mesh level is out of the question if we want to do this quickly. Instead, we will use an approach that will take advantage of the fact that the actor has a spatial tree of its own that can be traversed and updated. Our design approach will be very familiar to you since it is identical in concept to the way we generate the world matrices (combined matrices) for each frame.

Each frame in the tree will now store two sets of bounding box extents (four vectors). Our new D3DXFRAME_MATRIX structure is shown below.

```
struct D3DXFRAME_MATRIX : public D3DXFRAME
{
    D3DXMATRIX   mtxCombined;    // Combined matrix for this frame.
    D3DXVECTOR3  vecBoundsMin;   // Bounding box (in world space)
    D3DXVECTOR3  vecBoundsMax;   // Bounding box (in world space)

    D3DXVECTOR3  vecObjectMin;   // Bounding box (in object space)
    D3DXVECTOR3  vecObjectMax;   // Bounding box (in object space)
    bool         bObjectBounds;  // This bounding box describes the extents
                                 // of a physical object?
};
```

15.8.1 The Model Space Bounding Boxes

vecObjectMin and vecObjectMax will be calculated automatically when the actor's data is first loaded from the X file (via a call from the LoadActorFromX method to the BuildBoundingBoxes method). It will store the model space bounding box of any frame that directly stores mesh data. But what does the bounding box of a frame represent? In our case it will represent a bounding box that is large enough to contain all the mesh containers ***directly*** attached to a given frame. Only frames in the hierarchy that have mesh containers attached will store a model space bounding box, so there will not yet be any parent/child relationship as we see in a spatial tree of bounding volumes.

During the building phase of these boxes, the tree will be traversed and any frame that has a mesh container attached will have a bounding box generated for that mesh (or list of meshes if multiple mesh containers are assigned to the same frame). That model space box with be stored in the owner frame. You will notice that our updated frame structure also stores a new Boolean called bObjectBounds. This

will be set to true only for frames that store a model space bounding box in the vecObjectMin and vecObjectMax members (i.e., frames that have mesh data directly attached to them). However, we must also remember that the actor may contain a skinned mesh, in which case things are a little different.

Up until now we have been talking about the actor and its model space bounding boxes in the simplest form. That is, any frame that has a mesh container attached will also store a model space bounding box describing the position and size of that mesh in the actor's reference pose. However, if we think about the bones of an actor, they do not have mesh containers attached to them (usually the entire skin is stored in the tree attached to an arbitrary frame; most often the root) so does that mean bones should not store model space bounding boxes either? It certainly does not!

Although a bone may not have a mesh container structure attached to it, it does represent some portion of a mesh. For example, imagine a bone that has all the vertices of a skinned character's elbow mapped to it. That bone should contain a bounding box that describes the position and size of the elbow in the default pose. Therefore, we have two cases where a frame will store a model space bounding box. The first is when the frame has a mesh container attached and the second is when the frame is being used as a bone by a skinned mesh. In the latter case, its model space bounding box will bound the section of vertices (in their model space reference pose) in the skin that it influences.

For a skinned character, we can easily imagine having bounding boxes surrounding all the bones in the reference pose (see Figure 15.8). The black box shows what we are trying to ultimately achieve -- a bounding box that encompasses the entire actor, in world space.

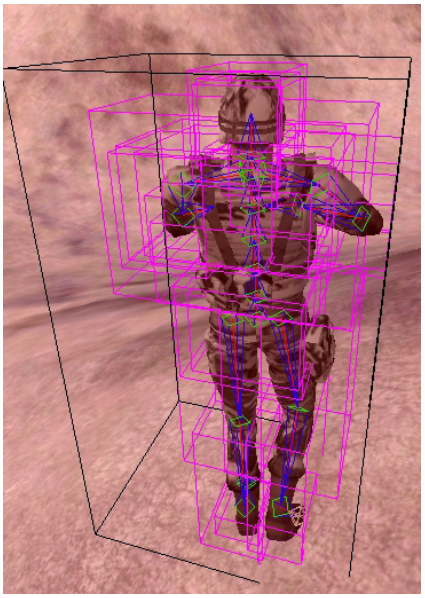

Figure 15.8

So we have determined that the object space bounding boxes of any frame that contains (or is attached to) vertex data will be calculated in a single function called once when the actor is first created. This function is called CActor::BuildBoundingBoxes and it is called from the bottom of the CActor::LoadActorFromX function.

The calculation of these boxes will not be fast enough for real-time work, which is why we are lucky it only has to be performed once. We will have to traverse the tree searching for frames that contain mesh containers and need to have an object space box created for them. When a mesh container is found, we then test to see if the mesh is a skin. If it is not a skin, our task is simple: we lock the mesh's vertex buffer and iterate through each vertex, adjusting the size of the frame's object space box extents until it is large enough to encompass all vertices of that mesh. If multiple mesh containers are attached to the frame, they must all be tested in this way and the bounding box of the frame will grow to fit all these attached meshes.

When the mesh container stores a skin, things are a little bit different. We have to loop through each bone and retrieve the vertices that are influenced by it. Once we have a list of vertices for the current bone we are processing we must transform those vertices into bone space. Remember, the skin itself will be in its own model space at this point and we want its vertices in the space of the actor. After

transforming the vertices attached to the current bone into bone space, we compute its bounding box and grow the extents of the frame's box if it is not large enough to contain it. We do this same step for each bone that influences the mesh.

We will now look at the code to the CActor::BuildBoundingBoxes method. One thing to bear in mind when you see this code is that it never initializes the bounding boxes of any frames to default values. This is done when the frame is first created in the CAllocateHierarchy::CreateFrame callback. This is quite important because a single bone may influence more than one skin. Resetting its bounding box before calculating the extents of any particular skin's vertices would cancel out the contribution of other skins.

BuildBoundingBoxes - CActor

This method is a recursive function that is called from the CActor::LoadActorFromX function. It is passed a pointer to the root frame and then traverses the frame hierarchy looking for frames that contain meshes or that influence the vertices of a skinned mesh. Once found, it grows the model space bounding box of the owner frame to contain any meshes/vertices it directly influences. We will cover the code one section at a time.

The first thing we do is loop through the list of mesh containers stored at the frame. If there are no mesh containers attached to this frame, no action is taken and the frame does not have a model space bounding box calculated for it. At the end of the function, it simply steps into the sibling and child lists.

At the start of the mesh container traversal loop, we determine whether the mesh stored in this container is a progressive mesh or a regular mesh, so that we can access the correct pointer in the D3DXMESHDATA structure. We then query the mesh for a D3DXBASEMESH interface so that we can work with both mesh types through a single interface for the remainder of the function.

```
HRESULT CActor::BuildBoundingBoxes( LPD3DXFRAME pFrame )
{
    HRESULT             hRet;
    D3DXFRAME_MATRIX * pMtxFrame  = (D3DXFRAME_MATRIX*)pFrame;
    D3DXFRAME_MATRIX * pBoneFrame = NULL;
    UCHAR            * pVertices  = NULL;
    ULONG               nVertexStride, nVertexCount, nBoneCount;
    ULONG               nInfluenceCount, i, j;
    D3DXVECTOR3         vecPos;

    // If this has a mesh container , we'll check for skinning etc.
    D3DXMESHCONTAINER_DERIVED * pContainer =
                               (D3DXMESHCONTAINER_DERIVED*)pFrame->pMeshContainer;

    for ( ; pContainer;
            pContainer=(D3DXMESHCONTAINER_DERIVED*)pContainer->pNextMeshContainer )
    {
        // Retrieve the mesh
        LPD3DXBASEMESH pMesh = NULL;
```

```
        switch( pContainer->MeshData.Type )
        {
            case D3DXMESHTYPE_MESH:

                // Skip if no mesh stored here
                if ( !pContainer->MeshData.pMesh ) continue;

                // Query the interface to get back the base mesh.
                hRet =
                pContainer->MeshData.pMesh->QueryInterface( IID_ID3DXBaseMesh,
                                                            (void**)&pMesh );
                if ( FAILED( hRet ) ) return hRet;
                break;

            case D3DXMESHTYPE_PMESH:

                // Skip if no mesh stored here
                if ( !pContainer->MeshData.pPMesh ) continue;

                // Query the interface to get back the progressive mesh
                hRet =
                pContainer->MeshData.pPMesh->QueryInterface( IID_ID3DXBaseMesh,
                                                             (void**)&pMesh );
                if ( FAILED( hRet ) ) return hRet;
                break;

            default:

                // We don't support other types
                continue;

        } // End mesh type
```

At this point we have our mesh pointer, so we will retrieve the vertex count of its vertex buffer and the stride of each vertex before locking the vertex buffer.

```
        // Retrieve additional info we need for processing
        nVertexStride = pMesh->GetNumBytesPerVertex( );
        nVertexCount  = pMesh->GetNumVertices( );

        // Lock the vertex buffer
        hRet = pMesh->LockVertexBuffer( D3DLOCK_READONLY, (void**)&pVertices );
        if ( FAILED(hRet) ) { pMesh->Release(); return hRet; }
```

Now that we have a pointer to the vertices, we have to figure out if this is a normal mesh attached to this frame or if the mesh is a skin that may be influenced by many other bones in the hierarchy. If a skin is not stored here then we know that the container's pSkinInfo pointer will be NULL. In the code snippet we see the code that handles the non-skin case. It loops through every vertex in the vertex buffer and grows the frame's bounding box to encompass the vertices. As mentioned previously, notice that we do not initialize the frame's object space bounding box extents. This is done when the frame itself is first created in the CAllocateHierarchy::CreateFrame method (called by D3DX during the loading of the hierarchy). We must not do that here as this may be one of many meshes attached to this frame. As we

know, it is possible for a frame to have a whole list of mesh containers attached via their pNextMeshContainer pointers.

```
        // Skinned mesh?
        if ( !pContainer->pSkinInfo )
        {
            // Compute this frame's bounding box
            // Note: This frame may have more than one mesh container,
            // boxes initialized during the 'CAllocateHierarchy::CreateFrame' call.
            for ( i = 0; i < nVertexCount; ++i, pVertices += nVertexStride )
            {
                // Retrieve the position of this vertex in it's reference pose
                vecPos = *(D3DXVECTOR3*)pVertices;

                // Test it against the frame bounding box and update if necessary
                if ( vecPos.x < pMtxFrame->vecObjectMin.x )
                     pMtxFrame->vecObjectMin.x = vecPos.x;

                if ( vecPos.y < pMtxFrame->vecObjectMin.y )
                     pMtxFrame->vecObjectMin.y = vecPos.y;

                if ( vecPos.z < pMtxFrame->vecObjectMin.z )
                     pMtxFrame->vecObjectMin.z = vecPos.z;

                if ( vecPos.x > pMtxFrame->vecObjectMax.x )
                     pMtxFrame->vecObjectMax.x = vecPos.x;

                if ( vecPos.y > pMtxFrame->vecObjectMax.y )
                    pMtxFrame->vecObjectMax.y = vecPos.y;

                if ( vecPos.z > pMtxFrame->vecObjectMax.z )
                    pMtxFrame->vecObjectMax.z = vecPos.z;

            } // Next Vertex

            // Frame has applicable bounding box
            pMtxFrame->bObjectBounds = true;

        } // End if standard mesh
```

As you can see in the above code, after every vertex has been tested against the current extents of the frame's bounding box (and adjusted where necessary), we set the frame's bObjectBounds member to true. We will see later that this Boolean is what will tell our CActor::UpdateFrames method that the frame contains an object space bounding box which must be transformed into world space and propagated up the tree to the root node (more on this later).

The next section of code shows what happens when the mesh container stores a skin. In this case, we first use the ID3DXSkinInfo::GetNumBones method to retrieve the number of bones (frames) in the hierarchy that influence the vertices in this mesh. We then initiate a loop to step through each bone.

```
        else
        {
            LPD3DXSKININFO pSkinInfo = pContainer->pSkinInfo;
```

```
            // Loop through each bone in the skin info
            nBoneCount = pSkinInfo->GetNumBones();

            for ( i = 0; i < nBoneCount; ++i )
            {
```

Now that we know the index of the current bone we are processing in the ID3DXSkinInfo's array of bone information, we call its GetBoneName method to retrieve the name of the current frame we are processing. This is then passed into the CActor::GetFrameByName method which traverses the hierarchy searching for the frame and returns a pointer to that frame when found.

```
                // Attempt to retrieve the frame for this bone
                pBoneFrame=(D3DXFRAME_MATRIX*)
                           GetFrameByName(pSkinInfo->GetBoneName( i ) );

                if ( !pBoneFrame ) continue;

                // Retrieve the total number of vertices that this bone influences
                nInfluenceCount = pSkinInfo->GetNumBoneInfluences( i );

                if ( nInfluenceCount == 0 ) continue;
```

After we have a pointer to the current frame/bone we are processing, we pass its index into the ID3DXSkinInfo::GetNumBoneInfluences method. This will return the number of vertices in this skin that are influenced by that bone (which we store in nInfluenceCount). If the return value is zero, then this bone does not influence the skin in any way and we can skip to the next iteration of the loop and process the next bone.

Now that we know how many vertices in the skin are influenced by this bone, we need to fetch the indices of these vertices so that we can adjust the bone's object space bounding box. Therefore, we allocate an array of indices large enough to hold an index for each vertex influenced by the current bone and we allocate an array of floats that will be used to store the weight for each vertex. We pass pointers to these two arrays, along with the bone index, into the ID3DXSkinInfo::GetBoneInfluence method. This function will fill the passed arrays with the indices and weights of all vertices that are influenced by the current bone we are processing.

```
                // Allocate enough space for influences
                ULONG * pIndices = new ULONG[ nInfluenceCount ];
                if ( !pIndices )
                { pMesh->UnlockVertexBuffer();
                  pMesh->Release();
                  return E_OUTOFMEMORY;
                }

                float * pWeights = new float[ nInfluenceCount ];
                if ( !pWeights )
                {
                    delete []pIndices;
                    pMesh->UnlockVertexBuffer();
                    pMesh->Release();
```

```
                    return E_OUTOFMEMORY; }

                // Retrieve the influence array
                hRet = pSkinInfo->GetBoneInfluence( i, pIndices, pWeights );
                if ( FAILED(hRet) )
                {
                    // Clean up and continue
                    delete []pIndices;
                    delete []pWeights;
                    pMesh->UnlockVertexBuffer();
                    pMesh->Release();
                    continue;

                } // End if failed to get influences
```

Now that we have the array of indices, we can loop through each one and fetch the position of the vertex at the corresponding index from the vertex buffer. We will store this in a temporary 3D vector, as shown below.

```
                // Loop through each influence
                for ( j = 0; j < nInfluenceCount; ++j )
                {
                    // Retrieve vertex in it's correct reference pose
                    vecPos = (D3DXVECTOR3&)(pVertices[pIndices[j]*nVertexStride]);
```

We now have the vertex position, but this in the local space of the skin model itself, not in the local space of the frame/bone to which it is attached. Therefore, we retrieve the bone offset matrix for the current bone and transform the vertex into bone space. We then test the position of the vertex against the object space (bone space) bounding box and grow its extents where necessary.

```
                    D3DXVec3TransformCoord( &vecPos,
                                            &vecPos,
                                            &pContainer->pBoneOffset[i] );

                    // Test against the frame bounding box and update if necessary
                    if ( vecPos.x < pBoneFrame->vecObjectMin.x )
                        pBoneFrame->vecObjectMin.x = vecPos.x;

                    if ( vecPos.y < pBoneFrame->vecObjectMin.y )
                        pBoneFrame->vecObjectMin.y = vecPos.y;

                    if ( vecPos.z < pBoneFrame->vecObjectMin.z )
                        pBoneFrame->vecObjectMin.z = vecPos.z;

                    if ( vecPos.x > pBoneFrame->vecObjectMax.x )
                        pBoneFrame->vecObjectMax.x = vecPos.x;

                    if ( vecPos.y > pBoneFrame->vecObjectMax.y )
                        pBoneFrame->vecObjectMax.y = vecPos.y;

                    if ( vecPos.z > pBoneFrame->vecObjectMax.z )
                        pBoneFrame->vecObjectMax.z = vecPos.z;
```

```
                } // Next Influence
```

After the index loop ends, we have correctly adjusted the object space bounding box for the current bone to contain all the vertices in the skin that are influenced by it. All we have to do now is set the bone's pObjectBounds Boolean to true and delete the temporary index and weight arrays.

```
                // Frame has applicable bounding box
                pBoneFrame->bObjectBounds = true;

                // Clean up memory
                delete []pIndices;
                delete []pWeights;

            } // Next Bone

        } // End if skinned mesh

        // Unlock the vertex buffer
        pMesh->UnlockVertexBuffer();

        // Release the pointer to the mesh we retrieved
        pMesh->Release();

    } // Next mesh container
```

After we have processed every bone that influences the skin and calculated the bounding box for each one, we unlock the vertex buffer and release the mesh interface we acquired.

Finally, the function continues its traversal of the tree looking for more mesh containers.

```
    // Has a sibling frame?
    if (pFrame->pFrameSibling != NULL)
    {
        hRet = BuildBoundingBoxes( pFrame->pFrameSibling );
        if ( FAILED(hRet) ) return hRet;

    } // End if has sibling

    // Has a child frame?
    if (pFrame->pFrameFirstChild != NULL)
    {
        hRet = BuildBoundingBoxes( pFrame->pFrameFirstChild );
        if ( FAILED(hRet) ) return hRet;

    } // End if has child

    // Success!!
    return D3D_OK;
}
```

Any frames which do not have meshes attached to them or are not used to influence skins do not have an object space bounding box. Consequently, they will have their bObjectBounds Booleans set to false.

15.8.2 World Space Bounding Boxes

So far we have an object space bounding box stored at every frame that contains a mesh. The problem is that we need our actor to return a world space bounding box for the entire actor that will automatically have its size updated when the actor animates. We can see in Figure 15.9 that when the character is animated, the actor's bounding box changes in size to encompass the world space bounding boxes of all its child frames.

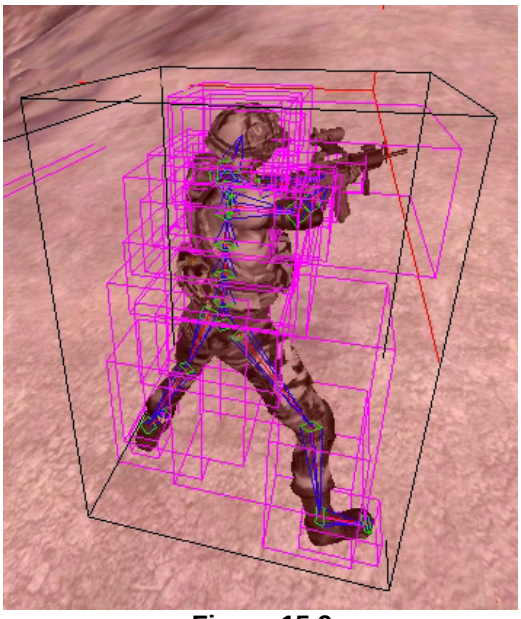

Figure 15.9

In Figure 15.9, the purple bounding boxes are *not* the bounding boxes we have just calculated; they are those bounding boxes after they have been transformed into world space. These world space bounding boxes (which need to be updated every time the actor is animated) are then merged together to compute the final world space bounding box for the entire actor.

The vecBoundsMax and vecBoundsMin members of our frame structure will be updated every time the actor is updated inside the CActor::UpdateFrameMatrices call. This is the method that traverses the hierarchy, combining matrices to ultimately store a world matrix at each frame. In many ways, our bounding boxes will work in exactly the same way as the relative and absolute matrices we are used to working with.

Recall that when the actor is first created, each frame contains a matrix that describes its position in parent relative space. However, each frame also stores another matrix that is updated every time the actor is moved. This update happens in the UpdateFrameMatrices method. You will recall that this function is passed a world matrix which is initially combined with the root frame's matrix to generate the world matrix of the root frame. This world matrix is then passed down to the children, where it is combined with their relative matrices to create the world matrices for each frame, and so on right down the tree. When UpdateFrameMatrices returns, every frame in the tree will store an absolute world matrix.

Our bounding boxes will basically work the same way. Our actor will store bounding box extents which will be used to store the bounding box of the entire actor. These will be updated every time the application calls the SetWorldMatrix method, which as we know, calls the UpdateFrameMatrices method. The UpdateFrameMatrices method will now have some code added so that as it steps through the tree, it will calculate the world space bounding box for every frame in the tree. The world space bounding box of a frame will be a box that has been adjusted to contain the world space bounding boxes of all frames beneath it in the hierarchy. When this process works its way back up the root, we will have a box that is in world space that encompasses every frame in the tree. The following description takes you through how it will work…

As we step into a frame we will calculate its absolute world matrix and store it in the frame as normal. We will then traverse into the sibling and child lists. When a frame is reached that has its bObjectBounds Boolean set to true, we will transform its object space bounding box into world space using our TransformAABB method. We will then store the world space bounding box in the frame and will pass it back to the parent frame when the function returns. The parent frame, having received the world space bounding box of its child(ren) will then adjust the returned box by transforming its own object space bounding box into world space (if it contains one) and grow the box to contain both its own box and the box returned by its child. The combined world space box will then be returned to its parent where the same happens again.

By positioning the bounding box propagation code after the lines that traverse into the child and sibling lists, we make sure that we are calculating the bounding box *not* on the way down the tree (as is the case with the frame matrices), but on our way back *up* the tree. As we begin unwinding the call stack and work our way back up the tree, we can combine the world space bounding box returned by the children with the current frame's own world space bounding box. Of course the world space bounding box returned by the children will also have been combined with the world space bounding boxes of all their children, and so on. What we end up with is a spatial hierarchy; a tree of bounding boxes such that every frame in the tree stores a world space bounding box that encompasses the world space bounding boxes of all the frames beneath it in the tree. The bounding box finally returned from the CActor::UpdateFrameMatrices method back to the CActor::SetWorldMatrix method is the world space bounding box of the entire actor in its current pose. We can then store this information away in the actor's bounding box extents member variables.

> **Note:** This bottom-up calculation approach is commonly used when assembling other types of popular bounding volume hierarchies like scene graphs, AABB trees, etc. We will examine some of these other hierarchy types in Module III of this series.

CActor has had two new members added to store the world space bounding box of the actor in its current pose. These two vectors will be populated by the data returned from the UpdateFrameMatrices call.

Excerpt From CActor

```
D3DXVECTOR3  m_vecBoundsMin;   // Minimum bounding box extents (in world space)
D3DXVECTOR3  m_vecBoundsMax;   // Maximum bounding box extents (in world space)

void   GetBoundingBox ( D3DXVECTOR3 & BoundsMin, D3DXVECTOR3 & BoundsMax ) const;
void   UpdateFrameMatrices(        LPD3DXFRAME   pFrame,
                           const   D3DXMATRIX  * pParentMatrix,
                                   D3DXVECTOR3 * pFrameMin /* = NULL */,
                                   D3DXVECTOR3 * pFrameMax /* = NULL */ )
```

CActor has also had two new method added, which we will discuss next.

GetBoundingBox - CActor

The GetBoundingBox method returns the world space bounding box for the actor. We saw earlier that our CScene::AnimateObjects method called this function to send the box into the ISpatialTree:UpdateTreeObject method so that the leaf list for the object could be updated.

```
void CActor::GetBoundingBox( D3DXVECTOR3 &BoundsMin, D3DXVECTOR3 &BoundsMax ) const
{
    BoundsMin = m_vecBoundsMin;
    BoundsMax = m_vecBoundsMax;
}
```

This method will only be valid once the application has called CActor::SetWorldMatrix or one of the other CActor methods that automatically calls the UpdateFrameMatrices method. It will always contain the world space bounding box calculated during the last CActor::SetWorldMatrix call.

SetWorldMatrix – CActor (Updated)

The application uses the CActor::SetWorldMatrix method to set the world matrix of the actor and optionally rebuild the world matrices of each frame in the hierarchy. This new version of the code initializes the actor's bounding box extents and then sends them into the UpdateFrameMatrices method.

```
void CActor::SetWorldMatrix( const D3DXMATRIX * mtxWorld /* = NULL */,
                             bool UpdateFrames /* = false */ )
{
    // Store the currently set world matrix
    if ( mtxWorld )
        m_mtxWorld = *mtxWorld;
    else
        D3DXMatrixIdentity( &m_mtxWorld );

    // Update the frame matrices
    if ( IsLoaded() && UpdateFrames )
    {
        // Reset the bounding box
        m_vecBoundsMin = D3DXVECTOR3(  FLT_MAX,  FLT_MAX,  FLT_MAX );
        m_vecBoundsMax = D3DXVECTOR3( -FLT_MAX, -FLT_MAX, -FLT_MAX );

        UpdateFrameMatrices( m_pFrameRoot,
                             mtxWorld,
                             &m_vecBoundsMin,
                             &m_vecBoundsMax );

    } // End if update frames

}
```

As you can see, the CActor::UpdateFrameMatrices method now supports two additional parameters that allow you to pass in two extent vectors to be filled with the world space bounding box of the passed frame. As the frame we are passing is the root node, and the vectors we are passing are the actor's world space extent vectors, we know that on function return the CActor's m_vecBoundsMin and m_vecBoundsMax vectors will contain the world space bounding box of the root node. This is the world space bounding box that encompasses the entire hierarchy of the actor and all its contained meshes.

UpdateFrameMatrix - CActor

This is the function where everything comes together. On top of its original job of calculating the world matrices at each frame, it now has to transform the object bounding box of any frame that contains mesh data into world space and return it back to its parent. Because we want the boxes to be calculated after we have returned from traversing the child list, the code for transforming the box will be at the bottom of the function.

The function is now passed pointers two extent vectors which will store the world space bounding box for the current frame being visited in any given recursion of the function.

```
void CActor::UpdateFrameMatrices( LPD3DXFRAME pFrame,
                                  const D3DXMATRIX * pParentMatrix,
                                        D3DXVECTOR3 * pFrameMin /* = NULL */,
                                        D3DXVECTOR3 * pFrameMax /* = NULL */ )
{
    D3DXFRAME_MATRIX * pMtxFrame = (D3DXFRAME_MATRIX*)pFrame;

    D3DXVECTOR3 vecBoundsMin = D3DXVECTOR3(  FLT_MAX,  FLT_MAX,  FLT_MAX );
    D3DXVECTOR3 vecBoundsMax = D3DXVECTOR3( -FLT_MAX, -FLT_MAX, -FLT_MAX );;

    if ( pParentMatrix != NULL)
        D3DXMatrixMultiply( &pMtxFrame->mtxCombined,
                            &pMtxFrame->TransformationMatrix, pParentMatrix);
    else
        pMtxFrame->mtxCombined = pMtxFrame->TransformationMatrix;

    // Move onto sibling frame
    if ( pMtxFrame->pFrameSibling ) UpdateFrameMatrices( pMtxFrame->pFrameSibling,
                                                         pParentMatrix,
                                                         pFrameMin,
                                                         pFrameMax );

    // Move onto first child frame
    if ( pMtxFrame->pFrameFirstChild )
         UpdateFrameMatrices( pMtxFrame->pFrameFirstChild,
                              &pMtxFrame->mtxCombined,
                              &vecBoundsMin,
                              &vecBoundsMax );
```

The first part of the function has hardly changed, with the exception that we now initialize temporary bounding box extents vectors and send them into the child recursions. The sibling recursions all share the same parent, so they are passed the same bounding box vectors that were passed into this function.

When the child list recursions return, the local bounding box extent vectors vecBoundsMin and vecBoundsMax will contain a world space bounding box that encompasses all of the children beneath the current frame. To see why this is the case, we have to look at the new second section of the function that calculates a world space bounding box for any mesh data that might be attached to this frame.

If the current frame's bObjectsBounds member is set to true then it means this frame either has a mesh attached or it influences a skin. In either situation, it means we have a frame that contains a model space bounding box. When this is the case, we transform the model space AABB using the world matrix of the current frame we are visiting.

```
    // Should we also update our actor's bounding box with the new information
    if ( pMtxFrame->bObjectBounds )
    {
        D3DXVECTOR3 vecMin = pMtxFrame->vecObjectMin,
                    vecMax = pMtxFrame->vecObjectMax;

        // Transform the mesh's object bounding box into world space
        MathUtility::TransformAABB( vecMin, vecMax, pMtxFrame->mtxCombined );
```

At this point we now have two world space bounding boxes. The first is the world space bounding box of the mesh data stored at this node (which we have just stored in the frame's world space extent vectors). The second, stored in vecBoundsMin and vecBoundsMax, was returned from the child list and bounds all the children of this frame. We will now merge these two boxes together by adjusting the world space bounding box at this frame so that it also encompasses the bounding box returned from the children.

```
        // Test it against the actor bounding box and update if necessary
        if ( vecMin.x < vecBoundsMin.x ) vecBoundsMin.x = vecMin.x;
        if ( vecMin.y < vecBoundsMin.y ) vecBoundsMin.y = vecMin.y;
        if ( vecMin.z < vecBoundsMin.z ) vecBoundsMin.z = vecMin.z;
        if ( vecMax.x > vecBoundsMax.x ) vecBoundsMax.x = vecMax.x;
        if ( vecMax.y > vecBoundsMax.y ) vecBoundsMax.y = vecMax.y;
        if ( vecMax.z > vecBoundsMax.z ) vecBoundsMax.z = vecMax.z;

    } // End if apply frame's bounding box
```

The frame now contains the world space bounding box for its mesh data stored and all of the meshes stored below it in the tree. Notice in the above conditional code that what we have actually done is grown the temporary bounding box that was returned from the child list to contain the bounding box we calculated for this frame's mesh data. The next line of code describes why we adjusted the local temporary box and not the box stored in the frame.

```
    // Store the bounding box in this frame
    pMtxFrame->vecBoundsMin = vecBoundsMin;
    pMtxFrame->vecBoundsMax = vecBoundsMax;
```

As you can see, the next step is to copy the temporary bounding box which we just calculated into the frame's world space box extents. However, this code is not in a conditional code block and will be executed even if the frame has no mesh data attached. If the frame has no mesh data, then it is simply assigned the world space box that was returned from the child list. This is actually true in both cases, but in the case where we have mesh data assigned, we simply adjust it first by the mesh's world space bounds before assigning it.

This function is also expected to return the bounding box of this frame back to the parent so that the parent can combine the box with its mesh data, and so on back up to the root. As you can see, that last step is to copy this frame's world space bounding box into the passed vector extents so that the parent will have them on function return.

```
    // Test it against the parent's bounding box and update if necessary
    if ( pFrameMin )
    {
        if ( vecBoundsMin.x < pFrameMin->x ) pFrameMin->x = vecBoundsMin.x;
        if ( vecBoundsMin.y < pFrameMin->y ) pFrameMin->y = vecBoundsMin.y;
        if ( vecBoundsMin.z < pFrameMin->z ) pFrameMin->z = vecBoundsMin.z;

    } // End if frame min extents requested

    if ( pFrameMax )
    {
        if ( vecBoundsMax.x > pFrameMax->x ) pFrameMax->x = vecBoundsMax.x;
        if ( vecBoundsMax.y > pFrameMax->y ) pFrameMax->y = vecBoundsMax.y;
        if ( vecBoundsMax.z > pFrameMax->z ) pFrameMax->z = vecBoundsMax.z;

    } // End if frame max extents requested
```

The final bit of this function is not new; it loops through each mesh container stored at the frame and invalidates it. This is important if software skinning is being used as it tells the actor that any skin stored here will have to be re-transformed into world space before being rendered again.

```
    // If this has a mesh container (or set of containers), we must invalidate them
    D3DXMESHCONTAINER_DERIVED * pContainer =
                            (D3DXMESHCONTAINER_DERIVED*)pMtxFrame->pMeshContainer;

    for (;pContainer;
          pContainer = (D3DXMESHCONTAINER_DERIVED*)pContainer->pNextMeshContainer )
    {
        // Flag as invalid
        pContainer->Invalidated = true;

    } // Next Container
}
```

We have now covered all the new actor code that calculates and returns the world space bounding box needed in order to use the actor as a dynamic object in our spatial tree. Of course, by implementing the hierarchy of bounding boxes the way we have, it means that we now have the ability to hierarchically frustum cull an actor even without using our spatial tree system.

For example, imagine you have loaded a single X file containing the entire scene. This scene, with hundreds of meshes and animations would now be contained in a single actor. Every time we update the actor, a world space bounding box is stored at each frame. This box contains the bounding boxes of all frames underneath it (just like a quad-tree or an oct-tree), so you could easily write a function that will traverse the frames of the hierarchy with a camera and perform hierarchical frustum rejection using the techniques we have covered in this chapter (including the optimizations). At each frame, the recursive function could test the world space bounding box of the frame to see if it is within the frustum, if not, the child list does not have to be stepped into possible rejecting hundreds of meshes stored below it. The actor has now become a bounding volume hierarchy (a spatial tree of sorts). You could even run hierarchical bounding volume or ray intersection queries on the actor's meshes if needed. This might be helpful if you wanted to include some form of body part specific damage for example.

15.9 Adding Visibility Determination to CTerrain

A few changes have had to be made to the CTerrain class so that it now makes use of the spatial tree. As we know, each CTerrain is made up of a series of CTerrainBlocks where each block is a rectangular mesh that represents a portion of the terrain. When the terrain blocks are created (in the CTerrain::BuildTerrainBlocks method), each terrain block has its world space bounding box registered with the spatial tree as a detail object. This forces the tree to compile a tree that is large enough to encompass the terrain, even though the terrain polygons are never passed into the tree and compiled into the leaves. As discussed in the previous chapter, the last thing we want is for the spatial tree to be only as large as the static data contained within it. It makes no sense for us to compile the terrain triangles into the tree since each block can be rendered more efficiently as a separate mesh. However, we do want the spatial tree to be large enough to encompass the terrain so that a dynamic object that is placed on that terrain is never in a position where it is not in a region of space that does not belong to the tree. This would mean the dynamic object would not exist in any leaf nodes and as such, could not benefit from the visibility system.

Each terrain block will be given a visibility Boolean which will be registered with the spatial tree as a dynamic/tree object. Although the terrain blocks are not literally dynamic (they will never move), by registering a tree object for each terrain block, we can have the terrain block Boolean pointers stored in leaves and set to true by the tree whenever that terrain block is visible. The CTerrain::Render method can then loop through each terrain block and skip rendering any that have not had their Boolean set to true by the spatial tree.

Below we see the CTerrainBlock member variables and have highlighted the two new ones added in Lab Project 14.1.

Excerpt from CTerrain.h

```
class CTerrainBlock
{
 public:

    ……Methods Not Shown……
```

```
    // Public Variables for This Class
    ULONG                   m_nVertexCount;     // Number of vertices stored
    UCHAR                  *m_pVertex;          // Simple temporary vertex array
    ULONG                   m_nIndexCount;      // Number of indices stored
    USHORT                 *m_pIndex;           // Simple temporary index array
    LPDIRECT3DVERTEXBUFFER9 m_pVertexBuffer;    // Vertex Buffer to be Rendered
    LPDIRECT3DINDEXBUFFER9  m_pIndexBuffer;     // Index Buffer to be Rendered
    UCHAR                   m_nStride;          // The stride of each vertex
    ULONG                   m_nFVFCode;         // The flexible vertex format code.

    D3DXVECTOR3             m_BoundsMin;        // Bounding box minimum extents
    D3DXVECTOR3             m_BoundsMax;        // Bounding box maximum extents

    long                    m_nTreeObjectIndex;     // SpatialID
    bool                    m_bVisible;             // Is this object visible?

};
```

long m_nTreeObjectIndex
This member will contain the spatial ID returned from the ISpatialTree::InsertTreeObject method. This method will be called to register the terrain block with the spatial tree as a dynamic/tree object.

bool m_bVisible
This is the Boolean whose address will be stored in the TreeObject when it is registered with the spatial tree. This Boolean will be set to true by the spatial tree during the visibility pass if any leaf in which the terrain block's bounding volume exists is currently visible. The CTerrain::Render function will loop through its array of terrain blocks and only render those which have m_bVisible set to true.

The CTerrain object will also store an ISpatialTree pointer that can be set via a new method called CTerrain::SetSpatialTree. This method simply copies that passed pointer and stores it in a CTerrain member variable. CTerrain::SetSpatialTree is called in the CScene::ProcessEntities method when it encounters a terrain entity and extracts the data to create a new CTerrain object. After the object has been created, the scene's spatial tree pointer will be passed into CTerrain::SetSpatialTree.

The following snippet of code shows a section of the CScene::ProcessEntities function which is called by CScene::LoadSceneFromIWF to extract and process any entities stored in the IWF file. You will recall from our previous discussions that if the entity currently being processed is a terrain entity, its data is extracted into a TERRAINENTITY structure which is then passed to the CTerrain::LoadTerrain method. This method loads the heightmap, textures, and any additional information stored in the passed TERRAINENTITY structure before calling CTerrain::BuildTerrainBlocks to actually create the vertex data for each terrain block.

Excerpt from CScene::ProcessEntities

```
If ( THIS IS AN ENTITY WE ARE PROCESSING)
{
   …Snip… : Extract terrain data from file into TERRAINENTTY structure (Terrain)

// Allocate a new terrain object
pNewTerrain = new CTerrain;
if ( !pNewTerrain ) break;
```

```
// Setup the terrain
pNewTerrain->SetD3DDevice( m_pD3DDevice, m_bHardwareTnL );
pNewTerrain->SetTextureFormat( m_TextureFormats );
pNewTerrain->SetRenderMode( GetGameApp()->GetSinglePass() );
pNewTerrain->SetWorldMatrix( (D3DXMATRIX&)pFileEntity->ObjectMatrix );
pNewTerrain->SetDataPath( m_strDataPath );

// Set the spatial tree, to allow the terrain to build detail areas
pNewTerrain->SetSpatialTree( m_pSpatialTree );

// Store it
m_pTerrain[ m_nTerrainCount - 1 ] = pNewTerrain;

// Load the terrain
if ( !pNewTerrain->LoadTerrain( &Terrain ) ) return false;

// Add to the collision system
m_Collision.AddTerrain( pNewTerrain );
}
```

We have snipped out the code that extracts the entity data from the IWF file and stores it in the TERRAINENTITY structure, but once this is done, a new CTerrain block is allocated and its device, render mode, and world matrix are set. Notice the new line (highlighted in bold) which sets the spatial tree pointer of the CTerrain object to the same spatial tree being used by the application. After this, the new terrain object is added to the scene's CTerrain array before its LoadTerrain method is called to actually build the terrain data and all of the terrain blocks. Finally, as we saw several lesson ago, the terrain object is registered with the collision system.

BuildTerrainBlocks – CTerrain (Updated)

After the terrain information has been loaded from the IWF file and the spatial tree pointer has been set, the CTerrain::LoadTerrain method is called to build the entire terrain and all terrain blocks. This method will call the CTerrain::BuildTerrainBlocks method to build the vertex data for each terrain block.

The next new section of code we will look at is executed in the BuildTerrainBlocks method. It occurs just after the current terrain block being processed has been built. At this point, the spatial tree has not been compiled so we can register the block bounding box as a detail area so that the region of space taken up by this terrain block will be compiled into the tree. The following section of code is actually embedded in a loop that creates each terrain block.

As you can see, we instantiate a TreeDetailArea structure and set its bounding box equal to that of the terrain block. We could store the terrain block pointer in the context pointer but we do not need to. We are only registering this detail area to shape the spatial tree; we do not need to know where it came from.

```
// Building for spatial tree?
if ( m_pSpatialTree )
{
```

```
    TreeDetailArea Area;
    TreeObject     Object;

    // Store detail area bounding box
    Area.BoundsMax = pBlock->m_BoundsMax;
    Area.BoundsMin = pBlock->m_BoundsMin;
    Area.pContext  = NULL;
```

As the bounding box of the terrain block is in model space we should transform it by the CTerrain's world matrix so that it represents the terrain block in world space. We then add the new detail area to the tree to shape the tree during compilation.

```
    // Transform the bounding box into world (tree) space
    MathUtility::TransformAABB( Area.BoundsMin, Area.BoundsMax, m_mtxWorld );

    // Add to the spatial tree
    m_pSpatialTree->AddDetailArea( Area );
```

In order for a terrain block to only be rendered when visible, we will register it as a tree object that has its Boolean pointer pointing at the CTerrain::m_bVisible member. In a moment, you will see that once the tree is built, we will call the ISpatialTree::UpdateTreeObject method to assign the terrain block's Boolean pointer to the leaves in which the terrain block is contained. We cannot do that just yet, since the spatial tree has not been built at this time. All we can do at the moment is create a new tree object in the spatial tree and assign it to point at our terrain block's Boolean pointer. Notice in the following code that our CTerrainBlock class now has an m_nTreeObjectIndex member that is used to store the terrain block's spatial ID.

```
    // Set new tree object details
    Object.pContext  = NULL;
    Object.pbVisible = &pBlock->m_bVisible;

    // Add as a tree object
    pBlock->m_nTreeObjectIndex = m_pSpatialTree->InsertTreeObject( Object );

} // End if spatial tree set
```

That is the only new section of code in the CTerrain::BuildTerrainBlocks method. At this point the terrain blocks is registered with the system but does not yet have its Boolean assigned to any leaves in the tree (no leaves exist yet since the tree has not been compiled).

After CScene::LoadSceneFromIWF has called all the processing methods to extract the IWF data, all objects contained in the file that needed to be created will have been. This means that any terrain entities that were in the file will have already been used to create terrains and the terrain blocks of each terrain will have been registered as detail areas and as dynamic objects.

It is now time to build the spatial tree as we saw in the previous lesson. However, we have an additional step to take with the scene's CTerrain array. Although the terrain blocks are already registered with the spatial tree, we had to wait until the tree was compiled before we could assign the terrain blocks to their relevant leaves. Thus, in the small section of code shown below (at the bottom of

CScene::LoadSceneFromIWF), you can see that after the spatial tree is compiled, we loop through each terrain in the terrain array and call its TreeBuildComplete method (a new method).

Excerpt from CScene::LoadSceneFromIWF

```
…SNIP : All Process…… Functions Called Here

// Build the spatial tree and notify the collision engine
if ( !m_pSpatialTree->Build( ) ) return false;

// Notify terrain that objects the spatial tree has been built
for ( i = 0; i < m_nTerrainCount; ++i ) m_pTerrain[i]->TreeBuildComplete();
```

CTerrain::TreeBuildComplete allows the terrain to perform processing after the spatial tree has been compiled. Let us take a look at this simple member function.

TreeBuildComplete – CTerrain

For each terrain block, this function exacts its model space bounding box and transforms it into world space using the world matrix of the terrain. It then uses the ISpatialTree::UpdateTreeObject method to assign the terrain block to its relevant leaves in the tree by passing in the spatial ID of the terrain block and its world space bounding box. This is no different from how we update the positions of our dynamic CObjects in the CScene::AnimateObjects method. The reason we do it here is so that it only ever has to be performed once. Our terrains will never move or be animated, so we make this a one-off leaf assignment function that is called post-build.

```
void CTerrain::TreeBuildComplete( )
{
    ULONG i;

    // Validate
    if ( !m_pSpatialTree ) return;

    // Render Each block
    for ( i = 0; i < m_nBlockCount; i++ )
    {
        D3DXVECTOR3 vecMin = m_pTerrainBlocks[i]->m_BoundsMin;
        D3DXVECTOR3 vecMax = m_pTerrainBlocks[i]->m_BoundsMax;

        // Transform the bounding box
        MathUtility::TransformAABB( vecMin, vecMax, m_mtxWorld );

        // Ask tree to update so that the block is inserted into it's final leaves
        m_pSpatialTree->UpdateTreeObject( m_pTerrainBlocks[i]->m_nTreeObjectIndex,
                                          vecMin, vecMax );

    } // Next Block
}
```

Finally, although we will not show the code here due to the trivial changes, the CTerrain::Render method has now been updated to only render terrain blocks that have their Booleans set to true. These Booleans will be set to true for any terrain blocks that are found to be in visible leaves when the application issues a call to ISpatialTree::ProcessVisibility.

Conclusion

In this chapter we have made significant progress with our rendering technologies and our geometry management. We have implemented a rendering system that will perform hierarchical frustum culling and efficiently collect and draw the static geometry in visible leaves. The rendering system in CBaseTree is certainly complex, and to fully understand the code you will probably need several passes through this book and the source code. Fortunately, with this core technology in place, we now have a system that will be carried into the remaining chapters of this course where we will take visibility processing to the next level.

So far, our visibility system has only partly lived up to its name. After all, it does not render only the visible polygons; it actually renders all polygons inside the view frustum, which is not nearly the same thing. If we imagine being in a small room (located within a larger complex) with no windows and maybe a small door, all that would actually be visible to us would be the four walls of the room and maybe a small section of the corridor we can observe from within the room. Using our current system, if we had a frustum with a far plane positioned a long way in the distance, many of the rooms in this example which are not visible would still be rendered since they fall within the frustum and are therefore considered visible in our system implementation. In truth, all we have really done in this chapter is laid the foundation for a proper visibility system. Our final visibility system will be implemented in the next two chapters of this course.

While we have learned how to efficiently render only what is within the camera's FOV, we have not taken into account that some portions of the level will be obscured by others. If our camera is located in front of a huge wall, ideally we should only render the wall. On the other side of that wall there might be a vast terrain or multiple buildings that should never be seen as they are occluded by the wall in front of us. Our current visibility system does not make provisions for this scenario. We have taken only a preliminary step towards determining a proper potential visibility set. That is, we certainly have narrowed things down to a set of polygons that are potentially visible using our frustum tests (and we have definitely rejected quite a lot of polygons that definitely are not visible), but many of those potentially visible polygons can also be removed from consideration with just a bit more work on our part.

The remainder of this course will work towards the goal of building a PVS (Potential Visibility Set) calculator that will pre-calculate at compile time exactly which leaves could possibly be visible from any other leaf in the scene by factoring in the notion of occlusion. PVS systems have been the backbone of commercial computer games since the days of Quake™. They are what allow seemingly massive environments comprised of a very high number of polygons to be rendered at real-time interactive frame rates. With a PVS system in place, the speed at which your game runs is no longer bound purely by the number of polygons in your scene, or even the number of polygons contained in the frustum. Rather, we

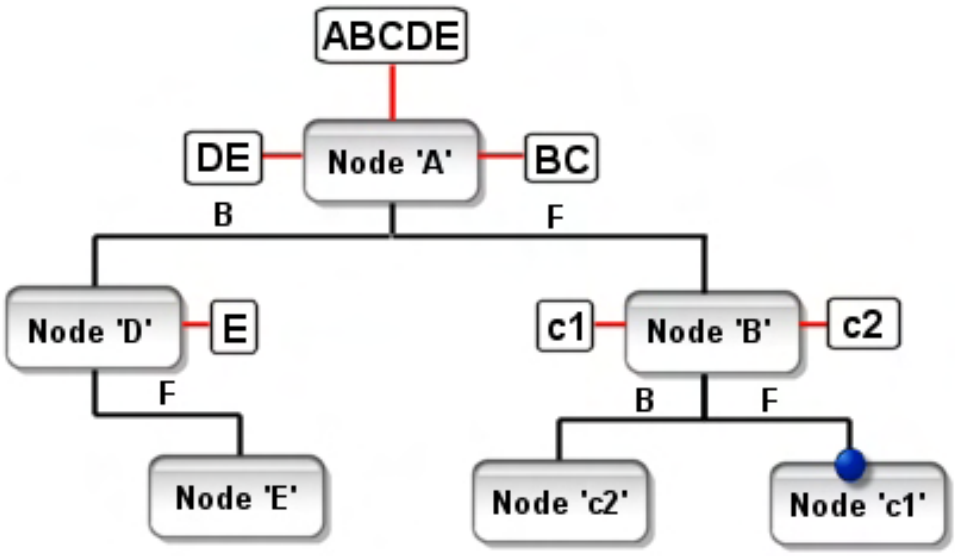
are dealing with only the polygons that can be physically seen by the viewer, which is obviously going to be a far smaller number in the general case. If you consider a room with no windows and closed doors, regardless of the size of the level and the number of polygons it contains, our PVS-based system would only have to render the four walls, the floor and the ceiling which the camera can currently see (the hardware clipping can handle any final bits of actual visibility testing within the room). So the next two lessons will open up a wide array of possibilities in terms of the art assets your engine will be able to handle. You will soon be able to draw incredibly high polygon count scenes that would otherwise be unthinkable, even on today's cutting edge hardware.

In the next chapter we will introduce BSP trees as they are going to be the foundation tree for the PVS system we will implement. We will also learn many other techniques that the BSP tree can be used for, such as perfectly sorting alpha polygons and rendering them in the correct order (something that our hash table design from Module I could not guarantee in all cases). We will also discover that BSP trees can be used to carve meshes from one another or fuse multiple meshes into a single mesh. BSP trees are prevalent in computer science and particularly in game development and they will be one of the most useful tools you will learn about in your training as a game developer.

Make sure that you fully understand how our rendering system works before moving on to the next chapter. We will be using this same system again as we move forward with BSP trees (at least initially), so it is important that you devote the necessary time to working through the system. While this was undeniably a fairly complex implementation (especially once the multiple vertex buffer support was introduced), the underlying logic is still quite straightforward. If you take your time and make sure that you are comfortable with the concepts we have covered here, you will be in good shape in the discussions to come.

Chapter Sixteen

Spatial Partitioning III



Introduction

In this lesson we will continue our discussion of spatial partitioning by introducing Binary Space Partitioning trees. Binary Space Partitioning (BSP) is a technique that has been the cornerstone design element in some of the most powerful and successful 3D game engines on the market. When John Carmack and id software used BSP trees for Doom™ and later Quake™, BSP quickly became an industry buzzword. While these games have aged a bit over the years, you may be surprised to learn that virtually all of the latest first person shooters still continue to use BSP based engines in one form or another. With the more recent introduction of pixel shader programs that often perform many complex rendering passes per polygon, eliminating overdraw and reducing the number of polygons that need to pass through these shader programs has once again become the key to fast game performance -- an area in which the BSP trees (along with accompanying technologies) excel.

The reason this spatial tree was not covered in the previous lessons is because it really does deserve its own chapter due to the myriad ways in which it can be used and its importance in the field of computer science and game development. Having BSP trees at our disposal will allow us to perform perfect alpha sorting very efficiently, allow us to create spatial trees that have arbitrarily shaped leaves (leaves that are not always just boxes), and will allow us to divide the world into areas that describe whether that space is empty or solid. Empty space is space that is not currently occupied by any geometry and can be freely moved around in by the game characters, where as solid space is space that currently describes an area that contains a solid object (e.g., a wall). Because the BSP tree can be used to discriminate between solid and empty areas in a game world, it can be used to calculate a potential visibility set, which is the goal we will be working towards both in this lesson and the next.

A potential visibility set (PVS) is a pre-compiled set of data built by an application called a PVS Calculator that tells our application which leaves can be seen from every leaf in the tree. If leaf A is not visible from leaf B then leaf A's polygon data will not need to be rendered when the camera is in leaf B. Although this process seems similar to the visibility system we developed in the previous lesson, there is a significant difference -- a PVS calculator accounts for the occlusion of geometry when determining what is visible from a particular leaf. If your scene uses a large number of polygons, but the camera is currently located in a small room with no windows or doors, the only polygons that the visibility system would flag for rendering would be the walls, the floor, and ceiling of the room in which the camera is currently located. This would be true regardless of how many polygons were currently intersecting the view frustum. The polygons situated behind those walls are occluded by the walls and therefore would not be seen (and thus not rendered).

The BSP tree will play a crucial part in the construction of the PVS calculator we will create in the following lesson. It is this usage of the BSP tree and the PVS data that it aids in compiling that allowed games such as Quake™, Quake II™, Half Life™, and Medal of Honor™ (and the dozens of games built around those engines) to run at high frame rates despite the vastness of the levels. It is not overstating the point to say that the ability to calculate and process a potential visibility set is one of the most fundamentally important technologies in a 3D graphics engine; it represents a way to process and render only what is visible with virtually zero run-time processing, thus decoupling the performance of your game from the scene polygon count in the general case.

Later in this lesson we will study another BSP use case commonly seen in many 3D world editing packages, such as GILES™. The ability to carve one solid object from another or to fuse two objects into a single mesh are likely familiar to you if you have spent any significant time working with GILES™ or any other world editor package such as WorldCraft™. Indeed you can create very complex scenes by carving and merging simple mesh objects into more complex shapes. This technique is referred to as Constructive Solid Geometry (or sometimes, Geometric Boolean Operations). These techniques are once again made possible by the solid/empty space discrimination that can be made when the scene data is compiled into one or more BSP trees. In GILES™, each brush is compiled internally as a mini-BSP tree that describes which regions of the brush are in solid and empty space. When two brushes are merged into one (called a *union* operation), the polygons from each brush are sent down the other brush's BSP tree. Any polygons that end up in solid space (in either tree) are deleted, leaving two sets of remaining polygons (the non-deleted polygons from each brush). These can then be collected and added to a new single brush that is the union of the original two. BSP tree based Constructive Solid Geometry (CSG) techniques can be used to carve explosion damage into surrounding geometry, to merge a multi-brush level into a single static mesh, or to remove polygons that are not visible because they are embedded in other objects (e.g., removing the bottom face of a crate that is resting on the floor and would therefore never be seen). The latter process can help reduce the polygon count of our scenes and as you will see later, can be used to mold geometric data into a form that will describe solid and empty areas when compiled into a BSP tree.

At the end of this lesson we will have understood and implemented the following:

- **BSP Node Trees:** This tree type will be used for storing alpha polygons and rendering them in a pixel perfect back to front order. Using the BSP tree for this purpose will allow us to get perfect alpha blending results with all geometry configurations (something we have not yet been able to do in our framework). This tree will be constructed in Lab Project 16.1 to manage any alpha polygons that the scene may contain. The application will use this tree (after all non-transparent geometry has been rendered) to render its alpha list in correct back to front order. We will also develop a rendering solution for the BSP node tree that renders the alpha polygons it contains efficiently, trying to maximize batch rendering.

- **BSP Leaf Trees:** This is a tree that compiles in the same way as the node tree but differs in that it collects and stores the polygons at the terminal nodes (i.e., leaves) of the tree. This type of tree will be very similar to the trees we implemented in the previous lesson (with the kD-tree being its closest relative). Our implementation of such a tree can be derived from CBaseTree and can therefore use all of the same rendering functionality. The difference between a BSP leaf tree and a kD-tree is that the leaves are not necessarily box shaped, but can be arbitrarily sized and shaped.

- **Solid BSP Leaf Trees:** This is essentially the exact same tree as the BSP leaf tree with the exception that it expects to have geometry passed into it that meets certain standards. Such a tree (when supplied with the suitable geometry) will compile the geometry into arbitrarily shaped leaf nodes like the standard leaf tree, but this will be done in such a way that the tree will be able to tell us exactly which areas in the scene are considered solid (e.g., inside a wall) and which are considered empty. In the next lesson we will see that it is this property that will allow us to generate portals that are used by the PVS calculator to build the visibility sets for each leaf in the

tree. That is, it is vital that we have a way to compile a spatial tree that will tell us exactly what is solid and what is not. Using this information, our PVS calculator can calculate, from any leaf, exactly which leaves are occluded due to there being a solid obstruction in the way.

- **Constructive Solid Geometry (Boolean Operations):** It is important that we learn how to build a BSP tree that can provide us with the solid/empty information about the scene since we will need this information in our PVS calculator. As mentioned a moment ago, whether we can do so depends on whether the geometry we are being given meets certain standards that the BSP compiler will expect. The CSG techniques we implement in this lesson will allow us to write routines that attempt to mend data that would otherwise be considered unsuitable for the compilation of a solid/empty BSP tree. We shall see that CSG techniques will ultimately be used to generate the data needed to compile a PVS.

16.1 Introducing BSP Trees

Although the kD-tree we discussed in the previous lesson is in fact a tree that performs a binary spatial partition at each node (and could theoretically be referred to as a BSP tree in that sense), the more industry standard view of the term 'BSP tree' is a tree that partitions space at each node (into two halfspaces – thus, binary) using an arbitrarily oriented split plane. Most often, the term is used to describe a ***polygon-aligned*** BSP tree, where the split plane chosen at each node is not an axis-aligned plane (like we use in the kD-tree) but is taken from the polygon dataset. That is, each polygon input into the compilation process has its plane used as a split plane once. Using such a technique, the number of nodes in the tree will be equal to the number of polygons since each one's plane is used to split a node. Figure 16.1 shows how a polygon-aligned BSP tree would divide the space of a scene composed of five polygons (A through E).

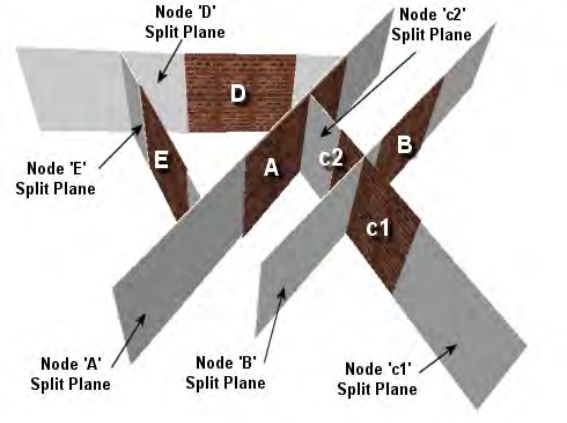


Figure 16.1 : Polygon Aligned BSP Tree

Since the scene is comprised of five polygons (forget about why polygon C is divided into two sub polygons at the moment), five nodes are created. The split plane stored at each node is the plane of the polygon that was selected from the polygon list at that node. As you can see, our scene is divided up into irregularly shaped regions, unlike the quad-tree, oct-tree and kD-tree we discussed in the previous lessons (which always carved the world into axis aligned box shaped regions). However, an important point to remember is that a BSP tree can be compiled using any arbitrarily oriented planes at each node; it need not use the planes of the polygons it has been passed for the compile process. As we will discuss in a moment however, there is great benefit in doing so under certain circumstances.

The compilation of a BSP tree is essentially the same as the building process of any of the other spatial trees we have developed thus far. Each node in the tree stores a split plane that is used to cut the space

represented by that node into two child nodes. While the kD-tree always used a split plane at each node that was aligned with one of the world axes, the BSP tree can use any arbitrarily oriented plane. The polygon list that makes it into that node is then divided into front and back lists, just as we saw with the kD-tree. Any polygons in the list that span the current node's plane are split and the relevant fragments added to both the front and back list. These lists are then passed into the two child nodes where a new plane is selected and the polygon data is further subdivided. This is all identical to the split trees we compiled in the previous lessons, and you will see that the code to both the BSP tree compiler and the kD-tree build function (for example) are almost identical. The only difference in our description so far is that the plane chosen to split each node is not necessarily chosen to be axis aligned; it can be arbitrarily oriented. As one might imagine, using arbitrary split planes at each node no longer divides the underlying region of space into a neatly organized stack of boxes.

There are two main flavors of BSP tree that we will develop in this lesson: node trees and leaf trees. A leaf tree works in the same way as the previous trees we have covered. The terminal nodes of the tree are the leaf nodes and they contain all the polygon data that belongs in that leaf (just as before). These are the polygons that are passed down to that terminal node during the build process. A node tree is similar, but not exactly the same. The only real difference between a leaf tree and a node tree is that the node tree does not contain the leaf structures that store polygon data at the terminal nodes. Instead a node tree might choose to store the polygon data in the nodes themselves or perhaps store no polygon data at all. With this small exception, the node tree is identical to the leaf tree.

In the next section we will introduce the BSP node tree, explain its properties, and see how it can be used for back to front rendering of polygon data. The BSP node tree we implement will generate its node planes from the polygon data compiled into the tree (i.e., a polygon-aligned BSP node tree). The polygons themselves will also be stored at the nodes. That is, each node will contain a split plane that was created by one of the polygons in the original set. That polygon and all others that share that plane will also be stored at the node. Although it might not be obvious why we would want to build a BSP tree that partitions the world using a set of polygon planes or why we would want to store polygons in the nodes at arbitrary levels of the tree (instead of at leaf nodes), all of this will be explained shortly.

16.2 Polygon-Aligned BSP Node Trees

In the early days of 3D game development, when end-users' systems were not equipped with hardware depth buffers and megabytes of video memory, one of the major tasks that faced any game engine programmer was how the scene was going to be rendered into the frame buffer such that polygons nearer the viewer obstructed polygons that were further away. These days, we take for granted the fact that the depth buffer will perform a per-pixel comparison before each pixel is rendered so that a pixel only gets rendered if its camera relative depth is less than the depth of a previous pixel already stored in the frame buffer at that same location. Prior to the introduction of 3D hardware acceleration and the inexpensive main memory found in the mid level PCs of today, 3D engine programmers did not have the luxury of throwing their polygons at the frame buffer in an arbitrary order, relying on the depth buffer to handle the occlusion of distant objects. On early systems, memory was very limited. It was barely possible to fit all the polygon data into memory, let alone allocate another large chunk of memory the size of the frame buffer just to store per-pixel depth information. Additionally, since these engines ran

completely in software, performing a per-pixel test prior to rendering each pixel was also something which could not be performed in real time on early microprocessors.

The 3D developer had bigger concerns than batch rendering by texture or material and in fact, was forced to use a technique that was mutually exclusive with respect to these concepts. The engine had to render the scene so that polygons further away from the viewer were rendered first and polygons nearer the viewer were rendered later. Remember, without a depth buffer, any polygon that was rendered would always be drawn over anything currently in the frame buffer. Even if the polygon that was rendered was further away from the camera position than the polygon currently occupying the same space in the frame buffer, that polygon would be overwritten. In other words, without any depth testing in the pipeline, rendering to the frame buffer was analogous to painting on a canvas. Regardless of the scene already painted on that canvas, anything you painted subsequently would be rendered over the top. Figure 16.2 shows a classic example of what can happen if no depth testing is available and the polygons are rendered in an arbitrary order. In this example we have a mesh of a corridor section consisting of five polygons. The long darker horizontal polygon is the polygon that forms the wall at the end of the corridor. Technically, it should be occluded by the left and right wall sections. However, because it was the last polygon that the artist added to the mesh, and we are simply rendering the faces of the mesh in the order in which they are stored, it is rendered to the frame buffer last, overwriting everything currently contained in the frame buffer in its overlapping pixel locations.

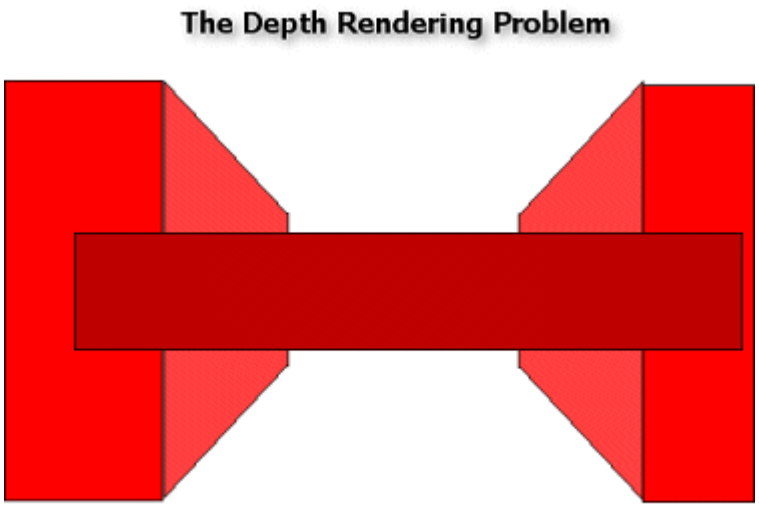

Figure 16.2

One of the early solutions to this problem was a rendering technique called the Painters Algorithm. The technique is so named because it is analogous to the way in which a painter builds up their scene on a canvas. Normally, a painter paints the background objects first and then later adds foreground objects. This ensures that the objects in the foreground are painted on top of the background objects, thus occluding them from view. The Painters Algorithm is a technique in which the polygons that are to be rendered are first sorted into a list based on their distance from the camera. The further a polygon is from the camera, the higher up in the polygon list it would be stored and the earlier it would get rendered to the frame buffer.

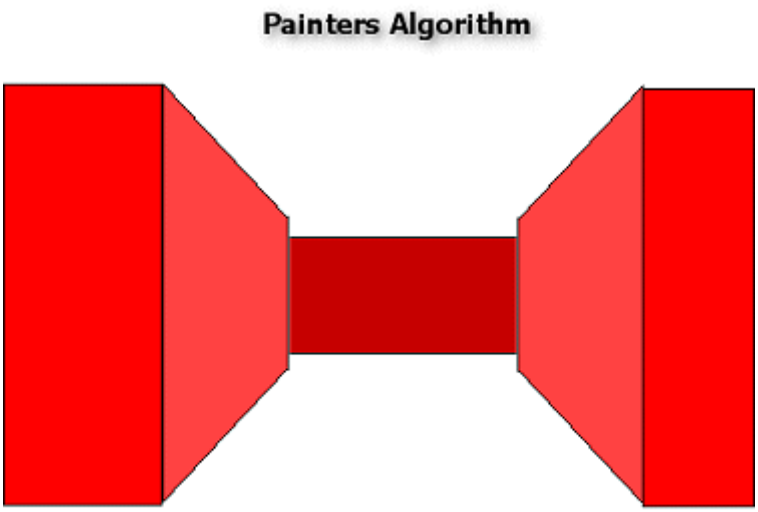

Figure 16.3

When the sorted polygon list was rendered from beginning to end, the polygons would be rendered in back to front order with respect to the camera. Nearer polygons that share the same screen space region as further polygons would automatically overwrite them, providing the correct depth based polygon occlusion.

In Figure 16.3 the same section of corridor is depicted as before, only this time the polygons have been distance sorted prior to being rendered. We can see that the first polygon to be rendered would now be the wall at the far end of the corridor. Since this one is rendered first, when the left and right wall sections are finally rendered, they automatically overwrite the correct sections of the far wall, giving the proper sense of depth.

So we see that in order to render a 3D scene correctly when no depth buffer support is available, we must sort our polygon data such that it is rendered in a back to front order with respect to the camera's current position. Keep in mind that the CPUs on these older machines were already constrained with just the actual rendering functionality; having to perform a back to front polygon sort before drawing each frame was certainly no help performance-wise. Of course, there are ways to improve depth sorting speed and efficiency. The hash table technique we implemented in Module I of this series was efficient enough, but it was far from being a perfect polygon sorter. The problem was not the technique itself, but the way that the distance to each polygon was originally calculated before being stored in that table.

Recall that in Chapter 7 of Module I, in order to sort the polygons (whether using a hash table or any other sorting technique) we had to use a point on that polygon as the sorting key. A common practice is to use the view space center position of the polygon such that the final list/table compiled describes a list of polygons sorted by the distance to their center positions from the camera. While using such a technique works quite well in a lot of circumstances, there are certain geometry configurations in which this technique will produce an erroneous render order (see Figure 16.4).

In Figure 16.4 we can see two polygons with a camera position represented by the sphere at the bottom of the image. The smaller polygon clearly overlaps the larger one from the viewer's perspective and therefore should be rendered into the frame buffer after the larger one. However, note the two arrows and their lengths representing the distance from the camera's position to the center of each polygon. We can clearly see that the camera is located closer to the center position of the larger polygon, even though the smaller polygon is in front of it. This means the method of sorting using the center point of each polygon would fail in this case and the smaller polygon would be rendered first, only to be partially overwritten by the larger polygon that is rendered afterwards. In this situation, the viewer would see depth artifacts.

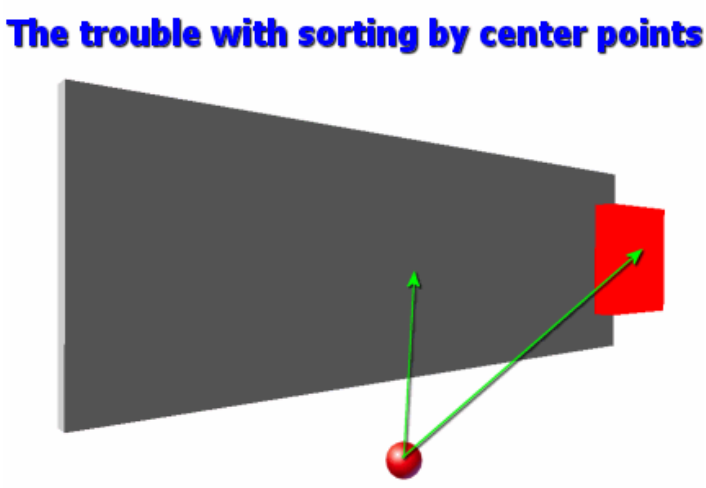

Figure 16.4

Even if a more thorough method was used to more accurately calculate the distance from the camera to the polygon and we could sidestep this particular problem, there are still certain geometric configurations for which a definitive draw order can not be ascertained. The configuration of the two polygon construct depicted in Figure 16.5 is so effortlessly handled by a depth buffer algorithm that it is easy to take depth buffers for granted.

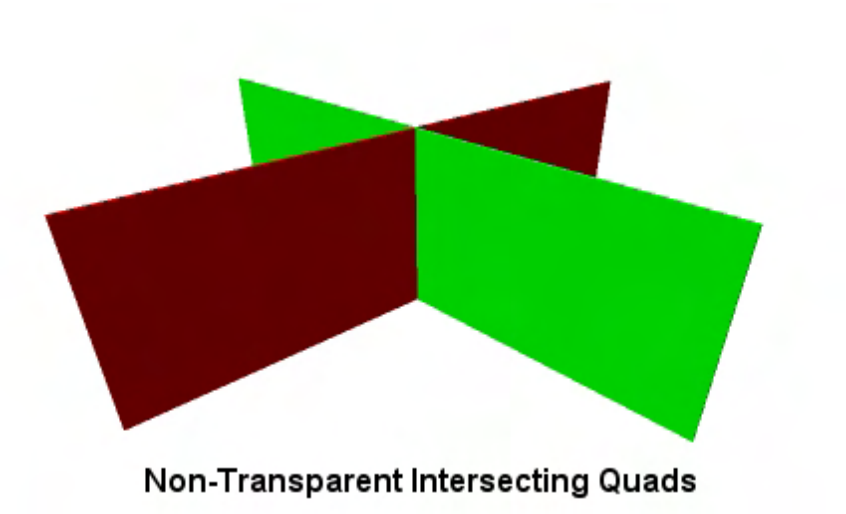

Figure 16.5

In this image we have two polygons that intersect each other to form an X shaped configuration when viewed from the camera's current location. The dark red polygon that starts at the bottom left of the image is both in front of and behind the green polygon that starts at the bottom right of the image. However, the green polygon is also both in front of and behind the red polygon.

With a depth buffer, the order in which these polygons are rendered is insignificant. If we render the red (right) polygon first, then the depth values for each of its pixels will be written the depth buffer first. When the green polygon is rendered, some of its pixels will have greater distances than those currently containing the red polygon's pixel and as such these pixels will not be rendered. We can see this in the top left of the image where, even though the green polygon was rendered second, some of its pixels are never rendered because they are found to lay behind some of the pixels of the red polygon. In the bottom right section of the image however, where we can see that the green pixels would have smaller depth values than the red pixels already contained at that location, the

red pixels are correctly overwritten by the green pixels. We have a situation where the two polygons both occlude and are occluded by each other. The depth buffer handles this case perfectly.

Looking at the above diagram one might wonder how such an arrangement could be rendered if the depth buffer was not at our disposal. Which polygon should be rendered first? As it happens, there is no solution to this problem using only polygon sorting. If the green polygon was rendered first then when the red polygon was rendered, it would overlap all the pixels in the green polygon sharing the same screen space locations, even if the red pixels were further away from the view point than the green pixels already drawn there. If the red polygon was rendered first, the same would happen in reverse and part of the red polygon would be overwritten by the green polygon in areas that should have been occluded by it. The only way this situation can be solved is by splitting the polygons into multiple sections such that the ambiguity is removed and a clear render list can be compiled for those polygon segments. This is one of the things that a BSP tree does when it compiles its data; it makes sure that when the tree is finally built, no situations like the one shown above exist in the geometry. Thus, a clear back to front rendering order can always be known at runtime.

16.2.1 When Depth Buffers Will Not Suffice

So far we have discussed the problems that faced the game engine developers of yesteryear when a depth buffer was not available for perfect depth sorting. While this discussion may have seemed nothing more than nostalgic now that we always have access to depth buffers, this is far from the case. In Chapter 7 we learned that we will need to render our alpha (i.e., transparent) polygons in a back to front order so that blending operations are carried out correctly. If we simply throw alpha polygons at the pipeline in an arbitrary order, artifacts can result since many common blending modes are order dependant.

Because we want transparent polygons to allow what is behind them to show through, we will want to render them after the main scene has been rendered. This way, the alpha polygon does not get its depth values written to the depth buffer and prevent geometry that is behind it (but should be seen through it) from being rendered. If we are looking at the outside of a house model, we should be able to see through its windows and into the room(s) on the inside. If the window was rendered before the room behind it and depth writing was being used to record the depth values of the alpha polygons in the depth buffer, when we tried to render the section of the room behind the window later, it would be rejected by the depth test. Thus, we will want to render our alpha polygons after all opaque polygons have been rendered to avoid this situation.

However, even if the alpha polygons are rendered in a separate pass after the rest of the scene has be constructed in the frame buffer, this situation can still occur if alpha polygon A is in front of alpha polygon B, but rendered first. The depth values for A will be written to the depth buffer first, and when alpha polygon B is rendered later, its pixels are depth rejected and never rendered behind polygon A. Since polygon A is supposed to be transparent, we are supposed to see polygon B behind it. Therefore B’s pixels still should have been rendered. As we learned, we can stop this from happening by simply disabling Z writing when we render the alpha polygons. This will ensure that they are correctly obscured by the opaque polygon data already contained in the frame/depth buffer and that alpha polygons

(rendered with Z writing disabled) do not occlude one another and prevent each other from being rendered.

This would work fine were it not for the fact that the blending operations that we perform are often order dependant. If polygon A is a blue window and polygon B (behind it) is a red window, the red polygon should be rendered first and the blue polygon rendered second so that we see a red window that has been tinted blue. If the red window polygon was rendered second, we would have incorrect blending where the two polygons overlap (we would see a blue window tinted red). This would indicate that we are viewing the blue window through the red window instead of the other way around.

The only way to render our alpha polygons correctly is to render them in a second pass with a perfect back to front ordering. As we can no longer rely on the depth buffer, and must sort the polygons ourselves, we find ourselves with the same problem that faced the early game engine developers. How do we render a set of polygons in a perfect back to front order that gives correct blending results every time, regardless of how the polygon data is oriented? Admittedly, we only have to do this for our alpha polygons (instead of the entire scene), but even so, a solution is required.

The hash table technique accomplished most of these goals, but occasionally failed due to the fact that it used polygon center positions as its sorting criterion. In Figure 16.6 we see both the intersecting polygon problem and the blending order problem. We are using the same two polygons from Figure 16.5, but now made transparent. Compiling polygons into a back to front render list is not always possible (see Figure 16.5) and by using the same example again but with alpha polygons, we also see the blending errors that are produced.

For the set of polygons shown in Figure 16.6, there is no clear draw order. In this example we have decided that because no draw order can be determined, we will just render the red (left) polygon first and the green (right) polygon second.

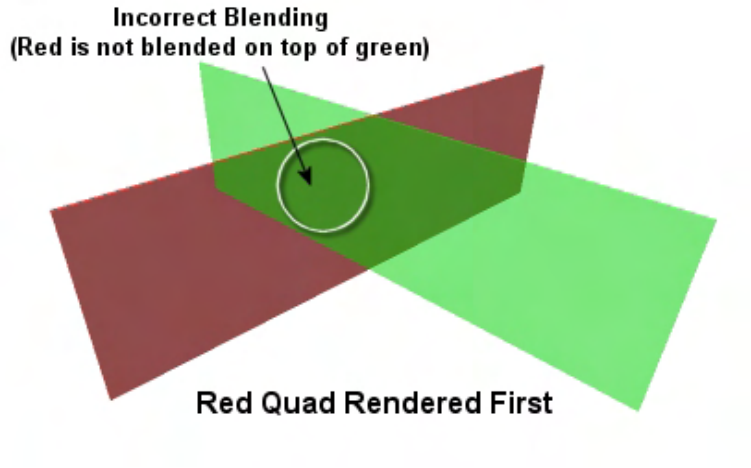

Figure 16.6

error would occur, as shown in Figure 16.7.

Because the green quad was rendered afterwards, it overwrites a portion of the red quad that is supposed to be in front of it. The rough area of green pixels that are supposed to appear to be behind the red polygon are highlighted by the circle in the diagram. Because the green polygon was rendered second, the blend order is wrong. The color of these pixels should produced by viewing a green pixel through a red polygon, but instead we are viewing red pixels through a green polygon. Of course, if we were to render the green polygon first, then the opposite

This example does not look as obviously incorrect, but after some investigation you will see that the approximate area of pixels in the region of the white circle in the red polygon should be located behind the green polygon and as such, should have been produced by blending green on top of red instead of red on top of green.

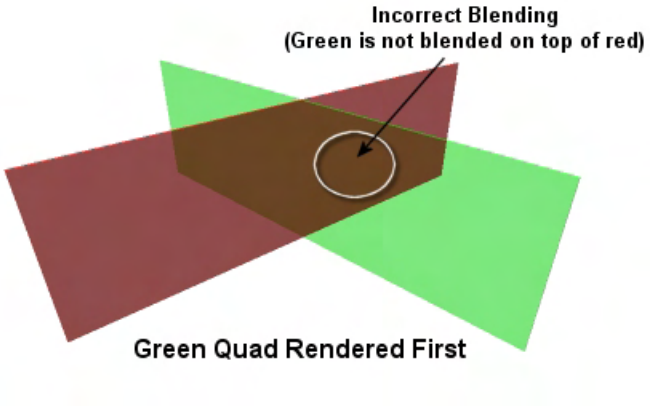

Figure 16.7

So even if we sort our polygons in a back to front rendering order so that the alpha polygons are blended in the correct order, we are still not fully covered in all cases. In a situation like this, there simply is no correct drawing order. Whichever polygon we render first, part of it will be overwritten by the second polygon in areas where it should not have been.

Figure 16.8 shows how we would like the two alpha polygons to be rendered. This is what compiling a polygon-aligned BSP node tree for our polygon data will allow us to do.

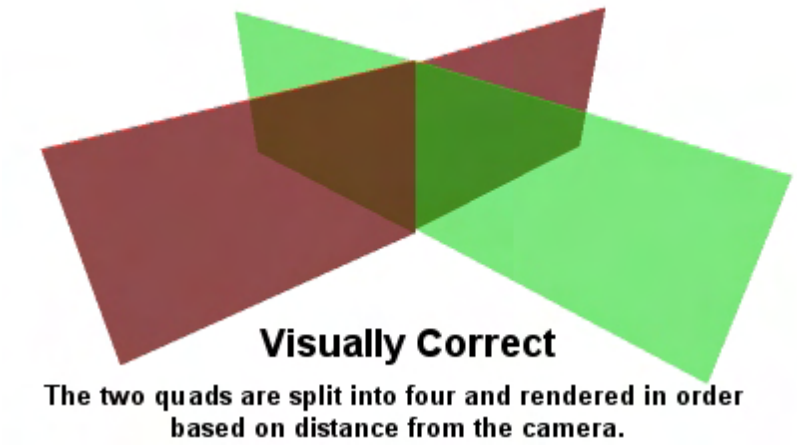

Figure 16.8

In this example, the BSP tree has used the plane of the green polygon to split the red polygon into two pieces and has used the plane of the red polygon to split the green polygon into two pieces. The original two polygons have now been replaced by four non-intersecting polygons which can be correctly ordered back to front.

In this example we can see that the back two quads (one red and one green) would be rendered first in the alpha pass. When the second two quads are rendered, the red quad is correctly blended over the back green quad and the green quad is correctly blended over the back red quad, giving us a perfect render order and perfect alpha blending.

In Lab Project 16.1, after every alpha polygon has been loaded and added to the BSP tree, the tree will be compiled. As we will discuss in the next section, this tree will allow us to render alpha data in a perfect back to front order from any camera position even though the tree is only built once. It should be

noted however that just because we are using it to sort alpha polygons, BSP trees could be used to sort the entire scene into a back to front rendering list. Indeed it was often the BSP tree that allowed the game engines of old to render polygons to the frame buffer with the correct depth occlusion without the aid of a hardware depth buffer. Thus, in the next section we will discuss building BSP trees from the more general perspective of compiling arbitrary polygon sets (not just alpha polygons).

16.2.2 Building our First BSP Tree

When we think about the spatial trees that we developed in the previous lessons, we can perceive a tree to be an arrangement of spatial relationships. Each node in the tree describes its position in the world relative to other nodes in the tree. In the case of a kD-tree for example, we know when we visit a node that the sub-tree of nodes attached to its back pointer are all representing space that has subdivided the space behind the current node's split plane. The sub-tree of nodes stored in its front list represent the space that subdivides the space in front of the current node's split plane. Thus we can think of the kD-tree as describing a collection of planes with an established relationship to one another. We know exactly which node is behind another node, and vice versa.

In order to render a list of polygons in a back to front order, we need to establish those same relationships between polygons. That is, we need to know if one polygon is behind another. Therefore, if the kD-tree tells us the relationships of planes to one another, we can use the exact same technique for our polygons. We can just use the planes of the polygons themselves as the split planes. Because we know that building a tree for these planes will describe their relationship to one another, it will therefore tell us the relationships of the polygons used to create those planes.

The process of building a BSP node tree is simple. The build procedure is passed the list of polygons that needs to be compiled into the tree. At each node, a polygon is selected from the list of polygons that made it into that node. The plane on which the selected polygon lies becomes the split plane for that node and (this is the important part) the polygon itself, and any others that may lie on the same plane, are removed from the list and stored at the node. The remaining list of polygons is then classified against the node plane and split into two polygon lists that belong in the front and back halfspace of the plane. The front list is then traversed, where it is used to create a branch of nodes in the same way as before. The back list is also traversed so that a series of back nodes are constructed, again in the same way. At the end of the process we will have compiled a BSP tree containing N nodes, where N is the number of polygons from the original dataset that lay on unique planes. Each node will store a split plane just like the kD-tree, although this split plane may not be axis aligned; it will instead be the plane of the polygon that was selected from the list at that node. Each node will also store one or more polygons that lay on that plane. Although we often refer to a tree of this type as having no leaves, what this really means is that all the polygons are not stored in the terminal nodes. If you wish, you can think of a node tree as being a tree where every node acts a leaf, because each node will store renderable data.

When the tree is built, we will be able to traverse the nodes of the tree and perform a classification test with the camera position at each node. The camera will be "pushed down the tree" so that it processes the nodes that are furthest from the viewer first. As each node is visited, the polygons stored at that node

(i.e., that lay on the node plane) are rendered. Therefore, while the tree is generated once and remains static, the order in which we visit the nodes of the tree depends on the camera position passed into the traversal function. The end result is a static tree that can be traversed in a back to front node order from any position in the scene. We will look at the rendering logic for the tree a little later; for now we will focus on the tree building process with a very simple example.

Figure 16.9 shows a level consisting of three polygons labeled A, B, and C. The camera position is not known or considered when building the BSP tree (i.e., it is view independent).

Using the example polygon set in Figure 16.9, the three polygons would be registered with our BSP tree at load time. After the polygons have been added to the tree, the BSP tree's Build function would be called to start the recursive compile process.

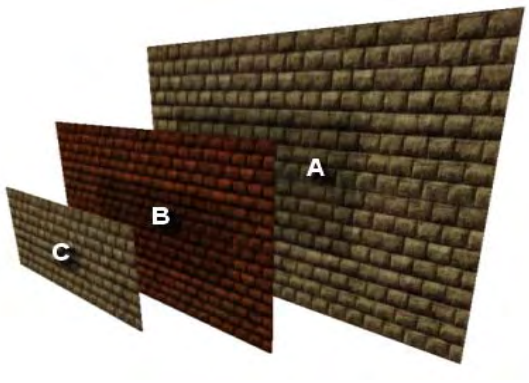

Figure 16.9

The first thing that would happen is the root node would be created and a polygon would need to be chosen from the list to use as the split plane for that node. The polygon we choose from the list at each node can be randomly selected from the list of polygons that made it into that node and the tree will still be successfully compiled (it can even be traversed successfully in the correct back to front order). However, we will learn later that there are tests we can perform at each node to find polygons which make better candidates for split planes higher up the tree, and are thus preferred. For now however, we will assume that polygon B has been chosen at random for the root node.

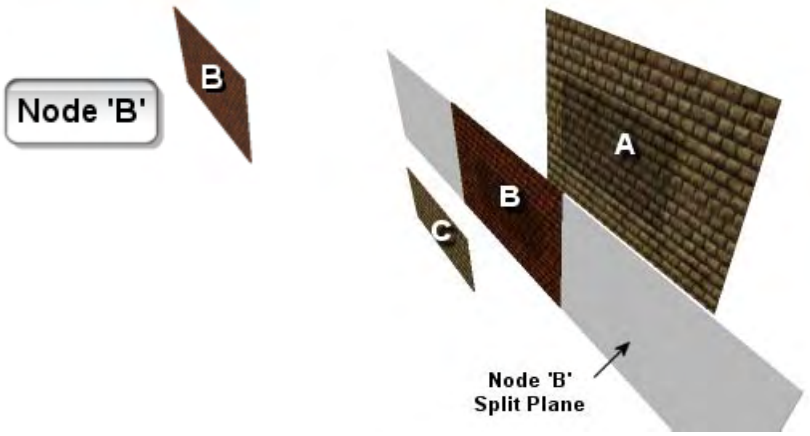

Figure 16.10

So polygon B is selected first and is removed from the list. The plane for polygon B will be calculated and stored in the root node (Node B) as the split plane. Polygon B will also be stored as the renderable data at that node.

At this point our tree has one node that stores a split plane, shown as the gray slab in Figure 16.10. Polygon B itself is also stored in the node, leaving only polygons A and C in the polygon list. This polygon list is then classified against the node plane to create two lists for both the front and back children of the root. We can see that polygon A, when classified against the split plane of node B, is found to be behind the plane and is added to the back list. Polygon C on the other hand is in front of the plane and is added to the front list. We have now done all the work we need to do at the root node. We have a split plane and a polygon stored at that node, and two polygon

lists describing the polygons that are both in front and behind the node plane. In this simple example there is currently only one polygon in the back list (A) and one polygon in the front list (C).

> **Note:** The split plane is infinitely extended in all directions, but we chose to display only the portions that match the vertical dimensions of the polygon for ease of viewing in the diagrams.

As the front and back polygon lists are not yet empty, we must recur down the front and back of the node and create additional child nodes. Two nodes are created and attached to the root node's front and back pointers. The function then recurs into each child passing in the respective list. In this example we will assume that we step into the back child first, passing in the back list which contains a single polygon (A).

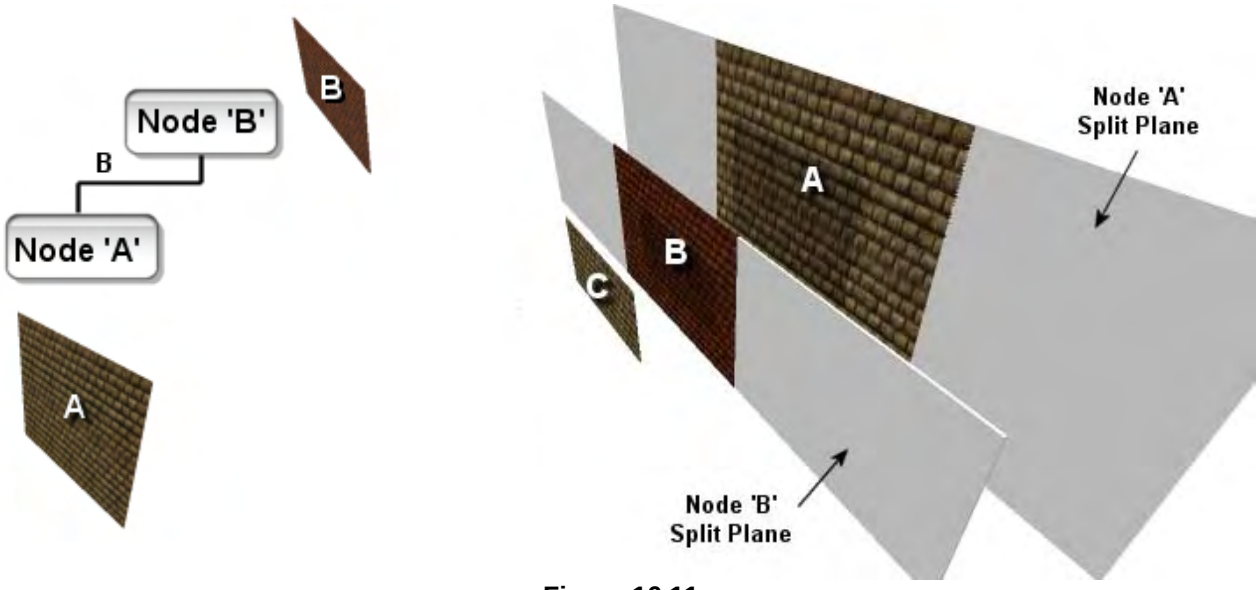

Figure 16.11

When we arrive at the back child of the root, the same process happens. A polygon has to be selected from the passed list so that its plane can be used as the split plane at that node. Since the polygon list passed into the back child contains only one polygon, Polygon A, the choice is easy. Polygon A is removed from the list and stored in the node. The polygon's plane is calculated and stored as the split plane for this node, which is called Node A in the diagram. As the polygon list is now empty, we have reached a terminal node. Because there is no polygon data left to subdivide, we no longer have to compile any front of back polygon lists for this node and we do not have to create any child nodes. With polygon A and its plane stored in the node, we return back up to the root.

At this point we have processed the root's back child but have not yet traversed into the front child with the front polygon list. This is done as the final step for this node.

As we step into the front child, we once again find ourselves at a new node that needs to have a plane selected for it from the passed polygon list. In this example, the polygon list passed into the front node contains a single polygon (C), and therefore this polygon is removed from the list and stored in the node along with its plane. As the polygon list is now empty, no child lists or nodes have to be compiled and

the function can step back up to the root. Once back at the root node, we return from the build process and hand program flow back to the application.

Figure 16.12 shows the final representation of our three polygon BSP tree after the front node has been visited and polygon C assigned to it.

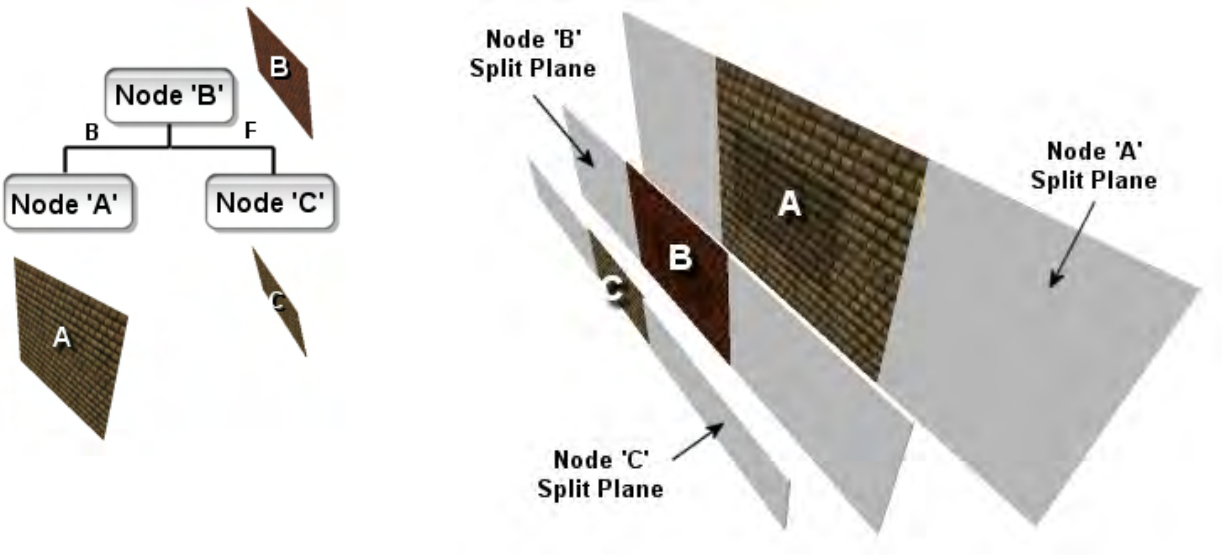

Figure 16.12

Looking at the tree diagram on the right hand side of Figure 16.2, you can see that we have created a three node tree from our list of polygons and we have stored a polygon at each node.

16.2.3 Rendering Our First BSP Tree

In this next section we will examine how to render a BSP node tree in perfect back to front order using the simple example tree discussed in the last section. We will look at two examples using two different camera positions so that we can see that while the tree is compiled once at startup and never changes, it can be traversed such that the polygon draw order is dynamically created in a back to front order from any camera position.

The rendering of the BSP node tree is a typical traversal which, as we would now expect, will be implemented using a recursive function. The application will render the tree by calling this function for the root node (passing a root node pointer and a camera position). The function will visit each node and perform a fast and simple test to determine which child should be visited first. This will depend on which halfspace of the current node's plane the camera is currently contained in.

For each node visited during the render traversal, the basic logic performed is as follows:

- Classify camera position against node plane

- If camera position is in frontspace of plane
    - Step into back child
    - Render polygon stored at the current node
    - Step into front child

- Else if camera position is in backspace of plane
    - Step into front child
    - Render polygon stored at the current node
    - Step into back child

This traversal logic at each node makes a lot of sense. We are essentially stating at each node, if the camera is in front of the plane, render the stuff behind it first, then render the polygon stored at this plane, and finally render the stuff in front of the plane. Alternatively, if the camera is behind the current node plane being tested, render everything in front of the plane first, render the polygon data stored at the node, and then finally render the data behind the plane. This traversal logic means that at each node the choice of which order in which to visit each child node is dependant on the camera position. Thus, when the entire tree has been visited, the node's polygons will have been rendered in a back to front order with respect to the position of the camera.

Imagine that the node structure for our BSP tree looks something like this:

```
struct BSPNode{
  POLYGON *splitter;
  BSPNode *FrontChild;
  BSPNode *BackChild;
};
```

Given the above, the following semi-pseudo code shows how our recursive BSP tree rendering function might look. This function would be called by the application just once each frame and passed the root node of the BSP tree and the current camera position.

```
void RenderBSP (BSPNode *CurrentNode , D3DXVECTOR3 &CameraPosition)
{
  int Result = ClassifyPoint( CameraPosition, CurrentNode->Plane );

  if (Result == Front || Result == OnPlane)
  {
      if (CurrentNode->BackChild != NULL)  RenderBSP (CurrentNode->BackChild );

      DrawPolygon(CurrentNode->Polygon);

      if (CurrentNode->FrontChild != NULL) RenderBSP (CurrentNode->FrontChild);
  }
  else
  {
      if (CurrentNode->FrontChild != NULL) RenderBSP (CurrentNode->FrontChild);
      if (CurrentNode->BackChild != NULL)  RenderBSP (CurrentNode->BackChild );
```

```
    }
}
```

In this example, the DrawPolygon function is assumed to be a function that renders the passed polygon to the frame buffer. Notice that there is no need to render the polygon data stored at the node if the camera is located in its back space. This would obviously mean the camera is looking at the back of the polygon, which would be back face culled by the pipeline anyway.

Rendering Example 1

In this first example which uses our three polygon BSP tree from the previous section we are given a camera position as seen in Figure 16.13. We can clearly see that in order for the polygons in the tree to be rendered in the correct back to front order we should render polygon A first, followed by polygon B and then finally polygon C. What is also worth noting is that the orientation of the camera is not used in the traversal logic at all, which may at first seem strange. Only the camera position is used and classified against the node planes to determine the correct drawing order.

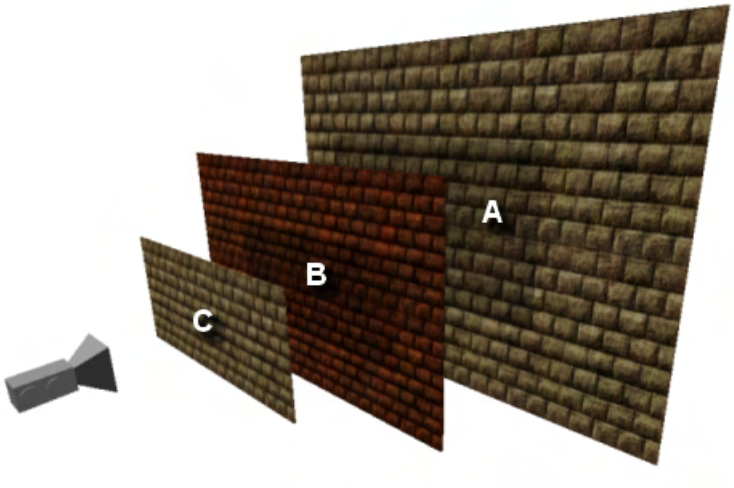

Figure 16.13

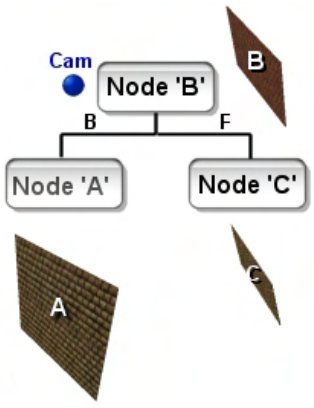

Figure 16.14

In Figure 16.14 we start our traversal of the tree by passing our camera position into the root node. This is shown as the blue dot labeled ‘Cam’ in the image. As discussed and shown in the previous pseudo code section, the first thing we do is classify the camera position against the plane stored at Node B. In Figure 16.13 we can see that the camera is currently in front of the split plane stored at Node B

Note: Remember, the split plane stored at each node is the plane that the polygon lies on. Therefore, we can see that the camera position would be in front of Node B because it is in front of polygon B, which is just a subset of the same plane.

As the camera is currently in front of node B, our logic tells us that we must visit the back child first before rendering the polygon stored at this node. So in the next step, we traverse into the back child of node B and arrive at Node A.

As Figure 16.15 shows, when the camera arrives at node A, it is once again classified against the split plane stored there and we determine that it is in front of node A. This would normally mean that we

would step into the back child first before rendering the polygon stored at that node. However, as no back list exists, we skip that part and simply render the polygon stored in the node (A).

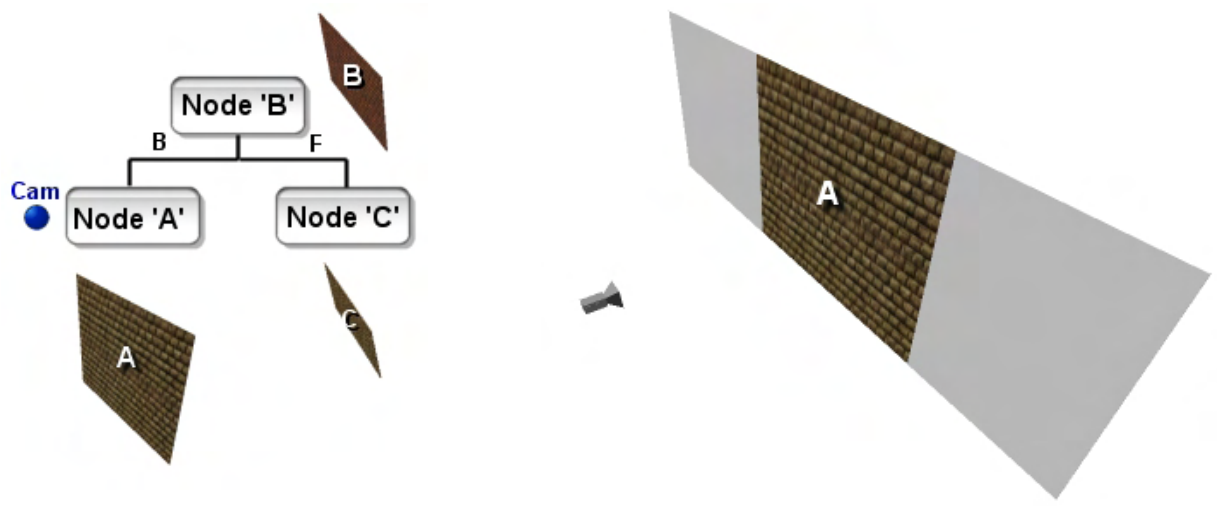

Figure 16.15

After rendering the polygon at node A we would step into the front child next, but this node is a terminal node that has no front list, so we return from the current instance of the recursive function and pop back up to the root node just after the point where the back child was stepped into.

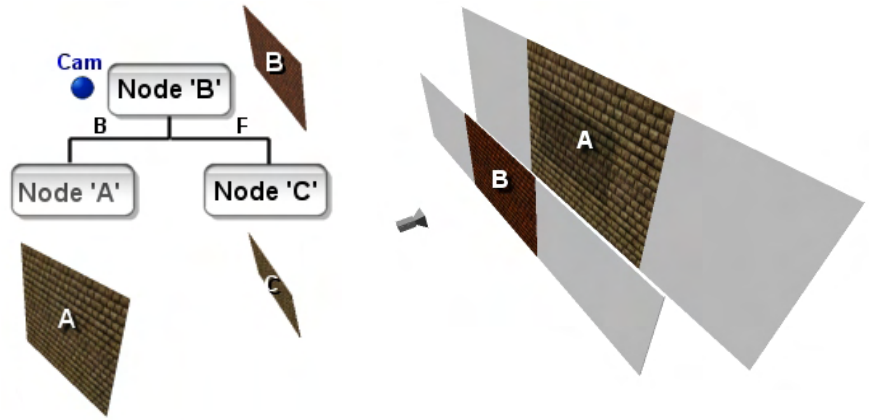

Figure 16.16

Before we stepped into the back child of the root node, we determined that the camera position was in front of the root node. This determined that we had to render the back child first, then render the polygon stored at the node and then traverse into the front child. We have now completed the first step and have stepped into and have returned from the back child. Therefore, our next job is to render the polygon stored at the node. The polygon stored at the root node B is polygon B, so we render this polygon next, as shown in Figure 16.16. Since this polygon is closer to the camera than polygon A, some sections of polygon A will be overwritten by polygon B in the frame buffer. This is absolutely correct because, from the camera's view point, polygon B should partly occlude polygon A.

We have now performed two of the three steps we had to perform at the root node (we rendered the back list and rendered the polygon stored at the node). All that is left to do now is step into the front child of the root node, where we visit node C.

Note: Remember that the order in which we decide to traverse into the front and back lists is dependant on the camera position. If we are in front of the plane, we step into the back child first. If we are behind the plane, we step into the front child first. This ensures that we always visit the nodes first that are in the opposite halfspace of the current node's split plane with respect to the camera position.

As Figure 16.17 shows, when we visit the front child we find that it has no children, so we simply render the polygon stored at the node (i.e., polygon C). As polygon C was rendered last, it will overwrite sections of polygon B in the frame buffer, which again is absolute correct. Polygon C is closer to the camera and therefore should occlude polygon B to some extent.

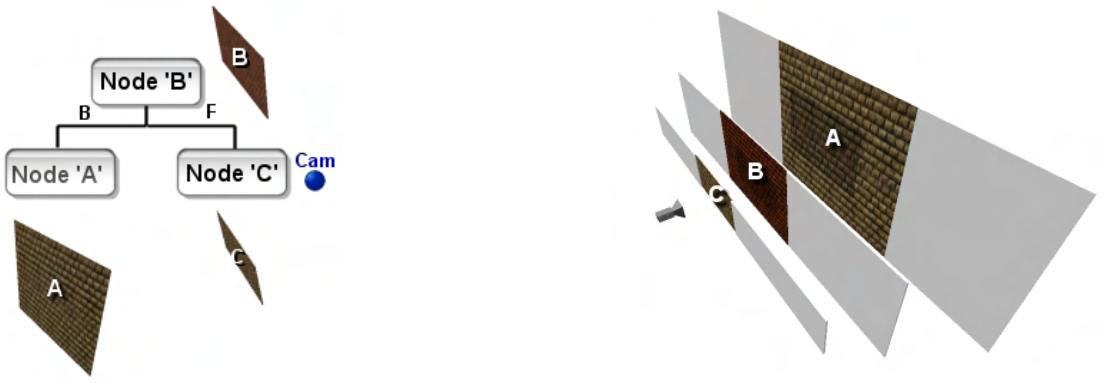

Figure 16.17

After polygon C is rendered, we return from node C back up to the root. At this point we learn that the root node has performed all its tasks, so the root node call returns and program flow passes back to the application. Although this was a simple example, we have just seen how to use a BSP tree to render our small scene in back to front order. Again, the same function can be used to render the same tree in a perfect back to front order even when the camera position changes. Stepping through one more rendering traversal using the same BSP tree with a different camera location will solidify our understanding of the traversal process.

Render Example 2

In this second example we will use the same BSP tree, but move the camera such that it is situated between polygons B and A as shown in Figure 16.18. Once again you should take note that although the camera in Figure 16.18 is facing in a given direction (in fact, almost opposite the earlier orientation), this is not factored during the traversal. Rendering order is determined using only the camera position.

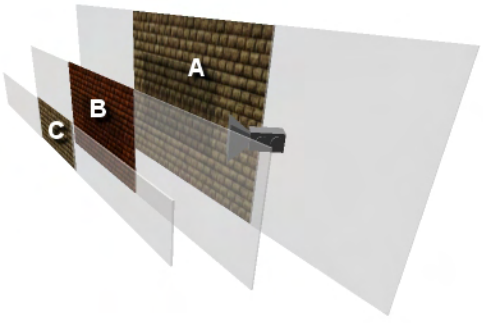

Figure 16.18

As before, we start off with nothing rendered and send the camera position into the root node to begin the traversal process.

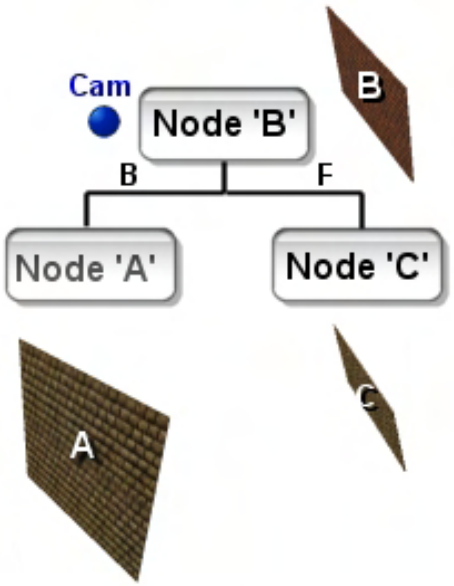

Figure 16.19

At the root node we classify the camera position against the plane of polygon B and find that it is located in the plane's backspace. This differs from our previous example where the camera was located in the root node's frontspace. As such, the order in which we traverse into the front and back children must be reversed. Because the camera is now located in the backspace of plane B we know that the more distant polygons must be located in the frontspace of B, and therefore should be visited and rendered first.

The order in which we do things at the root node will now be to step into the front child first and then render the polygon stored at the node (polygon B) before finally stepping into the back child. As we are currently at the root node, our first task is to step into the front node (Node C).

At Node C we find that we are visiting a terminal node and as such, there is no front or back child to traverse into. Therefore we just render the polygon stored there (see Figure 16.20). However, because the camera is behind the polygon it would be back face culled, so we would normally only render the polygon data stored at any node if the camera is in the plane's frontspace. But in this particular example, we will go ahead and render it for the purposes of demonstrating the correct traversal order being executed. At this point we have rendered C as our first polygon and when the function returns, we pop back up to the root node.

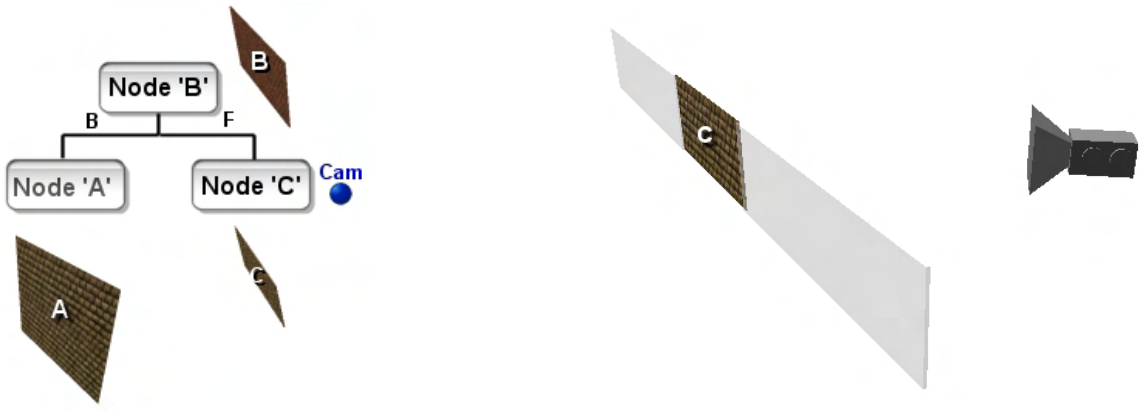

Figure 16.20

Once we are back at the root node, having traversed and (potentially) rendered the front tree of Node B (which in this example contains just Node C), we then render the polygon stored at Node B. However, once again, as the camera is in the backspace of node B, there is actually no need to render the data stored there as it would ultimately be back face culled. This means polygon B becomes the second candidate for rendering this time around (see Figure 16.21). Again, for this particular example, we will render the polygon anyway (at least in our images) so that you can see the order in which the polygons would be rendered if they were actually facing the camera.

Figure 16.21

Having rendered the polygon at the root node, we then step into its back child where we arrive at terminal Node A. This node then has its polygon rendered, as shown in Figure 16.22.

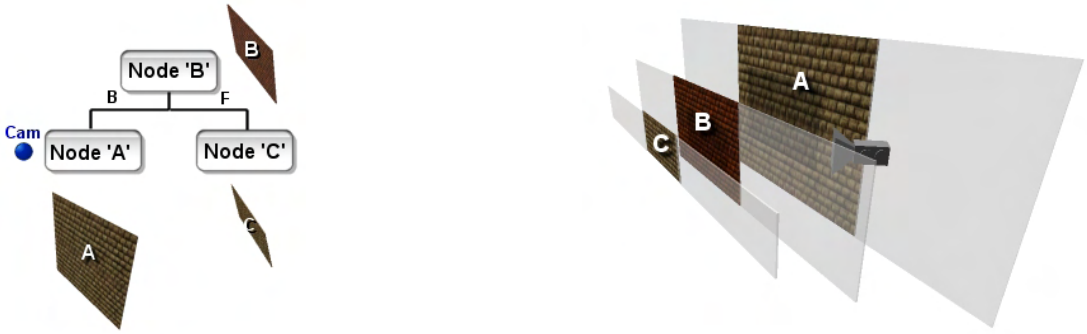

Figure 16.22

Just remember that in reality, polygon A would be the only polygon rendered in this scene as it is the only one in which the camera is located in its front space. At this point the polygon has been rendered and we step back up to the root node and return program flow back to the application.

We have now seen two examples of rendering the same BSP tree using different camera locations. It should be clear to you that even though the tree was only compiled once (hopefully in an offline process, although that would not be necessary for our simple example), it can be dynamically traversed at run time to generate a perfect back to front drawing order for polygons.

16.2.4 Perfect Back to Front Ordering with BSP trees.

In the previous section we examined a very simple example of a three polygon scene compiled into a BSP tree which we rendered using a specific set of traversal logic to determine a back to front draw order. Of course, the example BSP tree we used was deliberately simplistic to teach the fundamentals of BSP tree construction and traversal. All we have really done so far is introduce another technique to essentially give us the same results as our hash table (or any other sorting technique). After all, the polygons did not intersect each other and cause the ambiguous polygon order scenario. If our above example had contained such polygons, the technique we discussed would have failed since the same

problems still exist. So what if we were to discover a situation during the build process where polygon A is both behind and in front of polygon B? Should it be added to the node as a back child, a front child, or split by the node plane and have each fragment added to the relevant lists? The answer is that we must split polygons that span planes during compilation. Indeed it is this very concept that solves the geometric ambiguity issue for intersecting polygons.

In order to understand the full BSP tree building process, we will use a slightly more complex set of data that causes some spanning polygons that will need to be split during the build process.

In Figure 16.23 we see five polygons labeled A through E. We will assume that the camera is looking at the front of all the polygons here. That is, the polygon normals all face in the general direction of the camera. Looking at this collection of polygons, we have to try to distinguish which polygons should be rendered first and which should be rendered last based on the camera position.

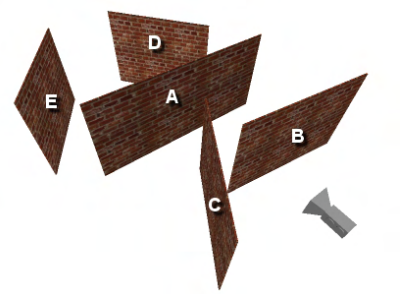

Figure 16.23

We can easily see that the first two polygons to be rendered should be polygons E and D, followed by polygon A. But which polygon should be rendered last, C or B? C is spanning the plane on which polygon B lies and is therefore both in front and behind polygon B. The order in which to render these polygons is now unclear and cannot be immediately determined. We can also imagine that such a geometric arrangement would be problematic in the build process of the tree using the techniques described above. Imagine for example that polygon B was chosen as the root node of the tree. We know that we then must classify the other polygons against this node plane to send them into the front or back list. We can see that polygons A, D and E would all be assigned to the back list of B but which list would polygon C belong to if it exists in both the front and back halfspace of node B's plane?

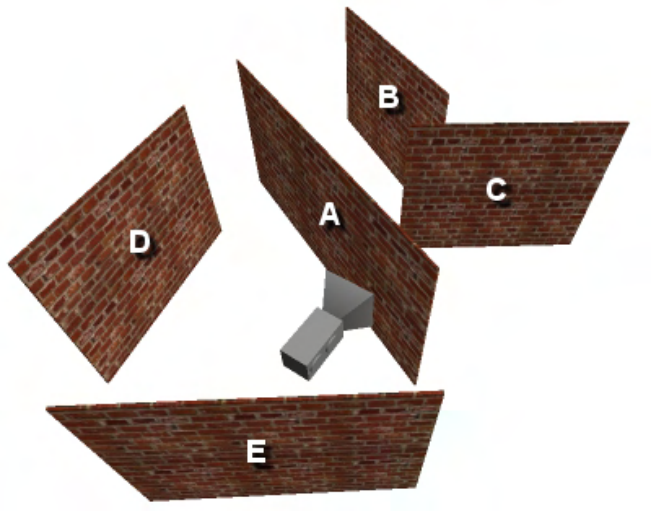

Figure 16.24

Figure 16.24 shows the same scene with the camera in a different position. This arrangement more clearly shows the problems that occur when one polygon spans the plane of another polygon.

Imagine what would happen if polygon C was chosen to create the split plane at the root node. Both polygons A and D would be spanning this plane, and this is not something we can allow to happen. For the BSP tree to provide a correct back to front polygon collection routine, every polygon must be either in front, behind, or on plane with another polygon. As soon as we have a polygon that spans a node plane anywhere in the tree, we lose the relationship between the polygons that tell us precisely

which polygon must be visited first.

The solution to this problem is simple. When a node is created, any polygons remaining in the list that made it into the node are classified against the node plane to decide whether they belong in the front or back list. Any polygon that is spanning the node is split, creating two new polygons which replace the original polygon in the list. Essentially, any polygon that spans a node plane, and is therefore causing us a problem, is split into smaller components that can be accurately described as belonging in either the back list or the front list of that node.

Without further ado, let us look at an example of building a polygon-aligned BSP node tree with the splitting logic introduced. With splitting in place, our BSP tree will be able to compile any geometry and render that geometry in a perfect back to front order from any camera position in real-time.

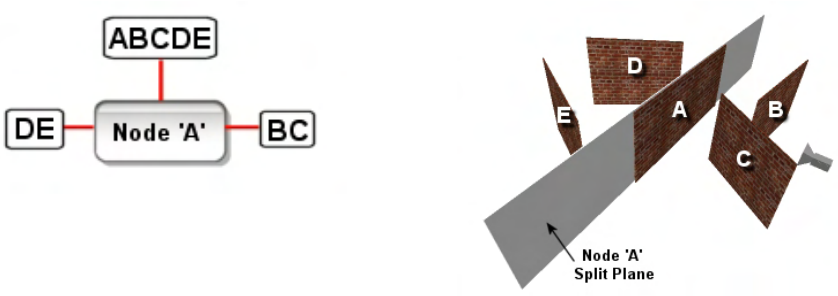

Figure 16.25

In this example we will use the same five polygons shown in the previous diagrams. For the sake of demonstration we will choose the split planes at each node in alphabetical order, but as discussed, the BSP tree will build and work correctly choosing the splitters in any order.

In the first step shown in Figure 16.25 the recursive build function is passed a root node and a list of five polygons labeled A through E. In this example, polygon A is chosen to be the splitter at the root node and is therefore removed from the list and stored in the node. In Figure 16.25 we have depicted the plane as the gray slab extending out from polygon A. As we can see, the root node now splits the space of the scene into two nearly equal sub-spaces. Polygon A is now stored at the node and the polygon list contains polygons B through E. In the next step, these polygons are classified against the plane of polygon A in order to construct front and back lists that will be passed down to the respective child nodes. If we look at Figure 16.25, we can see that D and E get assigned to the back list and polygons B and C get assigned to the front list. As we have non-empty front and back lists at the root node, it means we must create front and back child nodes and attach them to the root.

In this example we will recur into the front node first where the input list includes polygons B and C. A new split plane has to be chosen at the child node and, because we are going alphabetically, polygon B is selected from the list. The split plane is generated and stored in the node, along with polygon B. With polygon B now extracted from the list and stored in the node, the polygon list at node B now contains only one polygon: polygon C

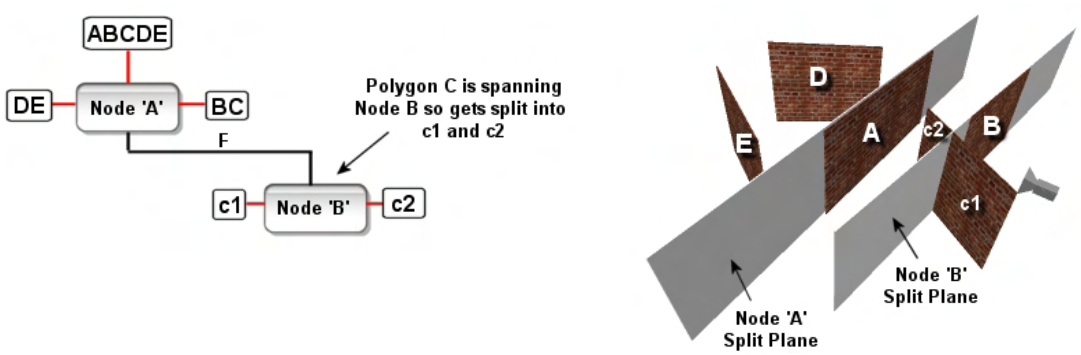

Figure 16.26

.

At this point, our job is to classify the remaining polygons in the list against the node's plane. In this instance, the polygon list contains just one polygon, so we would classify polygon C against the plane of Node B to determine whether it should be sent to the back or front of the node.

When polygon C is classified against the plane it is found to be spanning that plane and therefore polygon C must be broken into two child polygons. When we split a polygon against the plane of a node, the clipped fragment that is situated behind the plane is added to the node's back list and the fragment in the node's frontspace is added to the front list. After splitting polygon C into two child polygons (c1 and c2) and deleting the original polygon, we now have a front list and a back list compiled at node B. Each list contains a single polygon. The back list at this point would contain polygon c2 and the front list would contain polygon c1 (see Figure 16.26).

Because Node B still has polygons in its front and back lists, we will need to create both front and back child nodes. We then have to step into each of these children to continue the recursive building process. We will step down into the front child of Node B first.

When we enter the front child of Node B we are passed a polygon list that contains the single polygon c1. This final polygon is selected as the splitter at the new node, creating the Node c1 shown in Figure 16.27. At this point there are no more polygons in the list, so we return from Node c1.

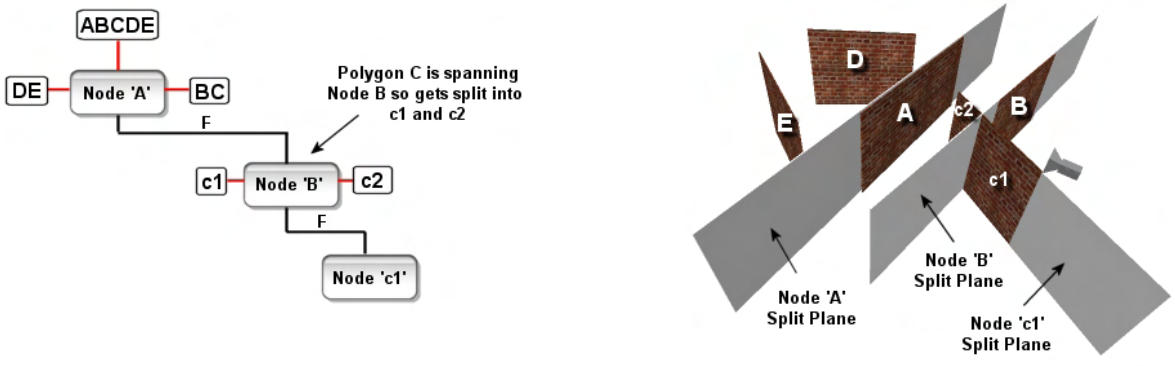

Figure 16.27

After we return from node c1 we find ourselves back at node B having built its front branch. As this node also has a polygon still in its back list (c2), we step into the back child of node B next and build its back tree.

As with node c1, when we step into the back child of B, we are passed a single polygon (c2), so the polygon to use as the split plane at this node is obvious. Polygon c2 is removed from the list and stored in the node labeled c2 in Figure 16.28

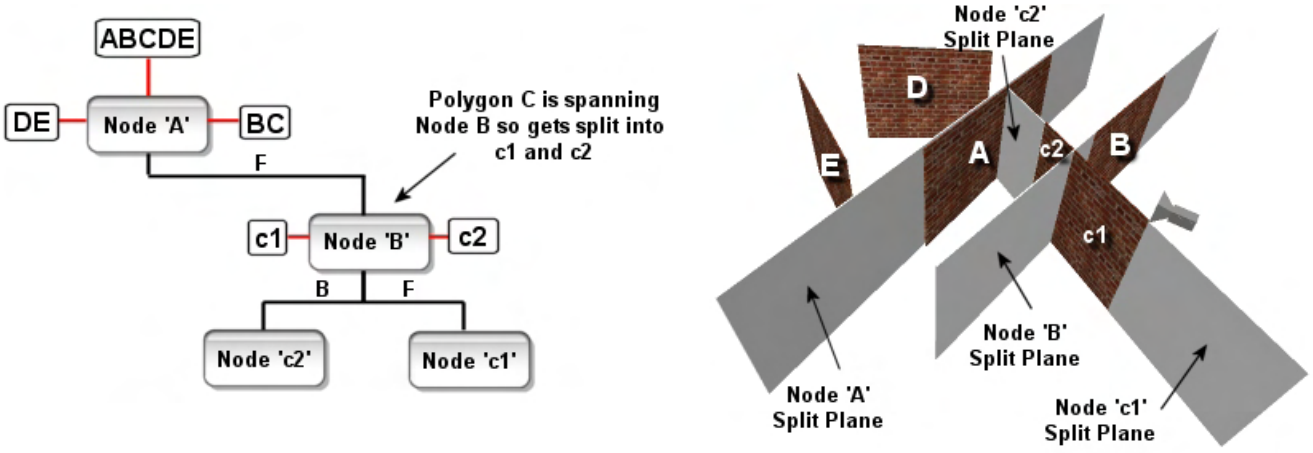

Figure 16.28

After storing the split plane and polygon at Node c2 we know we have reached a terminal node because there are no polygons remaining in the input list. In this case, the recursive procedure returns and program flow steps back up to Node B. At Node B we also realize that we have built its front and back sub-trees at this point, so there is no more work left to do at this node either. Thus, we return from Node B, popping up the tree and back to the root node A. At Node A we have only processed its front sub-tree, so it is now time to recur into its back child with the back list that was compiled at this node. The back list compiled for Node A contained polygons D and E, so these are the polygons that are passed into the newly created back child node of the root. When we step into the back child we are passed polygons D and E and one of them must be removed from the list and used as a splitter. In keeping with our alphabetical scheme, we will assume that polygon D gets selected and stored in the node as shown in Figure 16.29

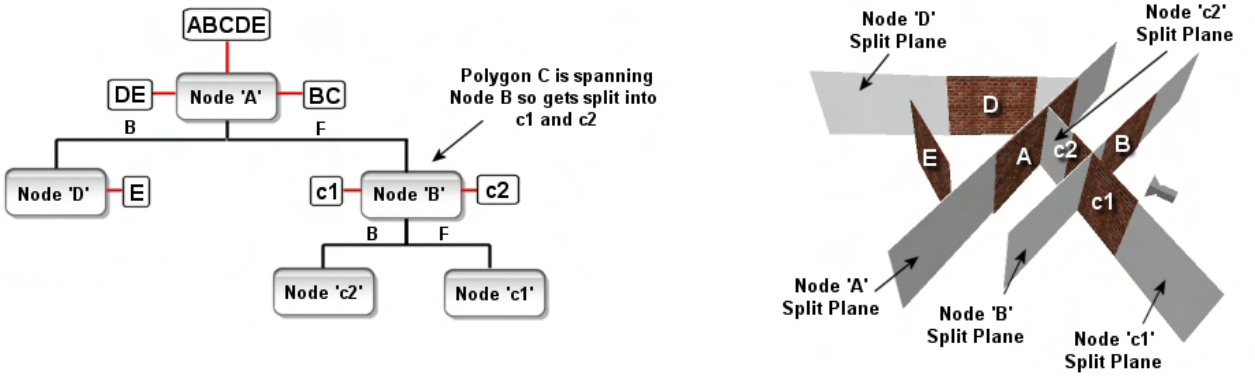

Figure 16.29

After the split plane for polygon D has been stored in the new node (called Node D), the remaining polygons in the list are classified into front and back lists. In this example, only polygon E remains in the list. Since it is found to be in front of Node D, it will be added to the front list. As there is no back

list compiled for Node E we do not have to create a back child node. However, there is still a single polygon in its front list, so we must create a new front child node and step into it.

In the front child of Node D we find only polygon E as its input data, so this becomes the splitter for the final node down this branch of the tree (see Figure 16.30).

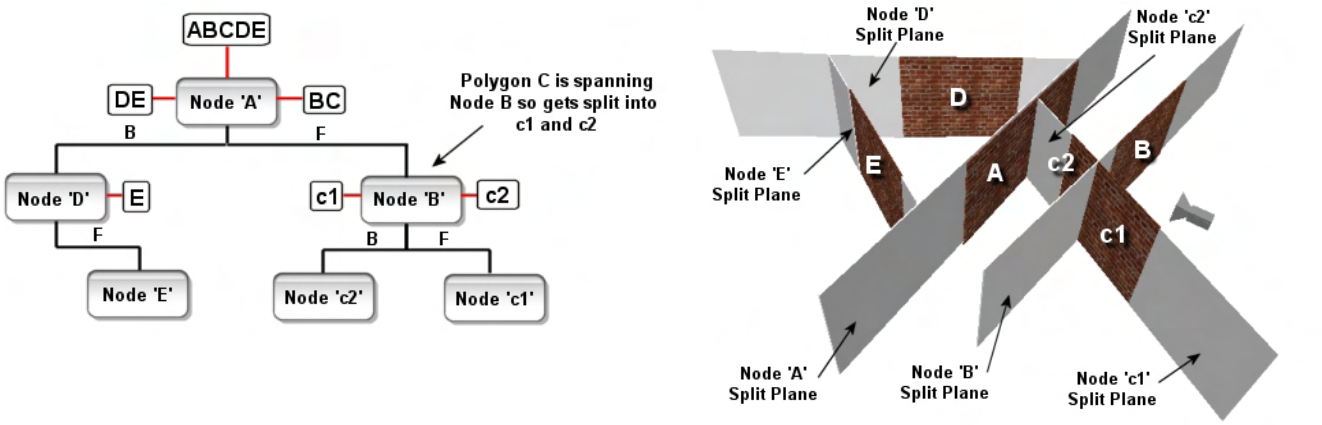

Figure 16.32

We return from Node E back to Node D where, after finding no back child has been created for this node, our task is done and we step back to Node A. When we unwind the call stack all the way back up the back branch of the tree and arrive back at the root node, we find that we have created the front and back trees of the root node and thus built the entire tree. At this point we return from the root node and the build process is complete.

16.2.5 An Overview of the Build Procedure

We have now built a BSP tree that has correctly split overlapping and intersecting polygons so that no rendering order ambiguity exists. It also worth noting that in our example the geometry set did not contain any polygons that shared planes. That is, we did not encounter a situation such that when classifying the polygon list against a node plane, we found a polygon that shares the plane with the node.

In such situations there are several things that can be done and they will all work with varying degrees of efficiency. Below we discuss possible strategies for dealing with the on plane case during the polygon/node classification step.

- You could test the normal of the polygon and add it to the front or back list depending on whether its normal is facing in the same direction as the node plane's normal or not. This would mean that each of the polygons that share the plane will have their own nodes created in the tree. Although this will work fine and still produce a perfectly valid tree, it does mean that we will have several nodes in the tree that essentially describe the same plane. As the BSP tree is being used to ascertain depth order based on view space plane distance, this redundancy is a little pointless. We know for example, that all polygons that share the same plane can be rendered

together since they cannot be occluding each other (they all describe the same depth slice of the scene).

- We could store any polygon that exists on the same plane as the node plane in the node itself, even if the normal of the polygon faces into the opposing halfspace. That way, even if 100 polygons spread throughout the level existed on the same plane (even if facing in opposing directions) only one node would be added to the tree and all 100 polygons would be stored at this node. The problem with this approach is that, because we now have multiple polygons stored at a node which may be facing in opposing directions, we must always render the polygons stored at that node even if the camera position is located in the plane's backspace. We mentioned earlier that during the rendering traversal we only render the data stored at the node if the camera is in front of the node and can thus potentially see the front side of the polygon stored there. However, with this technique, even if the camera is located in the backspace of a node plane, this does not mean that it will not contain polygons that are facing into the backspace. Therefore, we will have to render the polygon list stored there, whether the camera is behind or in front of the plane. This could mean that at a given node we render many back facing polygons that will be back face culled by the pipeline only after they have been needlessly transformed.

- The third option is to use a slight modification of the second strategy discussed above. That is, when we select a polygon whose plane is to become the node splitter, we find any remaining polygons in the list that share the same plane (even if facing in opposing directions) and store them at the node. Where this differs from the previous strategy is that the node structure itself will now have two polygon lists. One list will contain on plane polygons that face in the same direction as the plane and the other will contain the on plane polygons that were found to be facing into its backspace. With this technique, we get the best of both worlds with only a slight adjustment to our rendering strategy. Now, when the camera is located in the frontspace of the plane we only render the list at that node containing the polygons that face in the same direction as the node plane normal. If the camera is located in the backspace, we render only the list of polygons stored at the node that have opposing face normals. This technique is desirable because it means we create only one node in the tree for a given plane even if there are hundreds of polygons located on that plane. The result is a shallower tree that is more efficient to traverse. By storing many polygons at the nodes, we also have the ability to render them with a single call, speeding up rendering. Finally, as we have two lists of polygons stored at the node (of which only one is ever rendered depending on the camera's location with respect to the plane), we automatically perform back face culling with zero overhead.

- This final strategy is a mix of the ones described above and is the one we are going to implement in Lab Project 16.1's BSP tree compiler. We go back to the concept of a node storing just a single polygon list that is only rendered when the camera is in the node's front space. When a node is created and a polygon is removed from the list to create its plane, we will also remove any polygons that share the same plane and have same facing normals. We will store them at the node as discussed. Polygons that are found to be on plane with the node having opposing normals will not be stored at that node -- they will be added to the back list. This means, they will be used later to create additional nodes. That is, a node will contain a list of polygons that share the same plane and are facing in the same direction (the node's front space). These

polygons can all be rendered together when the node is visited and is found to have the camera in its front space.

One might wonder why we decided to opt for the fourth strategy instead of the third, when it seems to create more nodes. In truth, while both techniques provide good performance, our decision was slightly biased because the final strategy is the one that we ***must*** use during the building of a BSP leaf tree (discussed in the next section). Rather than having two different build strategies for the leaf and node trees, we felt that it would be better to unify the processing of the on plane case across BSP tree types. This will also help our transition into the BSP leaf tree discussion.

The following notes demonstrate how the BSP tree we build in Lab Project 16.1 will construct a node.

- Enter Node N.
- Select a polygon from the input list and store its plane at the node.
- For each polygon in the list.
    - Classify polygon against node plane
        - Front : Add to front list.
        - Back : Add to back list.
        - Spanning : Split polygon and add each fragment to front and back lists.
        - On Plane
            - Same facing normal : Store at node.
            - Opposing facing normal : Add to back list.
- If (Front list)
    - Create new front node and attach to current node.
    - Recur into front node passing in the front list of polygons.

- If (Back list)
    - Create new back node for the current node.
    - Recur into back node passing in back list of polygons.
- Return.

If you look at the CBSPNodeTree::Build function in the CBSPNodeTree.cpp source file that ships with Lab Project 16.1, you will see that these are the exact steps taken to construct each node. The source code to the entire class will be explained in the accompanying workbook

We now know how to compile a BSP node tree, and in the last build example we used a slightly more complex set of geometry which had intersecting polygons (or polygons with intersecting planes). The splitting process that occurs in the BSP tree build procedure resolved any ambiguity by clipping polygon C to the plane at Node B, thus creating two separate polygons which no longer span the plane. Let us now look at one final rendering example using the example BSP tree we have just built so that we are sure that we fully understand why the clipping of polygon C during the build process means that we can now calculate a perfect draw order.

Render Example 3

In this example we are using the tree that we used in the last build example. We start off by visiting the root node with the camera. To the left in Figure 16.33 we see our currently compiled BSP tree. The blue dot in this image represents the location of the node we are currently visiting as we step through the traversal. As you can see, the blue dot is currently at the root node since this is the first node we will visit with the camera. Although nothing has been rendered yet, the right hand side of Figure 16.33 shows the node planes that the tree represents and the way in which the space has been carved up. We can also see the location of our camera as currently being in front of nodes B and c1. All node planes in this example are assumed to be oriented in the general direction of the camera. It is this camera location we are now going to traverse the tree with to determine the correct draw order.

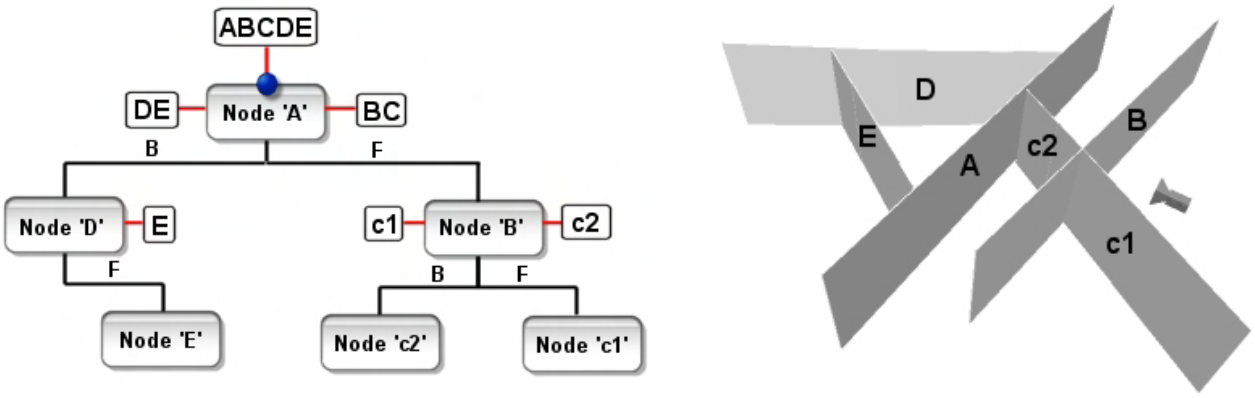

Figure 16.33

At the root node, the camera position is classified against node plane A and is found to be contained in its frontspace. This means we must step down the back of Node A first. When we step down the back of Node A we arrive at Node D (see Figure 16.34).

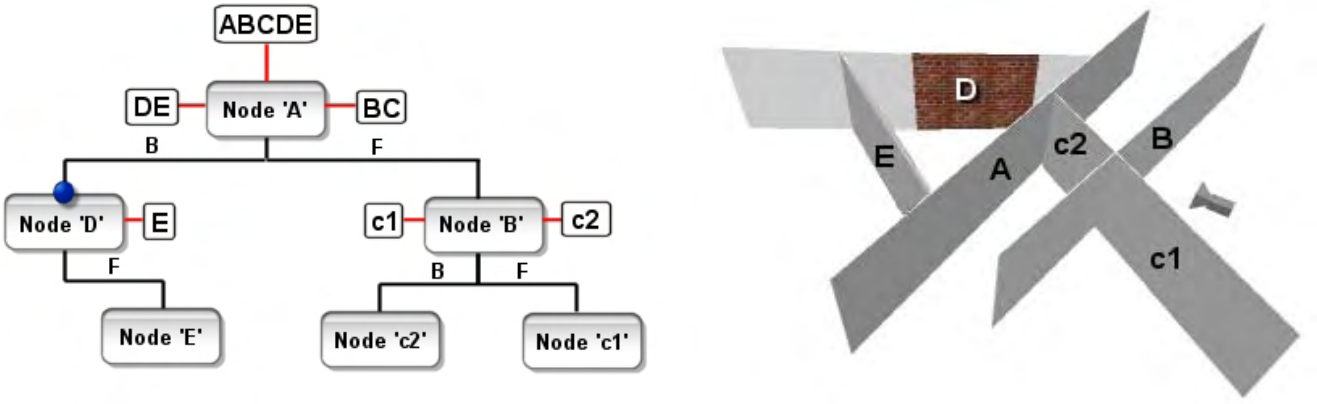

Figure 16.34

At Node D we find that our camera position is located in its frontspace, so we must render its back child first before we render the data stored at Node D. As Node D has no back child, we skip that step and just

render the polygon data stored there. This renders our first polygon so far (polygon D) as shown in Figure 16.34.

After rendering the data stored at Node D, we then step into its front child (E). Here we find a terminal node with no front or back children, so we simply render the polygon stored there, making polygon E the second polygon we render (see Figure 16.35).

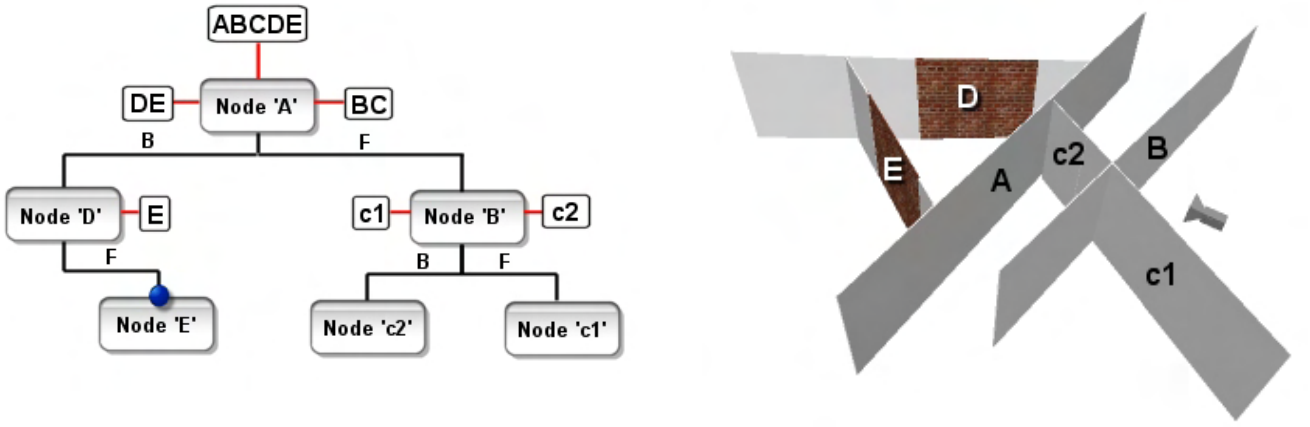

Figure 16.35

After rendering the polygon at Node E we pop back up to Node D and find that we have performed all the tasks necessary to process that node (having rendered its data and traversed its child list), so we return from that node and find ourselves all the way back up at the root node.

At the root node we have currently performed only one of the three tasks we must perform. As the camera was found to be in the node's frontspace we had to traverse into the back child first; we have now done that. The next thing we must do prior to stepping into the front list is render the polygon data stored at this node. This makes polygon A the third polygon to be rendered (see Figure 16.36). As we can see, so far, our scene is rendering in a perfect back to front order with respect to the camera position.

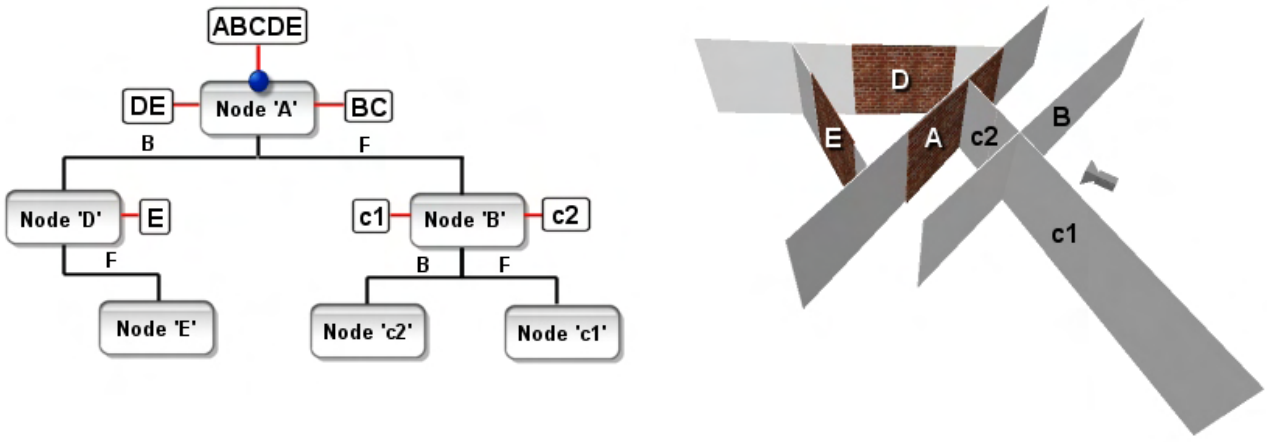

Figure 16.36

At this point we have rendered the data at Node A and should finally step into its front child where we arrive at Node B (see Figure 16.37).

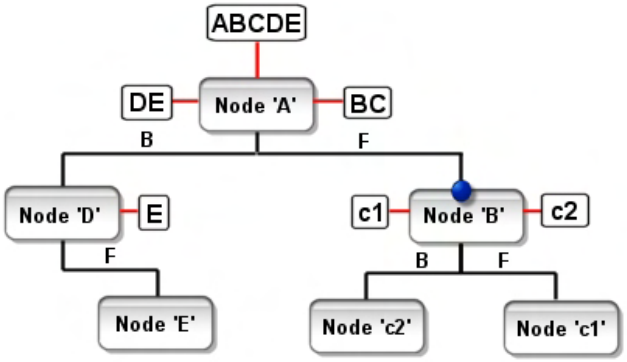

Figure 16.37

At Node B we classify the camera position against its plane and find that it is located in its frontspace. So we must step into its back child first, render the data stored at Node B, and then step into its front child. We step down into the back child of Node B first, where we arrive at Node c2. Node c2 is a terminal node, so there are no children to step into. As we now know, when this is the case we simply render the polygon data stored at the node (polygon c2 in this case).

As Figure 16.38 shows, polygon c2 becomes the fourth polygon we render, and we are still maintaining a perfect back to front draw order. This polygon did not exist in the original dataset sent into the tree; it was created from a larger polygon that originally spanned Node B. We can see now however, that polygon c2 can be perfectly described as being behind Node B.

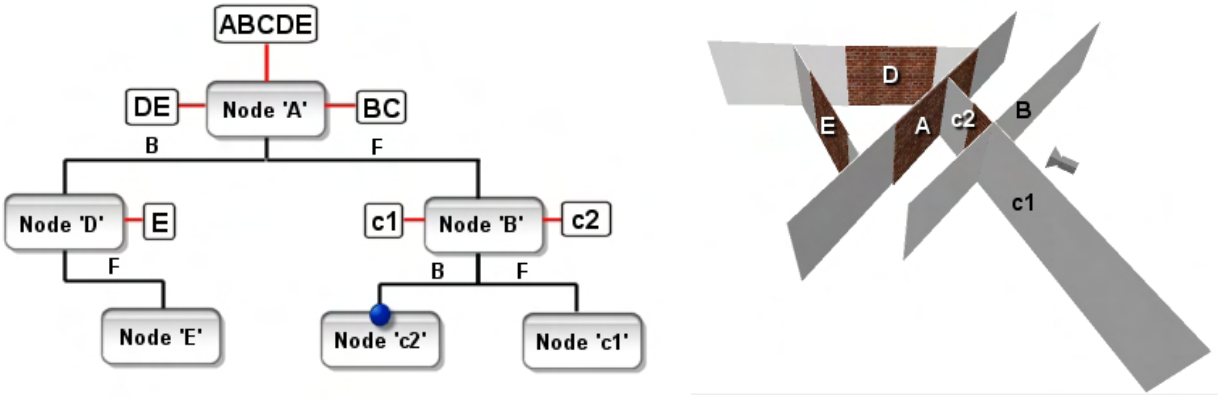

Figure 16.38

With the polygon data at node c2 rendered, we return and find ourselves back at Node B having processed its back child. Now we render the polygon data stored at Node B, which in this example is polygon B. Polygon B becomes the fifth polygon we render (see Figure 16.39).

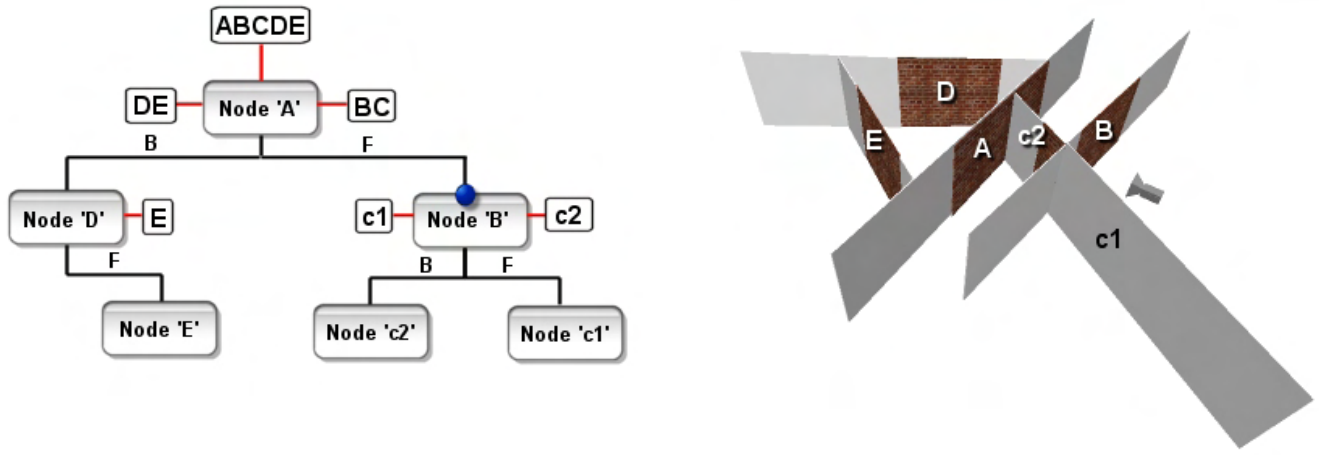

Figure 16.39

Having processed the back child of Node B and having rendered the data contained at Node B, our final task in the processing of Node B is to step into its front child where we arrive at Node c1. Node c1 is a terminal node, so we have to do nothing other than render the polygon data that is stored there. In this example that is polygon c1 (a child split of the original polygon C). This makes c1 the sixth and final polygon to be rendered, as shown in Figure 16.40.

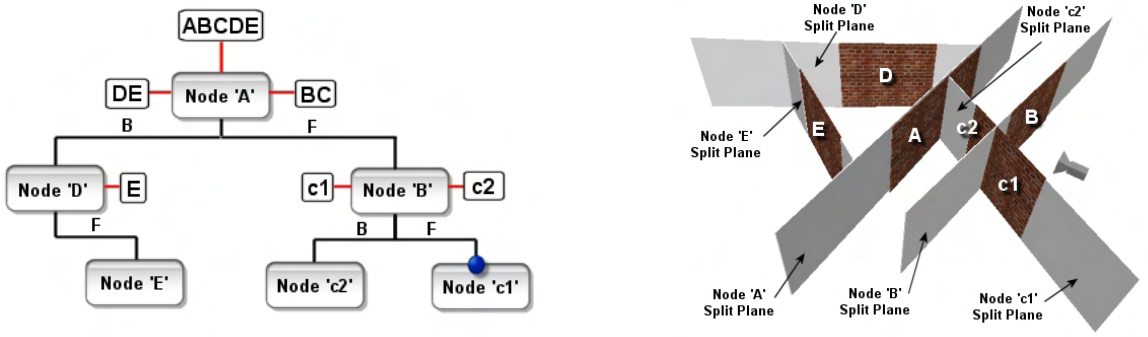

Figure 16.40

So by clipping the polygons to the node planes, we can generate a tree from an arbitrary polygon soup that can always be traversed in a perfect back to front order. This allows us to render polygons correctly such that nearer polygons will occlude more distant ones, even when we have no depth buffer support. While it is very unlikely given modern hardware that we would ever want to render our entire scene's geometry database using this technique, it certainly gives us a good solution for rendering our alpha polygons. This approach will ensure that blending always occurs in the correct order, even if multiple alpha polygons are layered on top of each other from the camera's perspective.

Since we will be building our tree such that on plane polygons that share the same normal direction as the split plane are stored at that node, the logic executed at each node during the rendering traversal is shown below:

- Enter node N
- Classify camera position again node plane
    - In Front or On Plane
        - Step into back child.
        - Render all polygons stored at node N
        - Step into front child
    - Behind or On Plane
        - Step into front child
        - Step into back child
- Return

Your attention is once again directed to the fact that if the camera is behind the current node, then the polygons stored at that node cannot be seen and are not rendered. If the camera position is in front of the plane, or situated on the plane, we render the polygon data.

One topic we have been deliberately steering clear from so far is the selection of a node's polygon as a split plane during the building process. While we can choose any polygon from the list passed into the node as the node's split plane and still get a BSP tree that works perfectly, there are some choices that are better than others when selecting a node's plane from a list of candidate polygons.

16.2.6 Choosing a Split Plane

We know already that our BSP compiler will recursively call itself with sets of polygons and that during iteration it will choose a polygon out of that list to become the splitter for the current node. All of the other polygons are then assigned to front or back lists, which themselves will be split, and so on until every polygon has eventually been chosen as a splitter. The last polygon left in a list will not actually split anything and will be assigned to the terminal node. The question is, during node construction how do we decide which polygon in the list should be used to create the split plane for that node? Is there some set of properties or some heuristic that we should consider to determine a preference?

While we could randomly pick a splitter each time from the list, there are actually some important distinctions that can be made between the candidates. That is, we can categorize polygons as either potentially good splitters or bad ones depending on certain criteria.

Every time we select a new polygon as a node's plane to divide a given subspace, any polygons in the list straddling the split plane (i.e., the splitter polygon's plane) will have to be split into two pieces. If you selected a splitter that intersected every other polygon in the list, all of them would have to be split into two pieces in order to be assigned to the front and back lists of the node. So on your first call to your compiler function you have just *doubled* the polygon count. This is definitely not a desirable outcome. Obviously the process continues as you traverse the new front and back lists and the polygon count (and therefore the node count) might quickly grow to a dangerous level with respect to

maintaining real-time rendering performance. It will also slow down the tree compilation time which, while not as onerous since it is an offline process, still impacts your development schedule.

While this example is a bit extreme, the point is that there are going to be some polygons that do not make great candidates as splitters early on in the tree creation process because they cause too many splits in the remaining dataset. So to build a more optimal BSP tree, we really want to consider candidate polygons that cause the fewest number of splits to occur in the remaining dataset.

Unfortunately, there is no way to build every potential BSP tree that would result from every potential splitter being accounted for at any given level in the tree. The number of permutations we would be talking about is a factorial based on the number of polygons (N!), so this approach is completely out of the question, even on a modern supercomputer. In case you were curious, or are unfamiliar with factorials, a tiny 50 polygon level would have $50! \approx 3x10^{64}$ possible BSP trees that would have to be built and examined for splitter preference.

So we can obviously forget about the possibility of building the perfect BSP tree, and instead settle for a very good one. One solution which gives good results is the following:

Each time we create a new node during the build process we will loop through each polygon in the list and process it. By 'processing' it, we mean that we will take its plane and test every other polygon in the list against it and record the number of polygons in the list that span that plane and would need to be split *if* the current candidate was used as the split plane. Whenever a polygon is processed which causes fewer splits than the previous minimum, we record the polygon and the split count. After every polygon in the list has been tested for a given node, we will have found the polygon in the list that will cause the fewest splits in the remaining dataset at that node and therefore is a great choice for the node's split plane. The process of polygon selection for a node's split plane is shown below. We might imagine that this is wrapped in a function called SelectBestSplitter which can be called by the node to select a splitter from its passed polygon list.

- Best Score = Infinitely High
- For each polygon in list A
    - Score = Splits = 0;
    - For each polygon in list B
        - Polygon B[*i*]->ClassifyPlane(Polygon A->Plane)
        - If (Spanning) Splits++
    - End for loop B
    - Score = Splits
    - if (Score < BestScore)
        - BestScore = Score;
        - pSelectedFace = Polygon A

- End for loop A
- Return pSelectedFace

As you can see, we first set the Best Score variable to a very high number. We will use this variable to search for the polygon that gets the lowest score (i.e., fewest splits) when tested as a split plane. We then loop through the polygons. The outer loop tracks the polygon being used as the split plane candidate. Inside this loop we set the current split count and score for this polygon to zero as we have not tested it against the other polygons yet. We then loop through every polygon in the list and classify it against the plane of polygon A. If polygon B spans polygon A then we know that choosing A as the splitter will cause this polygon (B) to be split, so we increase the split count. At the end of the inner loop we have tested every polygon (B) against the current split plane candidate (A) and have stored (in the variable Score) the total number of polygons that will get split immediately if this polygon is chosen as the split plane for the current node being constructed. If this score is lower than the best score we have recorded so far (for other polygons in the A loop) we record the score and the polygon which generated it. At this point we have stored the polygon which has generated the lowest number of splits so far. Once the outer loop has completed, every polygon in the list will have been tested as a split plane candidate and pSelectedFace will store the polygon that the current node should use as the splitter.

Although at first this might sound like the perfect tree compilation algorithm, keep in mind that choosing a splitter that causes very few splits at one level (node) of the tree could actually cause more splits further down the tree than might have been the case had we chosen a splitter which had initially split more polygons higher up in the tree. While we are content to work with this less than perfect approach to splitter selection, there is one other concept which we can factor into our choice of splitter, which is not new to us.

Although choosing a polygon that creates the fewest splits is arguably the most important criteria in splitter selection, there is also tree balance to consider. A perfectly balanced BSP tree (which is almost impossible to create without excessive splitting) is one with exactly the same number of nodes in both the back and front branches of the root (i.e., an even distribution of nodes). We discussed in the previous lessons the benefit of having a balanced tree and how it helps to achieve shallower trees and maintain consistent traversal times. Sometimes frame rate consistency is more important than pure speed. For example it is better to have a game engine run at 30fps consistently throughout the level than have it run at 90fps in some places and drop to 7fps in others. This is where tree balance becomes a factor.

Unfortunately, the downside to balancing a BSP tree is often the creation of more splits in the list. So we are going to have to find some middle ground here and adjust our split plane selection logic to also factor in the tree imbalance that will be introduced by choosing a particular polygon. As our split plane selection logic essentially has to classify every polygon against the candidate plane to record the number of splits, it is a small step to also record the number of polygons that are found to be completely in front or completely behind the candidate plane. If a candidate plane has the same number of polygons in its front list as in its back list, it means that the node splits its space in a perfectly balanced manner. The larger the disparity between the front and back face counts, the more imbalanced the node (and most likely the entire tree) will be. Therefore, we might imagine that the score for a given candidate polygon

would be the sum of the number of splits it creates and the absolute difference between the number of polygons found to be contained in both its halfspaces. This would make our polygon score calculation:

Score = abs(frontfaces - backfaces) + splits

So we will subtract the number of back faces from the number of front faces and take the absolute value. We then add to that the number of splits, giving us a score for the polygon that will be at its lowest when the polygon creates a perfectly balanced partition (frontfaces=backfaces) and causes no splits.

We are almost there, except that at the moment we are probably not giving enough influence to the number of splits. In most cases, reducing the number of splits will be our primary goal, so we will need a way of letting the selection process know that we would like to place more weight on the split count than on the imbalance score. Therefore, our SelectBestSplitter function will also take a split heuristic (a weight value) parameter which is multiplied by the split count to create the score for each candidate plane:

Score = abs(frontfaces - backfaces) + (splits * SplitHeuristic)

As you can see we now multiply the split count by the passed split heuristic so that we can give more or less priority to reducing splits by passing a higher or lower split heuristic value respectively.

Our new version of the SelectBestSplitter function will loop through the list of polygons passed in, choose a different candidate split plane each time and then test it against the rest of the polygons in the list. Each time a splitter has been considered, we will end up with the number of splits it caused and the number of front and back polygons that would end up in the front and back lists of the respective node. We can then calculate our score using the above formula. If the score is lower than any previous score we encountered during this call then we will keep track of this polygon. When the function ends, it will return a pointer to the polygon in the list with the lowest score. This polygon can then be used by the node to create its split plane.

- Parameter = “Split Heuristic” (single weight value)
- Best Score = Infinitely High
- For each polygon in list ‘A’
  - Score = Splits = Back Faces = Front Faces = 0;
  - For each polygon in list ‘B’
    - Polygon ‘B’->ClassifyPlane(Polygon A->Plane)
    - In Front :
      - Front Faces ++
    - Behind :
      - Back Faces ++
    - Spanning :
      - Splits++
  - End for loop ‘B’

    - Score = abs(Front Faces + Back Faces) + (Splits*Split Heuristic)

    - if (Score < BestScore)
        - BestScore = Score;
        - pSelectedFace = Polygon A;

- End for loop A

- Return pSelected

The logic to the code shown above is contained inside the CBSPNodeTree::SelectBestSplitter method in Lab Project 16.1. We will cover the actual source code to the BSP compiler to Lab Project 16.1 in the accompanying workbook.

16.2.7 BSP Node Trees Conclusion

We have now completed our introduction to the standard BSP node tree, using polygon-aligned planes to carve the geometry into pieces that can be rendered in a perfect back to front order. Although the node tree is the simplest of the BSP tree incarnations, you will be pleased to know that the leaf tree we develop in the next section is essentially exactly the same tree. The only real difference is some extra logic introduced during the build phase to collect convex clumps of polygons at the terminal nodes of the tree.

Covering the BSP node tree first was a good way to ease ourselves into the subject matter that we will need to explore both in this lesson and in the following lesson. However, let us not write off the BSP node compiler as simply an academic exercise with no real world application. Indeed, as we have discovered, even on today's latest cutting edge hardware, alpha polygons must be rendered in a back to front order to maintain proper blending. The BSP node tree is now going to be our tool of choice for handling alpha polygons. There are many other areas where BSP node trees can be used, such as in the realm of texture consolidation (efficiently packing multiple images onto a single texture surface). Also keep in mind that many applications it has in the area of geometry repair and constructive solid geometry.

Before moving on to the next BSP tree type, now would be a good time to open up the source code for Lab Project 16.1 and examine (along with the accompanying workbook) the node based BSP tree compiler.

16.3 Introducing BSP Leaf Trees

In this section we will examine a slight variation of the BSP tree building technique which will allow us to introduce leaves into our BSP tree. The BSP leaf tree is actually a lot more like the trees we have built in previous lessons because the polygons are not stored at the individual nodes but are passed down the tree during the build process and collected at the terminal nodes (i.e., the leaf nodes) of the tree. This is much more akin to the strategy used to build the quad-tree, oct-tree and kD-tree in the previous lessons. Although it may seem like we would now have to examine another form of tree, the good news is that this is not the case. Whether we build a leaf tree or a node tree, the tree itself is constructed in exactly the same way with respect to how the node planes are selected and the way that the space of the scene is subdivided. In fact, one might say that our node tree already has leaves; we are just not using them for anything yet. Closer examination of the BSP node tree that we constructed in the previous section will highlight the fact that although we decided to store the polygons in the nodes of the tree, the planes of the BSP tree still carve the scene into convex areas which can be navigated to by traversing the tree to the terminal nodes. Unlike the other leaf trees we have constructed however (quad-tree, oct-tree and kD-tree), the leaves of the BSP are not axis aligned bounding boxes, but are arbitrary convex regions bounded by the node planes which intersect to form that region. Yet just like any of our previous tree types, we can send objects or polygons down the tree and assign them to the terminal nodes in which they are eventually found to reside. We will see that these terminal nodes represent a convex region of the scene and what is considered to be a ‘leaf’.

This all sounds a little abstract at the moment, so let us take the node tree that we looked at in the previous section and examine what would be involved in turning it into a leaf tree. Figure 16.41 shows the BSP node tree we constructed in the previous section.

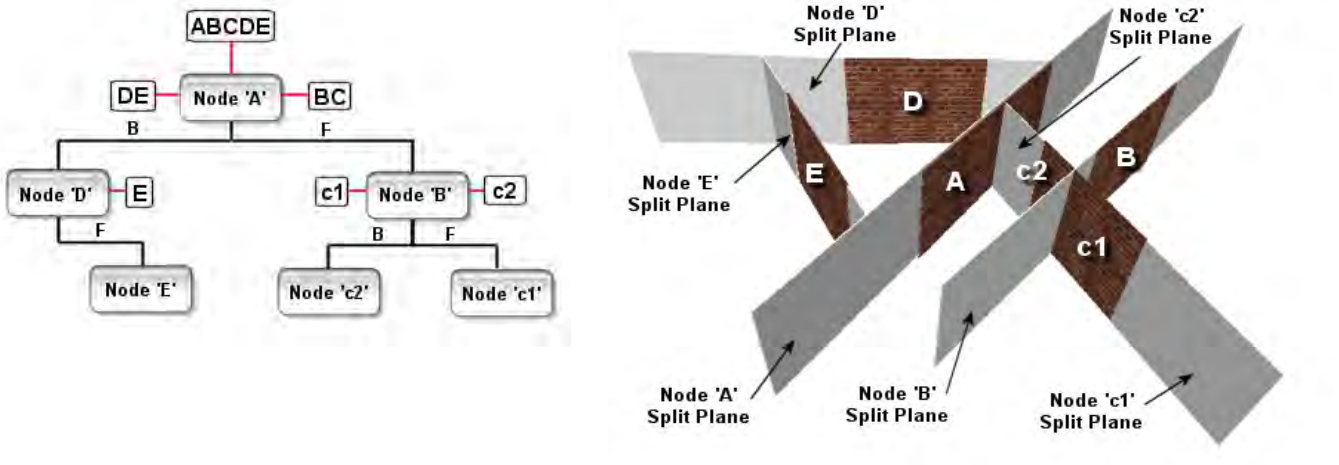

Figure 16.41

The node tree is referred to by its name simply because the polygons are stored at the nodes. Recall that this was done to solve a very specific problem related to alpha sorting. By realizing that the planes of the tree could be traversed in a back to front order and that the planes themselves were created from the polygons, every polygon in the scene will lay on one of these planes. It is logical to assume then, that we

can render the polygons in a perfect back to front order by storing them at the nodes they helped create and render them when those nodes are visited during an ordered walk of the tree. This is obviously a very useful strategy to use when perfect back to front order rendering is required. However, it would be extremely inefficient to also store our non-alpha polygons in this way due to the fact that we essentially process one polygon at a time. It would be much nicer to have a BSP tree at our disposal which works much like the quad-tree for example, where the polygons are collected at the leaf nodes and can be rendered in a batch when the leaf is found to be visible. Furthermore, although we already have trees at our disposal that allow us to do just this, you will see later that the leaf BSP tree will become one of the most important technologies we will implement in this course as it will allow us to construct potential visibility sets, do hidden surface removal, and perform a host of other really useful and essential tasks. Therefore, while the BSP leaf tree may seem like just another leaf tree (which it is), we will see later that because the polygon data is used to construct the node split planes, the tree is built with very important information about which areas of the scene are considered to be empty space and which areas are considered to be solid space. This is the only spatial tree we have covered so far that provides us with this information. This is precisely the information we will need in the following lesson to build a potential visibility set compiler for our scene data and accelerate rendering by an order of magnitude.

To understand where the leaves are located in a BSP tree and what they represent we will first highlight the similarities between the BSP tree and the other tree types. For example, we know that we can build an empty quad-tree by simply dividing empty space and assigning no polygon data to it. The result is a tree of empty bounding boxes. Such a technique can be useful if a game uses purely dynamic objects and would like to benefit from hierarchical spatial partitioning. The quad-tree starts with a large root node bounding box and subdivides that box down to a certain level. When the tree has finally been constructed, there are no polygons stored in the tree, but the leaves are still there -- they are just empty. We still have the ability to traverse the tree and find visible leaves and we will still have the ability to send volumes down the tree and assign them to the leaf nodes in which they are found to reside. The same is essentially true with our BSP node tree. That is, we have subdivided the scene into convex areas using a series of planes and as such, navigating to the terminal nodes allows us to describe ourselves as being in one of those areas. In the case of the node tree, we are just choosing to store nothing at the terminal nodes that represent those areas. Therefore, although the node tree did not store any polygon data in the leaves of the tree, the leaves still exist and are implied by the nature of spatial partitioning.

Let us imagine that we decide to build the same node tree illustrated in Figure 16.41 but decided not to store the polygons at the nodes. We will simply discard them after they have been used to create a node plane (along with any co-planar/same facing polygons). That is, after a polygon has been selected as a splitter and used to create a node plane, that polygon, along with any others that are co-planar and same facing, are deleted from the list and are never considered again during tree creation. The result would be an empty BSP tree just like that empty quad-tree we just discussed. The polygon data passed into the tree in this example was simply used to determine which split plane to use at each node. In fact, one can imagine how the BSP compiler could even be modified **not** to take a list of polygons but instead a list of planes in such a scenario. The resulting tree would be the same (see Figure 16.42). The only difference now is that we have not stored the polygons at the nodes. We have an empty BSP tree just like that empty quad-tree we discussed above, just carving up space using a different set of criteria.

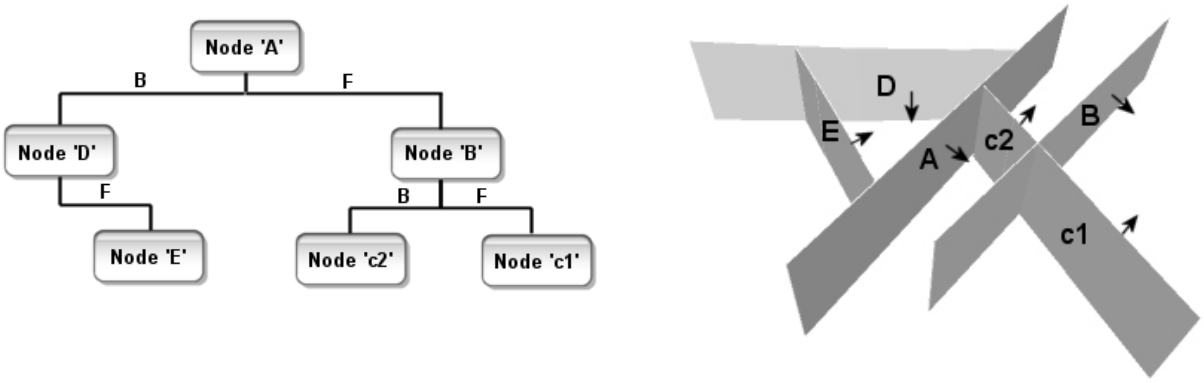

Figure 16.42

In Figure 16.42 the plane normals are shown as the black arrows in the rightmost image so that we can see the direction in which the planes are facing. When looking at the rightmost image and remembering that planes are infinite we can see that the planes divide the scene up into a series of convex areas.

> **Note:** Although planes are technically mathematically infinite, when drawing the planes of a BSP tree, the planes only carve up to the parent node space. This is because the plane is only used to carve up the designated halfspace of the parent node. Node D for example is assumed to carry on infinitely to the right of the image but stops at node A because it was selected to only partition node A's back space.

We will examine why using the polygon planes as the node planes of the tree divides the scene into a series of convex areas a little later, but for now just know that this is the case. For example, we can see that planes A, D, and E bound a triangular region of the scene. This region exists behind node A, in front of node D and in front of node E. Therefore, we can see from the tree diagram on the left hand side of this image, that if an object is found to be in front of node E during a tree traversal, it must be in this area and therefore, this area is the front leaf of node E. What structure we use to represent this area is not important for the moment (we might imagine that we use a structure that can contain a list of polygons and dynamic objects that have been passed through the tree and found to exist in that area). Furthermore, we can also see that if an object was found to be in front of node c2, it is obviously in the area of space bounded by planes A, c2, and B labeled 'leaf 3' in Figure 16.43 since node planes A and B were also navigated to reach node c2.

The conclusion we can draw from this discussion is that every terminal node in our tree is a plane which has a region down both its front and back sides. That is, each terminal node has a back leaf and a front leaf which represents one of the areas making up the scene. In fact, a leaf exists wherever a node has no front or back child. In this instance, we are referring to a leaf as a region of the scene that is bounded by the planes that have been traversed to reach that area of the tree. In Figure 16.43 we have color coded

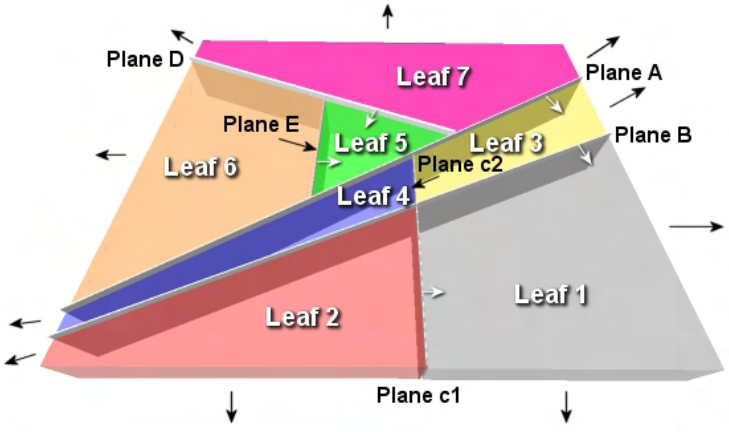

Figure 16.43

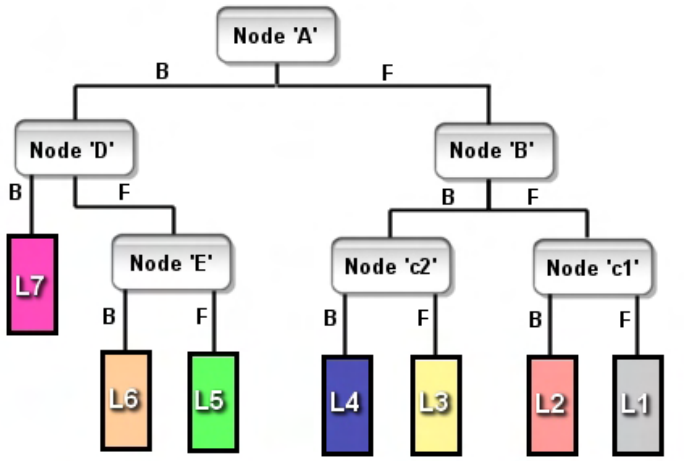
the convex areas of the scene and have also illustrated in the accompanying tree diagram where these areas exist.

Looking at the tree diagram for Figure 16.43 we can see that we have added leaves to the tree where a node has no front and back child node. To be clear, these leaves (labeled L1 to L7) are all empty and are labeled here to illustrate which area of the scene is reached by stepping down the front or back of a childless node. The boxes in the tree diagram might represent a leaf structure where polygons and dynamic objects are stored. The important point being made here is simply that whenever we step down the side of a node and it has no child node, we are in a leaf. This is a convex area described and bounded by the planes above it in the tree.



> **Note:** The leaves L1 through L7 could be represented as simple structures used to contain any objects or polygons that get assigned to that area. The important point is that we recognize this is really no different in principle from the node tree. The tree is exactly the same and the regions represented by these leaves always existed, the only difference now is that we are assuming the use of a leaf structure to catch and store any objects that get passed down the tree and eventually end up getting passed down the front or back of a node for which no child node exists.

Study the diagram and try out some test traversals of your own to see if you understand why the leaves are located in the tree in the locations that they are. Do not worry if you are still finding this a little confusing, we will step through some examples.

Figure 16.43 shows us that the BSP tree carves the scene up into regions that we call leaves and as such, is not unlike the quad-tree, oct-tree and kD-trees that we built in previous lessons. There are two big differences: First, a leaf is no longer an axis aligned bounding box, but is defined by the planes that bound the region (the planes above it in the tree). Second, not all leaves are fully surrounded by planes and as such, are assumed to carry in infinitely in the unbounded direction (this is only true for exterior leaves). In our simple example scene, all leaves except leaf 5 are exterior leaves, as they exist around the exterior of the scene. For example, we can determine the exact volume of leaf 5 since it is fully bounded by planes A, D and E. These are the parent planes of the leaf that need to be traversed in order to make it into that region. However, leaf 6 which is located behind node E is only bounded by planes on three sides and is therefore assumed to have infinite volume to the right of the image. We can also see that leaf 1 would also continue infinitely down and to the right of the image as the leaf is only bounded by planes on its left and top sides.

Let us now use some example locations which we will send through the tree and test that our theory is correct. In Figure 16.44 we have placed a red sphere in a region of the scene that visually places it in leaf 3. That is, it is located behind plane B and in front of planes A and c2. We might imagine that this red sphere represents the position of our camera in the scene and we would like to know in which leaf within the BSP tree it is currently located so that we can render any dynamic objects that have also been assigned to that leaf (the structure attached to the front of node c2). Finding what leaf a given position vector is in is no different from the kD-tree case. We simply send it down the tree starting at the root node and classify it against each node plane we visit, sending it down the front or back of the node depending on the result. Figure 16.45 shows us sending the query position shown in Figure 16.44 through our BSP tree.

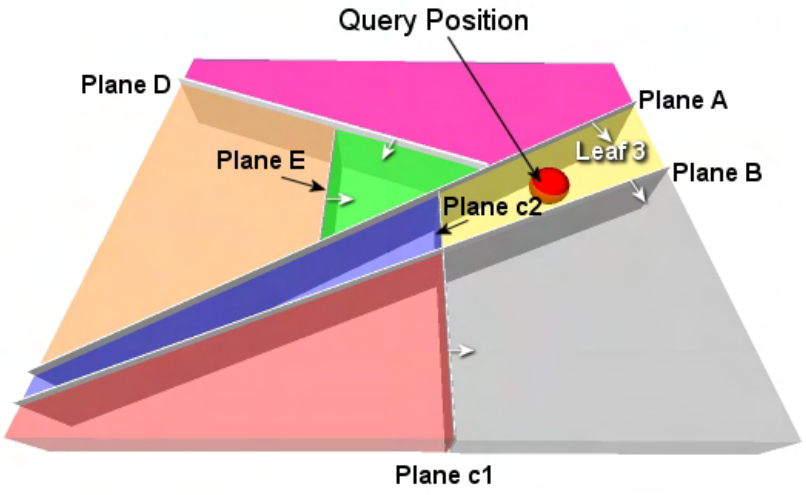


Figure 16.44

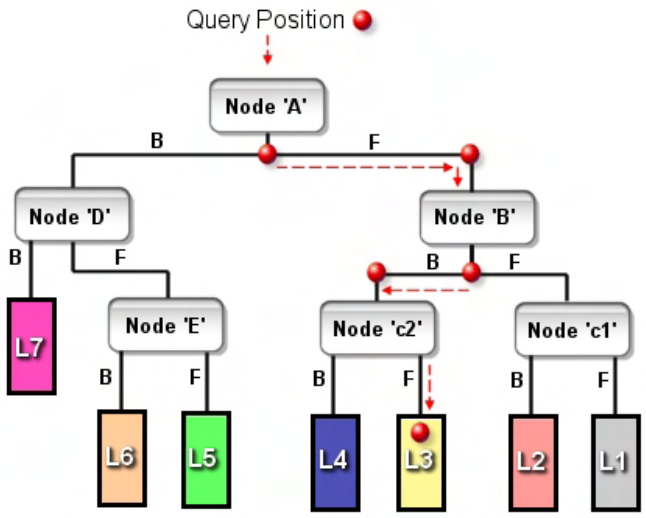

Figure 16.45

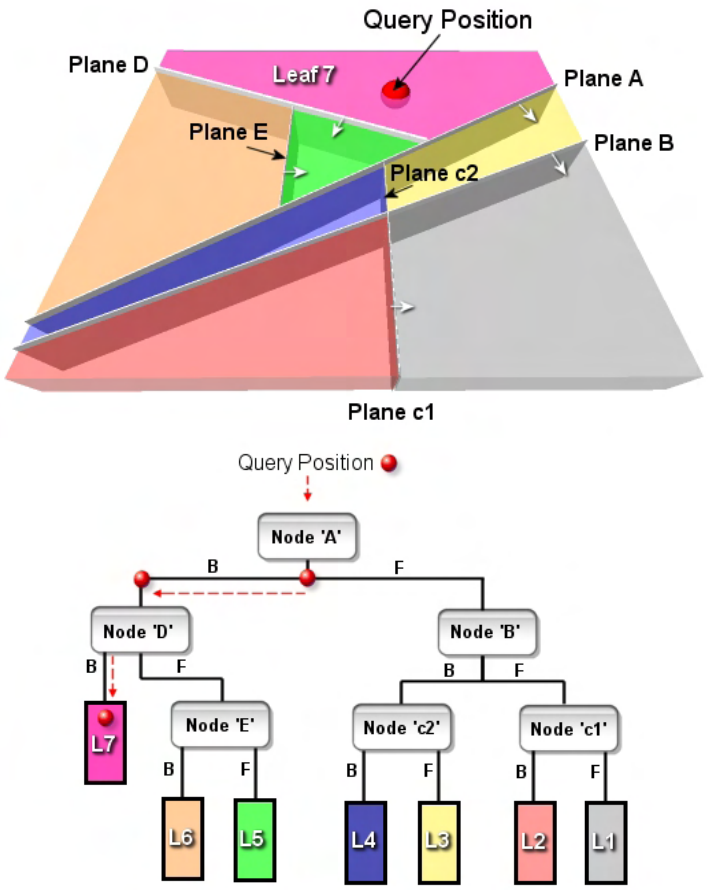
In Figure 16.45 we show the position in Figure 16.44 being passed through the tree. You should reference both of these images during this next examination of the traversal process.

At node A we classify the query position against the node and find that it is in front of plane A (as can be seen in Figure 16.44), therefore, it is passed down the front of A where it reaches node B. At node B the query position is found to be behind the plane stored there and is passed down the back of node B where it enters node c2. At node c2 the classification is performed once again and this time the query position is found to be located in the front halfspace of the terminal node c2 which places it in leaf 3, the region of space bounded by planes A, B, and c2. Leaf L3 might be a structure that contains all the polygon data that has been passed down the tree and clipped to the nodes and found to reside in c2's front halfspace. These polygons would also need to be rendered if leaf 3 was found to exist inside the view frustum.

In Figure 16.46 we see another example of traversing the BSP tree with a query position and further solidify our understanding of the regions of space represented by the leaves of the BSP tree.



The query position is shown in Figure 16.46 to exist in leaf 7. Looking at the topmost image we can see that this is a region of space that is bounded by planes A and D. It is located behind both of these planes. Thus, if we know that a given position is located behind planes A and plane D then it must be in the region of space we have labeled leaf 7. We can see that this is the case in the topmost image and furthermore, can see in the bottommost image that when we traverse the BSP tree with this query position, these are exactly the tests that are performed. The query position is fed in at the root node where it is found to be located behind node plane A. Because of this, it is passed down the back tree of A where it reaches node D. The query position is once again classified against node D where it is found to lay behind that node also. As node D has no back child we know that this is the end of the road and we have reached the convex area that we have labeled leaf 7. Finally, we will show one more example where the query position is located in leaf 5 accompanied by the tree diagram that shows the query position being passed down the tree. Eventually we will pop out in the front space of node E.

Figure 16.46

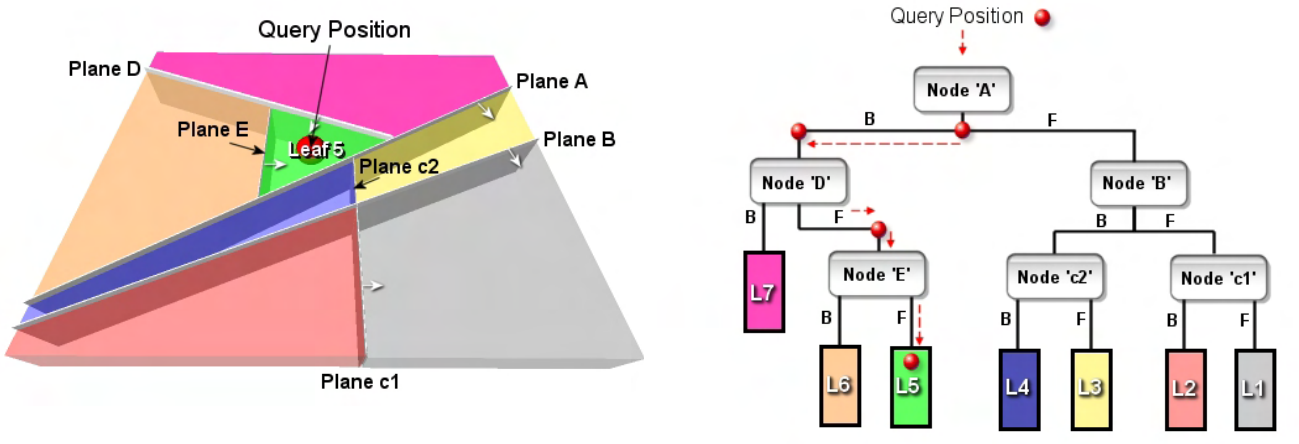


Figure 16.47

When we look at the rightmost image in Figure 16.47 we can see that if we were to describe this position in English we would say that it is in the region of space behind plane A and in front of planes E and D. However, notice that in the rightmost image this is exactly what we are doing when we traverse the BSP tree. We are testing the query position against these planes of the tree and eventually find that our query position is located in front of node E, in front of node D and behind node A.

16.3.1 Populating the BSP Leaf Tree

Now that we understand where the leaves of the BSP tree exist and what areas they represent, it is the next logical step to determine how we would compile the leaf tree and collect the polygon data at the leaves of the tree instead of storing them at the nodes. Before we look at how to modify the BSP build process to collect the polygons at the leaf nodes during the compile process, we will first perform the polygon population of the tree in a separate pass. This will give us the opportunity to become more familiar with the rules of passing polygons down the BSP tree before we merge this polygon passing and collection logic into the core build process. Therefore, in these next examples we will assume that the BSP tree was built as in our previous example and is an empty tree initially. That is, during tree construction, after a polygon was used as a splitter, it was simply deleted from the list and considered no further. As we saw in the previous section, this creates a tree of separating planes only. Once we have this tree we will then send the polygons that were used to create the tree into the root node one at a time and will track their progress as they descend through the tree into the leaf nodes in which they belong. This will demonstrate the polygon passing logic that we will eventually merge into the core build process.

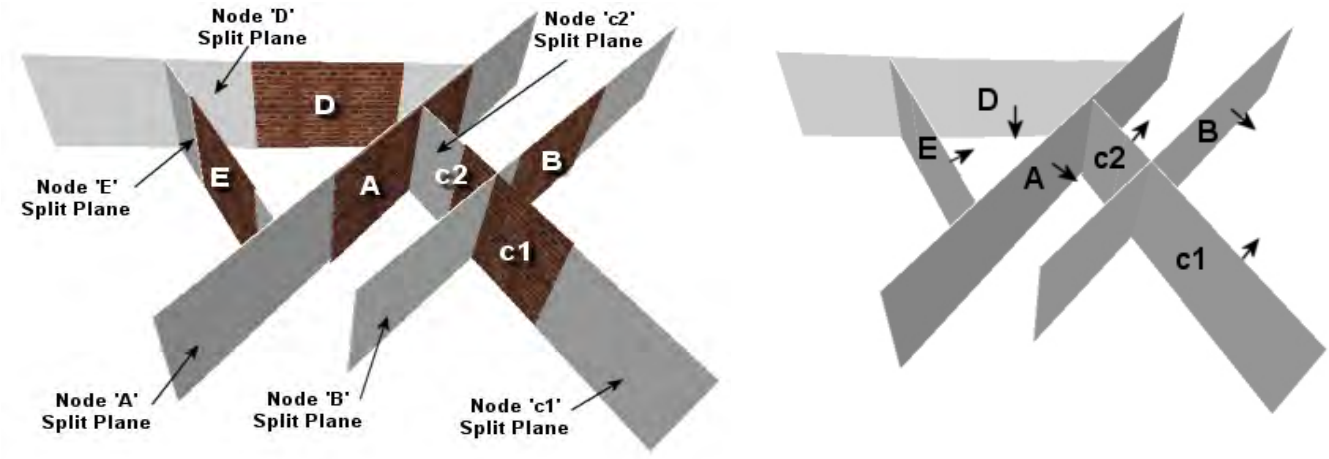

Figure 16.48

The leftmost image shows the polygons that were initially passed into the tree and also shows the node plane created by each. The rightmost image shows the BSP tree after compilation with no polygon data assigned to it. As you can see however, the polygon data was still used to determine the node planes to be used.

Assuming that our tree has been constructed as shown above, what we will now do in a second pass is loop through polygons A through E and send each one down the tree starting at the root node. At each

node, the polygon will be classified against the plane and sent down the front or back child depending on the classification result. If a polygon is found to be spanning a node plane then it will be split by that plane and the two child fragments dispatched down the front and back of that node respectively. If the polygon is found to lie on the plane and face in the same direction as the node plane it will be passed down the front of the node, if it is co-planar but faces in the opposite direction to the node plane it will be passed down the back of the node.

> **Note**: Later in this lesson we will learn why dealing with the co-planar classification case as described above is so important. With the leaf tree, we must pass co-planar same-facing polygons down the front of a node and co-planar opposite-facing polygons down the back of a node. Take this on face value for the time being as the reason for this will not become clear until we wish to exploit the solid/empty space determination properties of the tree. However, if we do not handle co-planar polygons in this exact way, we will lose the ability to query the solid/empty space properties of the geometry stored within the tree.

Figure 16.49 shows us that polygon A will be the first to be passed down the tree. Figure 16.50 shows the journey of this polygon through the tree where it eventually gets clipped into two fragments that exist in leaves 3 and 4 respectively. The first plane it is tested against is node A. As it is co-planar with this plane and pointing into the same frontspace, it is passed down the front to node B. It is found to lie behind node B so is passed down the back to node c2. Polygon A spans node c2 so is split into polygon fragments a1 and a2 and the original polygon A is deleted. Polygons a1 and a2 are passed down the front and back of node c2 respectively. The two fragments end up in leaves 3 and 4.

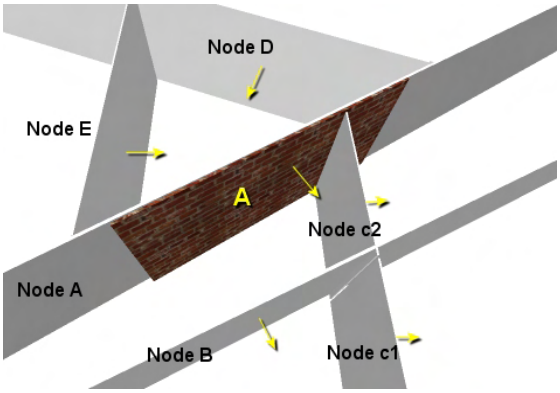

Figure 16.49

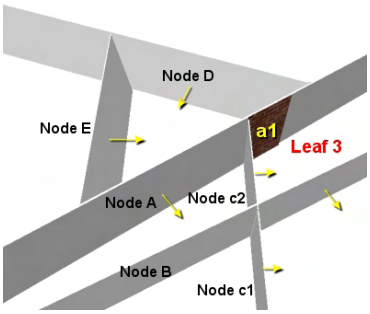

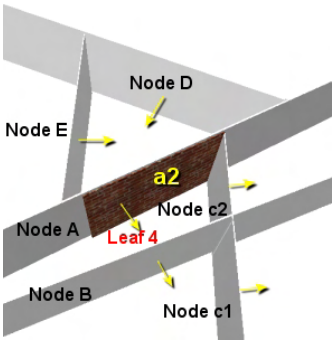

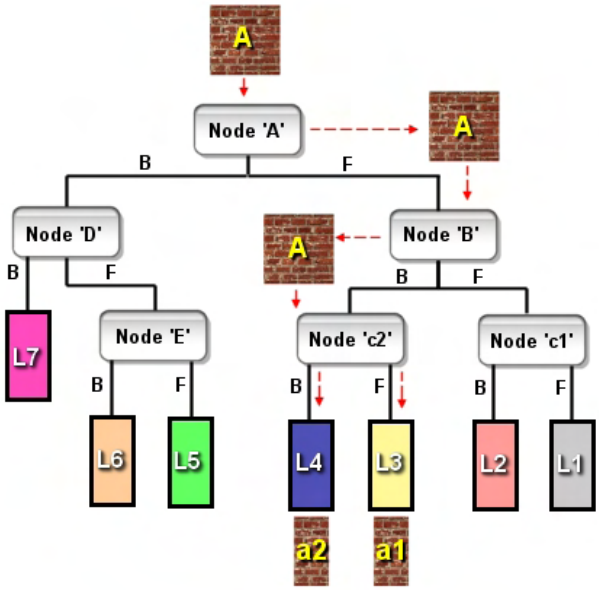

Figure 16.50

At this point then, we have two polygons stored in our tree, a1 and a2, which were both originally created from polygon A. These polygons will have been added to leaves L3 and L4. Next we send polygon B through the tree. Its journey is shown in Figure 16.51 where we see that it ends up in leaf 1.

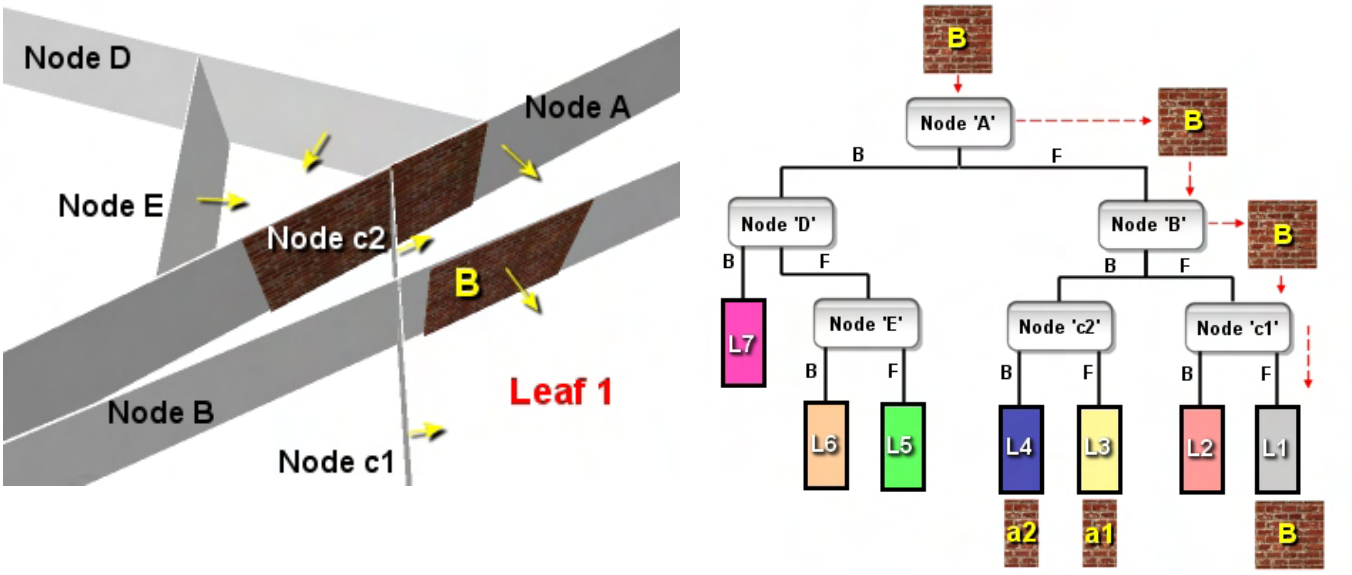

Figure 16.51

We would like to draw your attention to a very important trait of the BSP tree which we are already starting to see manifest itself, even with the two polygons that we have added to the tree thus far. In the quad-tree, the oct-tree and kD-tree, although the leaf nodes represented convex regions within the scene (in these instances the region was an axis aligned bounding box), the polygons were assigned to these regions as a soup. That is, the leaf nodes contained a soup of polygons which filled up the space of the leaf node to some extent. However, this is not the case with the BSP tree.

Because the polygons themselves are used to create the split planes we know for a fact that every polygon in the tree will lay on one of those node planes. As we also know that the node planes always form the boundary of one or more leaves, it stands to reason that the polygons assigned to a leaf will actually bound the region represented by that leaf and will not be contained in the middle of the leaf's space. We can clearly see that this is the case in all of our diagrams to date. In Figure 16.51 for example, we can see that although polygon B was assigned to leaf 1 (the leaf it faces into), it is located on the boundary plane of that leaf. This is a very important point to bear in mind as we go forward.

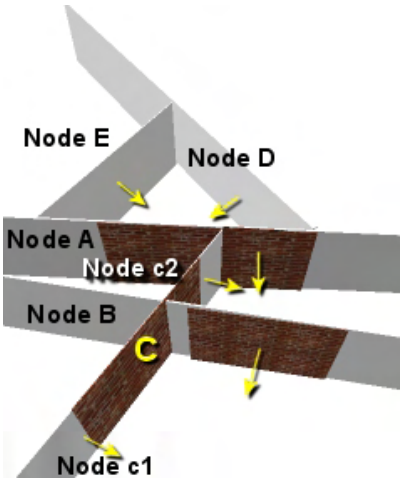

Figure 16.52

In the next example we will feed polygon C into the BSP tree. The original polygon C is shown in Figure 16.52 and we can already see that it will be split into two fragments and will therefore live in two leaves. Figure 16.53 shows the polygon's journey through the BSP tree.

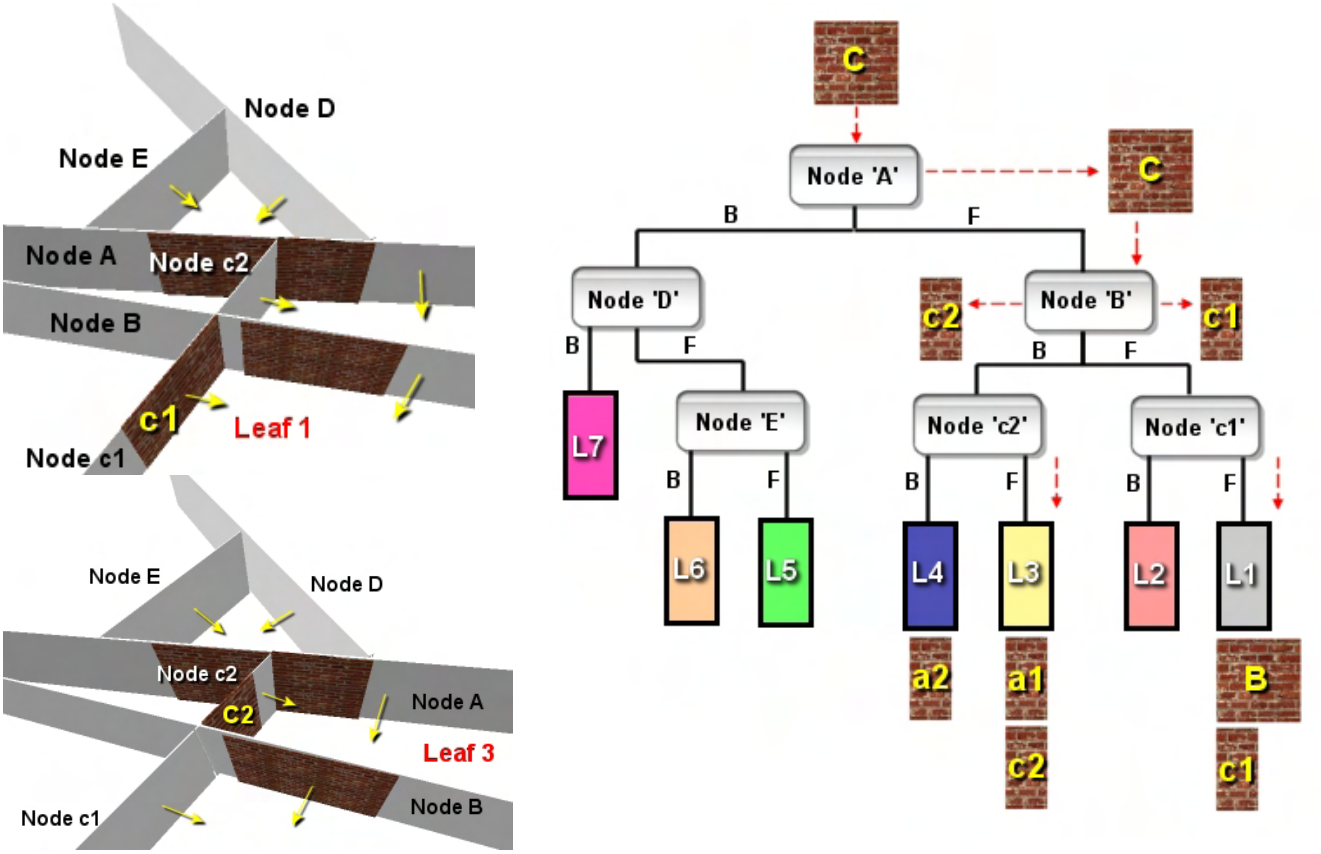

Figure 16.53

As the rightmost image in Figure 16.53 shows, polygon C is fed into the tree and is classified against the root node. Polygon C is found to be located entirely in the front space of node A so is dispatched down the front side to node B. At node B a similar classification takes place between the polygon and the node plane and this time polygon C is found to be spanning node B. This means polygon C will have to be split into two new fragments, c1 and c2 and the original polygon C will be deleted. Split fragment c1 is in the front halfspace of B so we will follow that fragment first.

As c1 is passed down the front of node B it arrives at node c1. It is obvious in this example that c1 is on plane with node c1 as this was the polygon that was originally selected to create the node's plane. Remember, we have built the tree and populated it in two different passes in this example. As polygon c1 is co-planer with node c1 and has a normal oriented into the node's front space it is passed down the front of node c1. However, node c1 is a terminal node so we know that to the front of this node must exist a leaf and in this example, that leaf is leaf 1. Polygon c1 is added to leaf 1's polygon list where it joins polygon B that was added to the leaf a moment ago. Polygon c1 has been fully processed and assigned to its leaf node so we unwind back up to node B again where we still have to process split fragment c2, which is located in its back space. Polygon c2 is passed down the back of B where it is found to be co-planar with node c2 and is therefore added to leaf 3 where it joins polygon a1.

With polygons A,B and C assigned to leaves in the tree, next we pass in polygon D whose original location is shown in the leftmost image in Figure 16.54. The rightmost image shows its route of classifications as it is passed down the back of A to node D. At node D it is found to be co-planar and

facing into the same frontspace and is therefore passed down the front where it arrives at node E. Polygon D is also located in node E's frontspace so is finally passed down the front and stored in leaf 5.

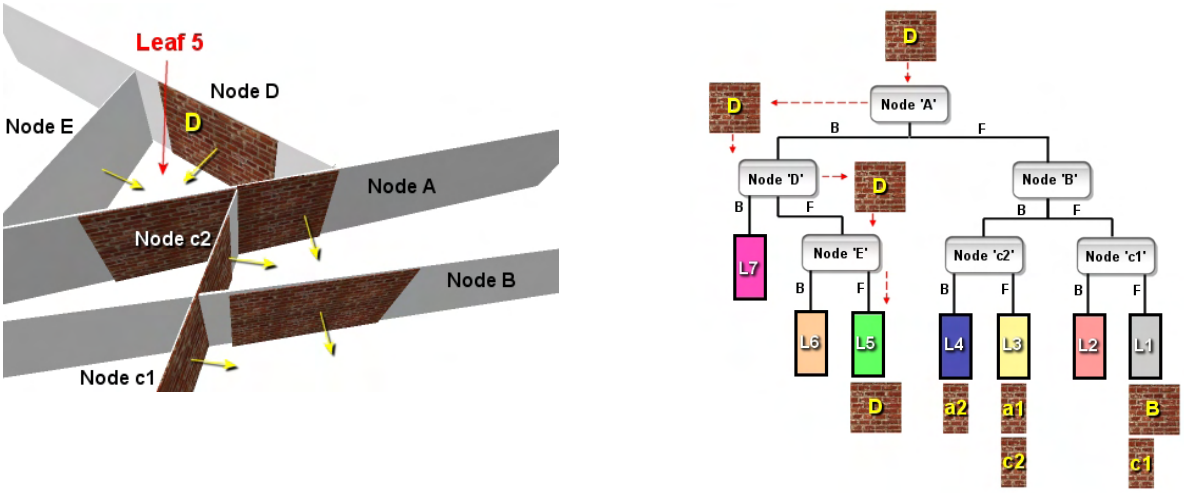

Figure 16.54

Finally, we have one polygon left to process, polygon E. It takes an identical route through the tree as polygon D (see Figure 16.55). It too ends up being assigned to leaf 5 where it joins polygon D.

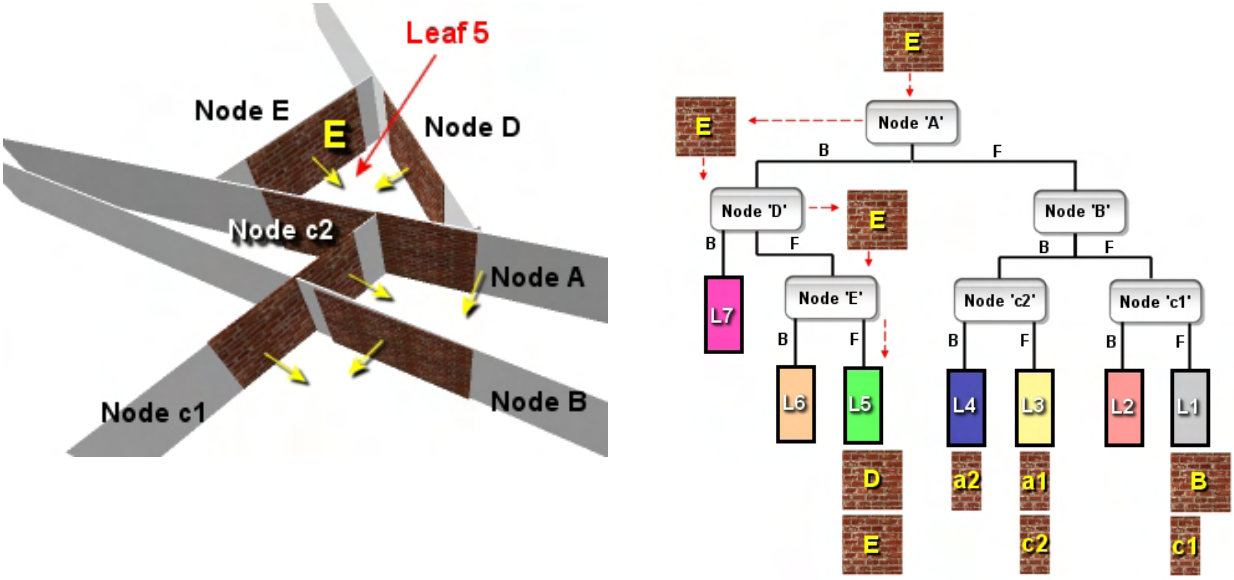

Figure 16.55

To clarify the process, we have performed the BSP compile in two different passes. Hopefully this has highlighted for you just how much the BSP tree is like any other tree we have developed so far. It has also shown us that the node tree also is the exact same tree as the leaf tree with the exception that we chose not to use the leaf information that was implied by the partitioning scheme. Our original node tree example now has been converted into a leaf tree and the final result is shown in Figure 16.56

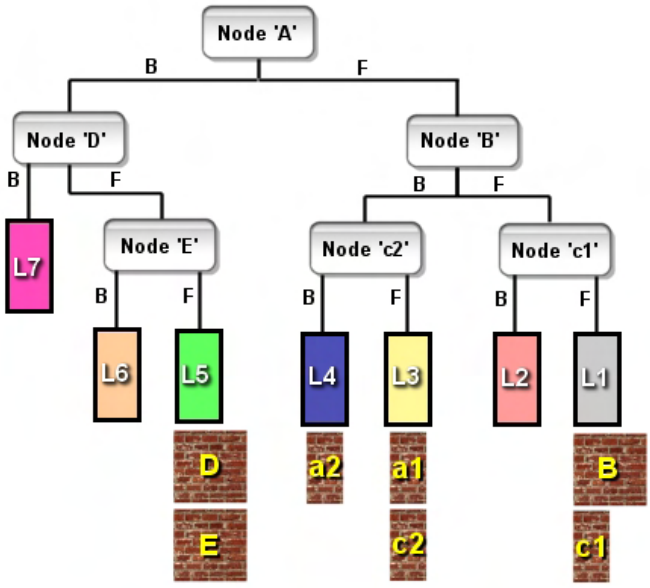

Figure 16.56

Notice that some leaves have had no polygon data assigned to them (leaves 2, 6 and 7). Also notice in all the previous diagrams that because of the way that we send a polygon that is co-planar and same facing down the front of that node, a polygon will always be assigned to the leaf that it is facing into. It might seem strange to think of the camera being in leaf 5 and not being able to see polygon A whose plane also bounds that region but polygon A would be back-facing and therefore would be back face culled by the pipeline. ***The only polygons assigned to a leaf are the ones that exist on one of the leaf's bounding planes and that have normals that face into that leaf.***

This would seem to cause a bit of problem. If the camera was located in leaf 5 for example, we would expect to see polygon A would we not? This is true, but this whole problem is caused by the fact that we have used as our example (quite deliberately) a completely infeasible data set. That is, we have developed data where it is possible for the player to see the backs of polygons, which is something you would never be allowed to see in a real scene. As we know, back face culling means that if we were to ever be allowed to walk around a polygon and view its back side, it would essentially disappear in front of our very eyes causing a complete breakdown in the solid integrity of the level. You will see shortly that when provided with proper legal geometry, this situation will never arise and any leaf which represents empty space (the space in which the player is allowed to be) will be bounded only by polygons that face into the space of that leaf.

In the above examples we built a tree of planes first and then pumped the polygons through the tree in a second pass to populate the leaf nodes. While this method certainly works it is a little redundant to perform a second pass when we already have the polygon data available during the first pass. Later, we will show some example code of how to merge these two processes together to create a function that will compile a BSP tree from an input polygon list and populate the leaf nodes with the polygon data as it is being constructed. While this might sound quite complicated, it really is not. When you think about it, this is exactly how our quad-tree, oct-tree and kD-tree were built in the previous lesson. There are some added complications for sure due to the fact that the polygon list is not only being passed down the tree and collected at the leaf nodes but is also being selected to construct node planes at each step, but they are trivial and can be resolved with a line or two of conditional logic. However, for the time being we will stick with the two pass approach which will help us more clearly demonstrate certain topics over the coming sections.

16.3.2 BSP Trees and Convex Areas

In this section we will briefly discuss how and why the BSP tree compiler always manages to break the most complex level into a series of simple convex areas. This will also highlight the BSP tree's ability to represent any complex mesh internally as a series of convex areas that can be easily queried for point/ray/etc. containment. This is important because we will often wish to determine whether a point is contained within a non-convex object, which is much more expensive than testing against a simple convex volume. It should be noted that you do not need to know this information in order to build a BSP tree but may find it an interesting read and helpful to really understanding the inner workings of the BSP compilation process.

Perhaps the best first example of how binary space partitioning using the polygon planes works to break the scene down into convex areas can be shown by examining the process of breaking a non-convex polygon into a convex one. All the technologies we have developed thus far are designed to work with convex polygons and therefore, this information may become useful to you if your scene has been designed in such a way that it contains non-convex polygons. In such an instance, you will have to isolate these polygons and break them down into a series of convex ones. This is not something you will usually ever have to do as most level editors and modeling applications will enforce the exportation of convex polygons and perform the convexity process for you. However, imagine if you were writing your own world editor like GILES™ and you allowed the user to edit a polygon at the vertex level. It is quite possible that the vertices of the polygon could be manipulated in such a way as to form a non-convex polygon. It is important that the editor break this up into convex polygons as our collision routines and point in polygon tests rely on convex polygons being used.

Figure 16.57 shows a non-convex polygon. A useful definition of a convex primitive is one that states that the infinite planes which form the boundary of an object must **never** intersect that same object's interior space. If we were to apply that same definition to a polygon, this would mean that if we were to iterate through each of the polygon edges and construct planes from them, at no point should the polygon itself be found to be spanning any of those edge planes if it is to be considered convex. In Figure 16.57 an edge is highlighted red which clearly shows that its infinite plane would cut through the polygon's interior.

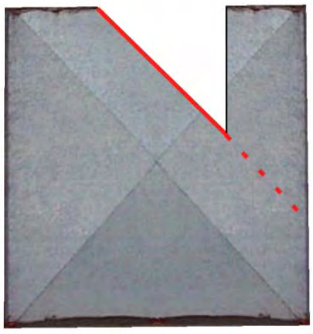

Figure 16.57

Using such a primitive would completely break our point in polygon intersection tests because we can no longer test whether a planar point is interior to a polygon simply by testing if the point is contained behind all of its edge planes (as we can in the convex case). It is quite possible for a point to be situated within the interior of the polygon shown in Figure 16.57 but still be located in front of one of its planes. Our point in polygon test would reject this point as soon as it was found to be in an edge plane's frontspace and would assume that the point is not interior to the polygon. You should be able to easily find a region in this polygon where a point could be located in front of the edge plane highlighted red in Figure 16.57.

Imagine that we wished to test if this polygon was convex or not. We could loop through each edge of the polygon and construct a plane from it (we learned how to do this in earlier lessons). For each edge

plane we would classify the points of the polygon against it. If we find an edge plane that has vertices in both of its halfspaces, we know this is a non-convex polygon and thus we split the polygon along that plane into two child polygons which are hopefully convex. Figure 16.58 illustrates that once the red edge plane in Figure 16.57 has been located, we could split the polygon by this plane thus creating two convex polygons which can be used in its place. The original non-convex polygon can then be discarded.

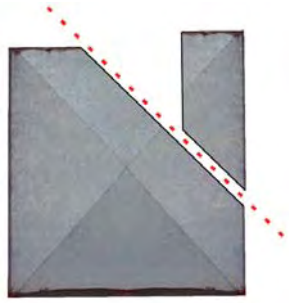

Figure 16.58

In this particular example our task would be complete because by finding this spanning plane and splitting the polygon, the result is two convex polygons which can be used instead of the original. We can now see that we can determine if a point is inside any of these two convex polygons simply by testing if a point is contained behind all of their edge planes (or in front of the edge planes depending on the directions you choose for your edge plane normals).

You may also notice that we could have easily solved this problem using the other spanning edge plane shown in Figure 16.59. As you can see, had the edges been tested in a different order, a different spanning edge may have been found first and used to split the polygon into two convex pieces. In this case, the results are different but the overall goal has still been achieved. That is, the two resulting polygons are different from those generated from the edge plane used in Figure 16.58 but the two resulting pieces are still convex. This is not unlike the BSP tree compiler where, regardless of the order in which we choose the split planes, the level will always be broken into convex regions. The shape and size of those regions may be totally different and dependant on the order in which polygons were selected as split planes, but the overall goal of convexity is achieved regardless of the splitter selection order.

Figure 16.59

Of course, it is entirely possible that even after the non-convex polygon has been split by a spanning edge plane, that the two resulting pieces may themselves still not be convex. Therefore, after the non-convex polygon has been split into two child polygons, the same process must be repeated on both of those children to test for convexity. If we find while classifying one of the child polygons against each of its edge planes that a spanning case arises, we know that the child must be split by this plane into two further child polygons. The process repeats itself until we finally test the edges of the child polygons and find no edges which intersect the interior of the polygons.

In Figure 16.60 we see another example of a convex polygon which cannot be resolved into two convex components using a single edge plane split. In the leftmost image we show the original non-convex

polygon and we have highlighted the first edge plane we found that the polygon vertices are spanning. We split the polygon by this edge plane resulting in the two new polygons shown in step 2. The rightmost polygon in step 2 is clearly convex and when we test its edges we find that none of them intersect the interior of the child polygon. However, the leftmost polygon in step 2 does still have edges which intersect the polygon and therefore this child polygon will need to be further subdivided into two new children.

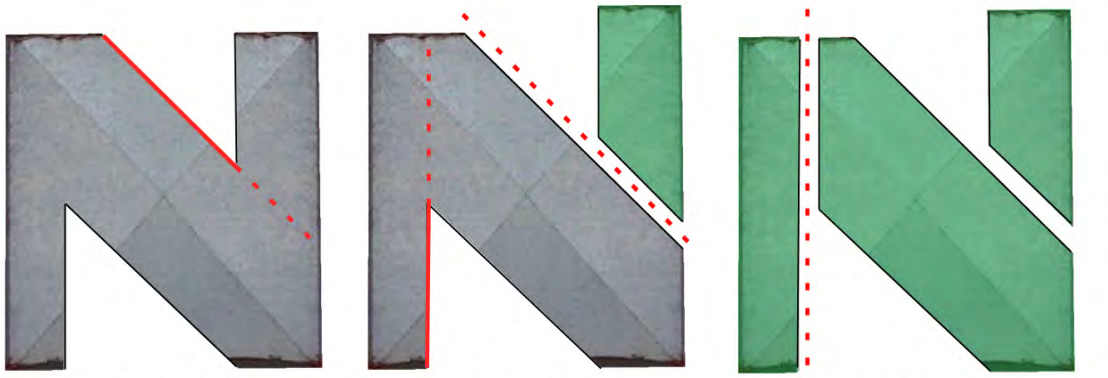

Figure 16.60

In step 2 we highlight the edge in red which we find in the leftmost polygon to be intersecting its interior and once again perform a split. This divides the leftmost child polygon into to new convex polygons shown in step 3. When we test the edges of these children we find that none of their edges intersect the interior space of the polygon to which they belong and thus, we have successfully broken the complex non-convex polygon into three convex ones.

When we examine the images in Figure 16.60 it becomes clear that using the edges of the polygons as the split planes will eventually always carve the polygon up into convex areas. It is a simple process of eliminating all spanning edges until they are removed. A convex object has no spanning edges so when we finally achieve this goal, we have logically eliminated everything from the original polygon that made it non-convex.

What also starts to become clear is that this is essentially how our BSP tree compiler subdivides our level geometry by using the planes of the polygons that comprise the level. For example, if we imagine that the polygon shown in step 1 of Figure 16.60 was actually a top down view through the roof of a building, we can see that the building would be broken up into convex areas using this technique. Our BSP tree compiler does exactly the same thing -- it makes sure that every polygon in the level is used as a split plane and when a plane is found which does intersect the geometry in the level, the geometry is split and assigned to polygon lists that are passed down either side of that node.

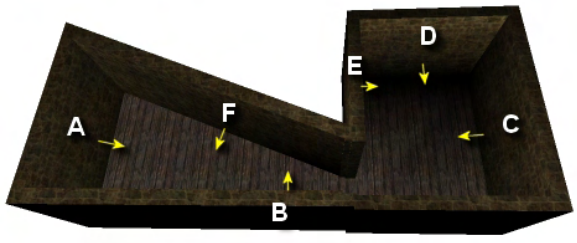

Figure 16.61

In Figure 16.61 we see a top-down view of a piece of 3D geometry. The geometry is a single room, but that room is non-convex. We will now see how the BSP compiler would break this non-convex geometry into two convex leaves. ***Again, each leaf always represents a convex area in the BSP tree.***

> **Note:** In Figure 16.61 and the images that follow the polygons are assumed to all be facing in towards the interior of the room. Back face culling has been disabled to show a better illustration of the geometry being compiled. Furthermore, the polygons in these diagrams have been given some degree of thickness to aid the clarity of the diagram, but as we know, in reality these polygons would be infinitely thin. Finally, although we have shown the room as having a floor polygon, we will ignore this polygon for now to help simplify the number of nodes and operations that would need to be done. The floor is simply there to aid the 3D perspective of the image. We will compile only the walls.

We will now step through the process that would be involved in building a BSP tree using this level. We will use this example to get more comfortable with the idea of passing the polygons down the tree into the leaf nodes during BSP compilation. As this is a fairly simply level to compile we will not accompany each image with a tree diagram. All we are trying to accomplish here is an understanding of why the BSP tree carves up the space of the scene into convex regions. The polygons in these images have been labeled A through F, which indicates the order they are to be selected as splitters during the compile process.

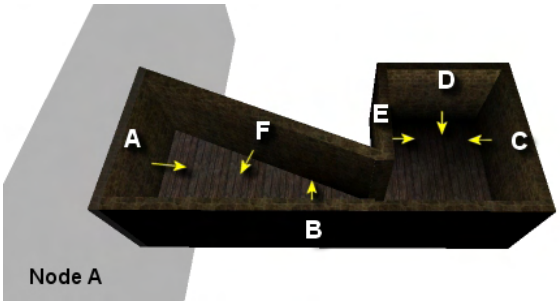

Figure 16.62

In Figure 16.62 polygon A is selected as the root node and marked as having been used as a splitter so that it will not be selected again. All the polygons (A through F) are classified against node A and are found to exist in its front halfspace, so they are compiled into a front list and passed down the front.

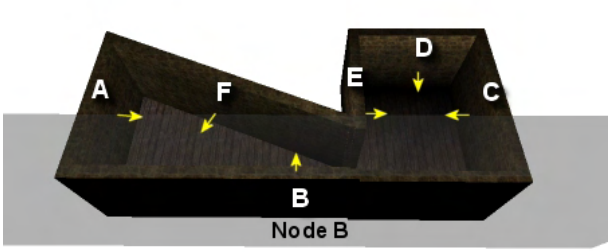

Figure 16.63

Polygon B is selected from the list at A's front child and is marked as having been used as a splitter. All the polygons (A through F) are in node B's front space so are passed down the front.

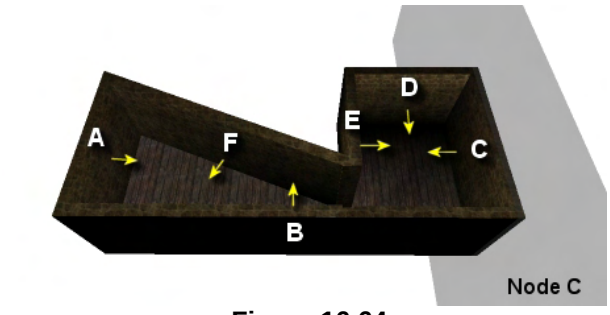

Figure 16.64

Node C is selected next to be the child node of B (Figure 16.64). Polygon C is marked as having been used as a splitter and all the polygons are classified against node C and found to exist in its frontspace. Once again, they are all added to the front list of the current node and sent down the front of node C where a new child node will be created.

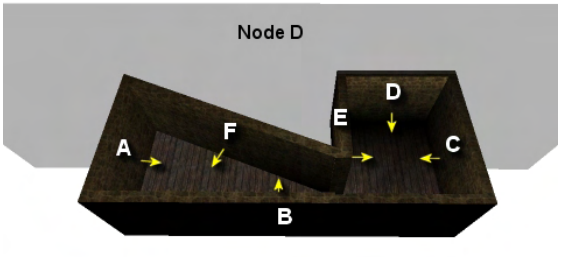

Figure 16.65

In Figure 16.65 we can see that polygon D is selected as a split plane next and the polygon is marked as having been used as a splitter. All the polygons in the list that were passed into node C (polygons A through F) are classified against node D and are once again found all to exist in its frontspace. They are packaged into the front list and passed down the front of node D.

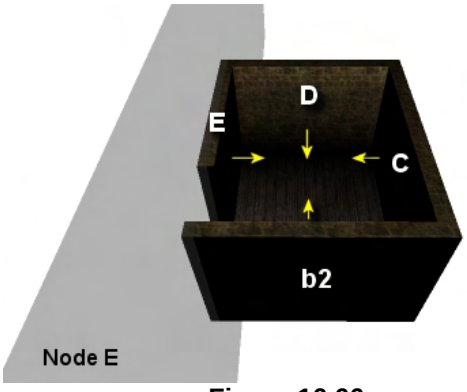

Figure 16.66

Down the front of D the BSP compiler chooses polygon E as the next split plane. This is the interesting bit. Plane E is the plane that intersects the interior of the geometry and therefore the geometry in the list will need to be split. When the polygons are classified against node plane E, polygons E, D and C are found to exist in its frontspace and are added to the front list, while polygons A and F exist in its backspace and are therefore added to the back list. Polygon B however is spanning the plane and is split into fragments b1 and b2 with b2 being the fragment located in the front halfspace of node B. b1 is added to the back list and b2 is added to the front list. What is vitally important to know is that when polygon B, which has already been used as a split plane, is split, we carry over the status of its 'BeenUsedAsSplitter' Boolean into the child splits b1 and b2. This will stop b1 and b2 from being used as split planes later since their parent polygon has already been used. Otherwise we would have redundant split planes which would create more nodes in the tree.

The front list at node E will contain polygons E, D, C, and b2 and these will be passed down the front of node E as shown in Figure 16.66. When we get down the front of node E however, we find that we have no more polygons that have not yet been used as splitters and therefore, our job is done. At this point we must have a group of polygons whose planes represent a convex volume and therefore we have determined that there is a leaf in front of node E. Furthermore, by clipping and passing the polygons down the tree during the build process, we have also collected the polygons for this leaf at the same time. As you can see in Figure 16.66, the first leaf we create is comprised of four polygons which all face into the center of the leaf. If we query the tree for a position and find that the query position is located in this leaf, we now it is located in the section of the original room shown in Figure 16.66.

Note: A leaf is created whenever we have a list of polygons passed into a node have all been used as splitters. Unlike the quad-tree, oct-tree and kD-tree which can have many stop codes which determine when a leaf is created, with the BSP tree we keep creating child nodes until we find that a node is passed a list of polygons which have all be used to create split planes. No other stop code is necessary. As soon as no split candidates remain, a leaf is created and the planes of the list polygons passed into that node are guaranteed to form a convex region that bounds the leaf.

With the leaf in front of node E created we must now process node E's back list which contained polygons A, b1, and F. When we step down the back tree of node E we find that only one polygon remains in the list which has not yet been used as a split plane. This is polygon F which is used to create the back child node of E. Polygons A, b1 and F are classified against node F and are all found to exist in the front space. However, as polygons A, b1 and F have all been used as splitters we do not create a new front child for node F but instead attach a leaf structure to its front containing these three polygons. We now have our second convex leaf. Our level as now been divided into two convex leaves as shown below in Figure 16.68.

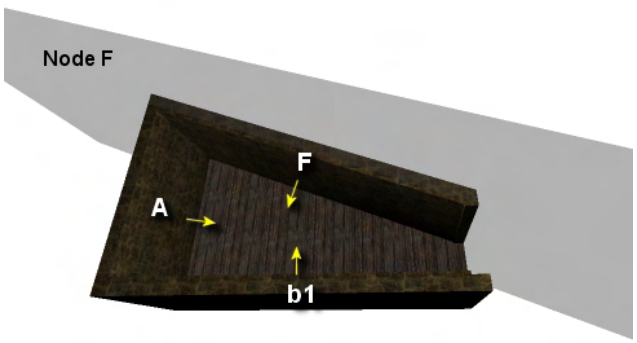

Figure 16.67

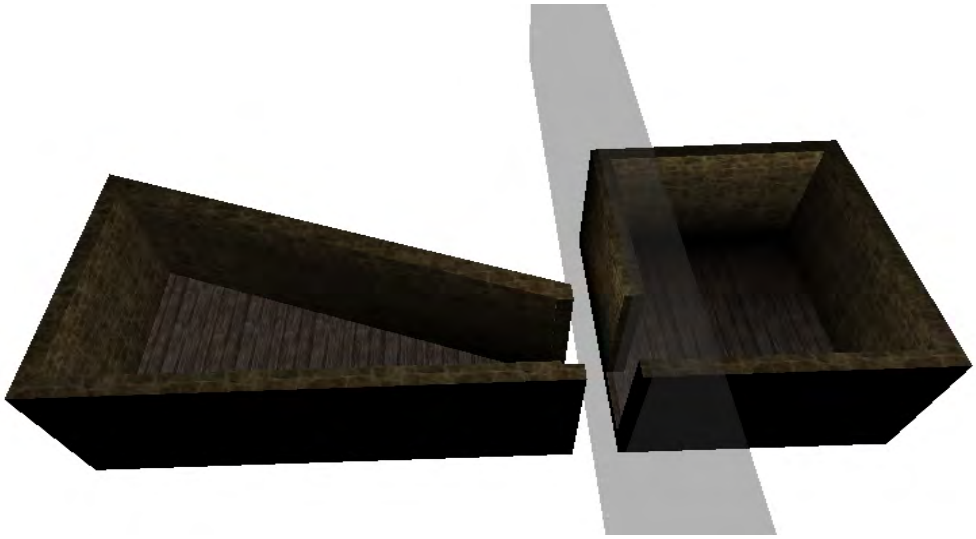

Figure 16.68

We have now seen exactly why the BSP tree compilation technique breaks the world into a series of convex areas and we have also seen how much it is like the polygon examples we examined earlier. In this case, it was node E's plane that was found to be the spanning plane and responsible for dividing the initial polygon list into two child lists in front and behind the split plane. We have also seen how a leaf is created whenever we reach a point in the recursive process where every polygon in the list passed into a node has already been used as a splitter, making it impossible for another node plane to be selected. It is also worthy of note that whenever no polygon data gets passed down one side of a node, an empty leaf is created there. Figure 16.69 shows the final resulting planes of the BSP tree that was just compiled and we can see that it has carved the world up into seven convex leaves. Only two of the leaves contain polygon data and those are the only two leaves that have all their bounding plane normals facing into the interior of the leaf.

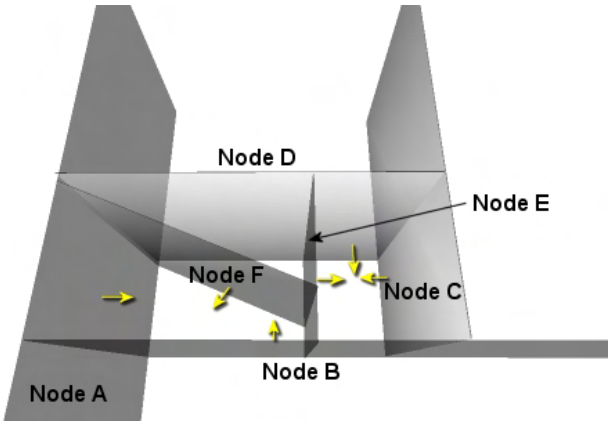

Figure 16.69

16.3.3 Solid / Empty BSP Trees

The title of this section might lead you to believe that we are going to discuss a different type of BSP tree that can encode solid and empty information. However, the current tree we have will already do that if we send it geometric data in an ordered and sensible format. Providing that we send the compiler geometry that obeys certain conditions (i.e., *legal geometry*), a level will be compiled such that polygon data will only ever be stored in front leaves. Back leaves will always be empty of polygon data and therefore, represent areas of solid space within the game level.

When we refer to a BSP tree as a 'solid' BSP tree, it simply means that because of the way the input data has been constructed, we can easily deduce which areas of the scene are empty of obstructions and which areas of the scene are assumed to be solid space (e.g., the space in the middle of a brick wall). Solid space is space that the player cannot see through and is a region where the player should never be allowed to move. We will see shortly that assuming we send the geometry to the BSP compiler in the correct format, every leaf attached to the back of a node will represent a solid area (i.e., a leaf of solid space). Every leaf attached to the front of a node will represent an empty space leaf. That is, a leaf in which the area of space is assumed to be empty and that the player can both see and navigate through. The polygons of the level will always be assigned to empty leaves (front leaves), which may sound strange at first as we normally consider the polygons to be the solid objects that we cannot navigate through. This is still the case of course in theory. However, as discussed earlier, the polygons will always lay on the boundary planes of a leaf and therefore, it is the empty space between those polygons in which the player is allowed to navigate. Furthermore, because of the way we handle the on-plane case during BSP tree construction, polygons will always end up in leaves which their normals face into. This means, when the player is located in empty space, the polygons assigned to that leaf will be facing into the leaf, and therefore, facing into the same halfspace as the player.

Although this might all sound a little abstract (until we look at some examples of geometry that will compile a solid BSP tree), assuming that this is correct, why is it important that we have access to this solid/empty space information? The reasons are actually numerous and quite important.

First, if we can guarantee that every back leaf represents solid space, then performing line of sight tests becomes trivial. If we wish to determine whether point A can see point B, then we would create a ray from point A to B and send it through the tree. At each node the ray would be sent down the front or back of the tree depending on the ray/plane classification result at that node. If the ray is found to span the plane then the intersection point C with the plane is calculated and the ray is split into two by creating two child rays A->C and C->B. These two ray fragments are passed down their respective sides of the node. This process continues until the ray fragments pop out in the leaf nodes. We performed an identical process to this in lesson 14 when we discussed passing a ray through the kD-tree (CollectLeavesRay). However, for a line of sight test, if at any point we find that a fragment of the ray has been passed into a back leaf (i.e., a region of solid space), we know that no line of sight can possibly exist between these two points. That is because part of the ray passes through an area of space that is solid, such as a section of wall or floor for example. When this is the case we can immediately return false for the line of sight test. Performing line of sight tests in this way is much faster than testing each polygon for intersection with the ray. Using the BSP tree, we have no point in polygon tests to perform at all.

Another important reason for needing solid and empty space determination will become clear when we calculate a potential visibility set in the following and final lesson. A potential visibility set is a block of data that describes to us which leaves are visible from any other leaf within the tree. If we have a potential visibility set at our disposal, we can simply traverse the tree each frame to find the leaf in which the camera is currently located and fetch the visibility set for that leaf. This will instantly tell us which leaves are visible from the current leaf we are in and we can render each of these leaves. The potential visibility set will not calculate the visibility information based on leaf inclusion within the camera frustum, as with our previous rendering systems. Instead, it will be calculated at development time and will take occlusion into account. This means that if a leaf represents a small room with a small open doorway, the only polygons visible to that leaf will be the polygons forming the walls, floor, and ceiling of the room itself and the small number of polygons that can be seen through the open doorway from within that room. All other leaves that lay behind the walls will not be in the leaf’s visibility set and thus we typically render only a small number of polygons and reduce overdraw significantly. Essentially, instead of rendering everything that is inside the frustum, we render only what is actually visible from that location. Polygons that are located well within the frustum but are occluded by nearer geometry will not be in the visibility set for that leaf and will not have to be processed in any way. The potential visibility set for each leaf takes a very long time to compile (sometimes many hours) so it is done as a development time process. The information is then saved out to disk and loaded into the game at runtime and used. In the following lesson we will write a PVS (Potential Visibility Set) calculator and one of the chief pre-requisites for being able to calculate the PVS for a game level is that the level be compiled into a solid BSP tree. Take a look at Figure 16.70 to see why this is the case.

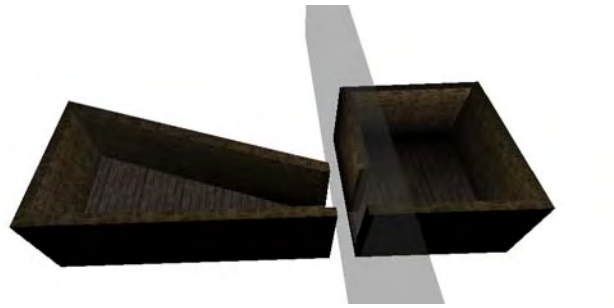

Figure 16.70

Here we see the two leaves that the non-convex room was broken into in our previous example. In this image we have deliberately separated the leaves so that we can see the gaps in the polygon data were the two leaves connect. We can think of this gap as the doorway between the two leaves. The plane that created the split into two leaves is also shown. You can imagine how in a really complex level thousands of leaves will be created which all have similar doorways that lead into one another. In order to calculate the visibility for a leaf, we will need to know the size of each of these doorways so that we can build view volumes out of them which will describe everything that a leaf can see through its doorways (that lead into other leaves). Do not worry about how this is done as this will be the entire focus of the following lesson. The problem we have is that we need to know the size of these doorways which is information we currently do not have. We know the planes on which these doorways will lie because they are the node planes that split the geometry (the gray plane shown in Figure 16.70) but we do not know the size of the doorway. We will need to build temporary polygons (called portals) that will fit these doorways exactly. Once we have calculated all the portal polygons for a given leaf we will have created polygons that fit these doorways. We will then be able to construct view volumes from these portals which will describe what can be seen from the leaf, through those portals, and into other leaves. This will tell us which other leaves are visible from the current leaf having its visibility set calculated. If we know which areas of the world are solid space (such as located in a wall for example) and which areas are empty, we can build an initially huge polygon on that split plane and send it through the BSP tree. Any fragment of the polygon that ends up in a solid leaf (a back leaf) can be deleted as it is obviously situated inside a solid object or is outside the exterior walls of the level. At the end of the process we will end up with a polygon fragment that ends up in empty space and this is the portal(s) to the leaves that were subdivided by that split plane.

The calculation of a PVS will be discussed in the following lesson but what has become very apparent is the need of the PVS calculator to be able to determine during the portal creation phase whether or not a portal fragment has ended up in solid or empty space. Thus, we need to make sure we provide the PVS calculator with a BSP tree which has been compiled with geometry such that every back leaf can be considered solid space and every front leaf can be considered empty space. This is all about the geometry we send into the tree and not about changing any of the BSP compiler code in any way, as we will soon examine.

Another reason we will need to be able to compile a solid tree will be when performing CSG operations which will be discussed in the final section of this lesson. CSG operations allow us to carve one object from another or union two objects together into a single mesh. We will see later that the union operation is especially important to us as it allows us to fuse all the meshes comprising the level into a single static mesh which can be compiled into a solid BSP tree. The union operation will remove hidden surfaces, which are essentially polygons from one object embedded (or partially embedded) inside the interior space of another object. Geometry that has such arrangements of polygons is considered illegal geometry as it breaks the rules laid down by the solid BSP tree. The tree compiled from such data will contain invalid solid/empty space information thus causing PVS calculation and any future CSG operations on that geometry to fail.

Note: Such data is referred to as 'illegal geometry' from the BSP tree's perspective and will result in an invalid BSP tree. We will discuss illegal geometry in some detail later on in this lesson and will discuss ways to correct such problems in the geometry. CSG operations allow us to remove these hidden surfaces that would cause the BSP tree created to be invalid and is another process that relies on solid/empty information.

So we have seen that the need to be able to build a BSP tree which contains solid/empty information is important especially to future processes that we will undertake. We have also learned that a solid BSP tree is fundamentally no different from a normal BSP tree with respect to the code -- it all comes down to the geometry that we send our compiler. If we send legal geometry to our BSP compiler, a level will be created which will always have empty back leaves and polygons stored in the front leaves. Those back leaves will always represent solid space and the front leaves will always represent empty space.

This may all seem incredibly hard to imagine at the moment. Indeed it seems odd that by just supplying geometry constructed in a certain way we will get this solid/empty information for free. However, it is absolutely true and is the exact reason that artists that are developing scenes for a game engine that uses BSP/PVS technology will use world editors such as WorldCraft™ or GILES™. These editors allow the artist to construct worlds from a series of simple solid primitives using CSG operations to carve and union these simple shapes into more complex objects. The editors force (for the most part) the artist to build scenes that are considered legal geometry just by the very way that they are constructed. This will all make more sense when we cover exactly what solid/empty space is and what is considered legal/illegal geometry by the solid leaf BSP compiler.

In our node tree discussion we used an example level that was extremely unrealistic and made reference to the fact that because a polygon lay on of the node planes, it may actually lie on the boundaries of a front and back leaf. Figure 16.71 highlights such an example from this level. We can see for example that polygon B has been assigned to the leaf in its node plane's frontspace and therefore this polygon would be assigned to leaf 1. However, notice that this polygon (and its plane), also form a boundary for the leaf that lies behind the plane. If our camera was located in the leaf bounded by planes A, B and c2 for example, we would be looking at the back of polygon B, which would be back face culled. This would allow us to see right through this polygon into leaf 1 which would completely destroy the visual integrity of the level.

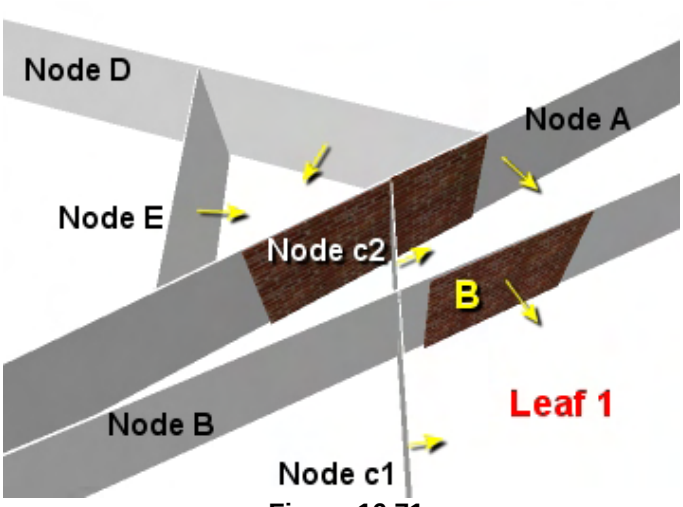

Figure 16.71

Of course, this never happens in a real game since our artists would not include a wall that can be viewed from all sides as a single polygon. As Figure 16.72 shows, if we were to represent a section of wall as a single polygon it would only be visible to the camera when viewed from its front side. If the player was allowed to navigate the camera such that it could view the polygon from behind, it would be back face culled and would therefore be invisible.

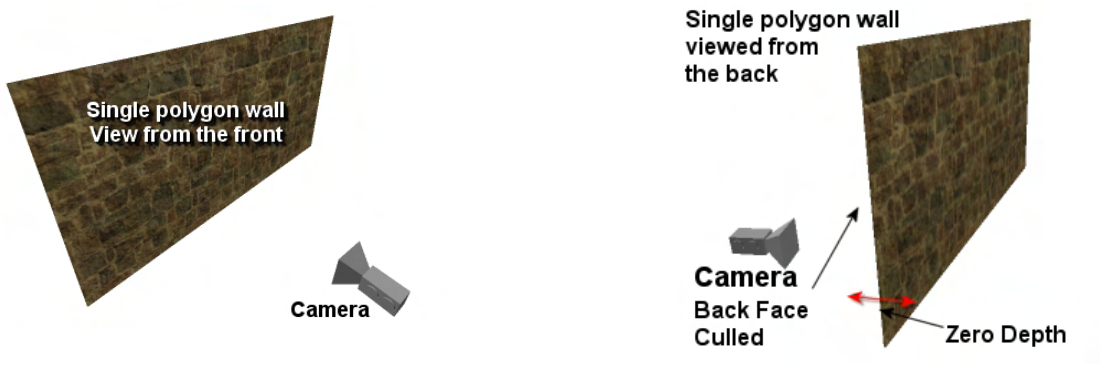

Figure 16.72

Representing a wall in such a way would only be acceptable if that wall formed one of the exterior walls of your interior scene and as such, the camera could never navigate around the back of it. In fact, even when viewed from the side or top we compromise our belief that this is supposed to be a solid wall as it would become clear that this polygon is nothing but a thin sliver of texture.

World editors such as GILES™ aid in helping the artist avoid such mistakes by forcing the placement of solid objects. For such a wall section, a cube would be placed and scaled to fit the desired dimensions. The cube has 6 faces instead of 1 and can be viewed from all sides. Regardless of the side you are viewing the wall from, there will always be faces with normals oriented towards the view direction. This obviously means that 6 faces get added to the scene instead of 1, but it also means that we now have a wall that is not only viewable from all directions, but also has a thickness when viewed from the sides, above or beneath, as shown in Figure 16.73.

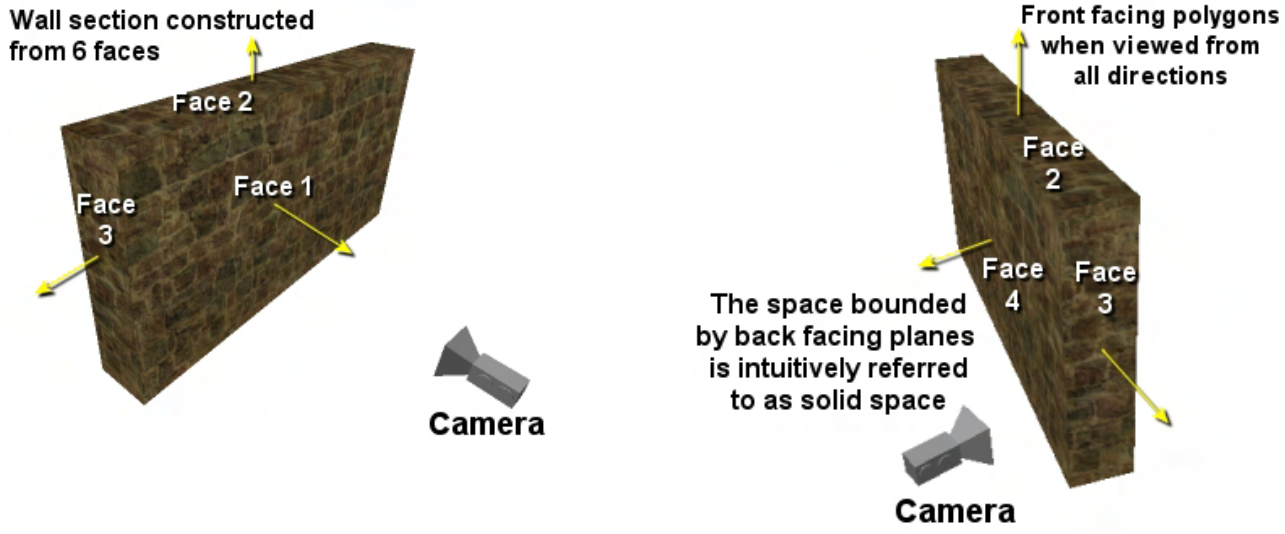

Figure 16.73

Assuming that this wall was the only geometry in our scene, let us see what happens when we compile it into a BSP tree. For the rest of this example we will simplify to a 2D top down perspective and will ignore the top and bottom faces. That is, we will assume that we are compiling a 4 faceted cube instead of a 6 and are viewing that cube from above.

Figure 16.74 shows the compilation of this 2D wall section (the cube). Polygons pA, pB, pC and pD are the outward orientated faces of the wall and the gray arrows show their face normals. The polygons are assumed to be selected as splitters in alphabetical order during the build process, creating node planes A, B, C and D. To the right we see the BSP tree that is generated from such data.

As you can see, node A is selected first and all of the polygons are classified against it. pA is co-planar and same facing which means it is sent down the front of node A. As the only polygon in the front list is polygon pA, which has already been used as a splitter, a leaf is created and polygon pA is assigned to it. The rest of the polygons are added to the back list and sent down the back of node A.

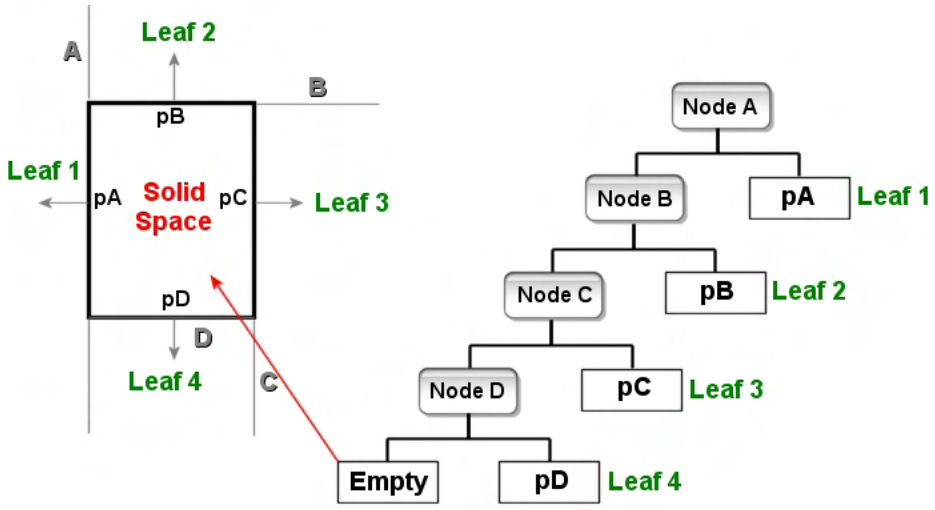

Figure 16.74

Down the back of node A polygon pB is selected as the next splitter which creates node B. Polygons pC and pD are added to the back list and polygon pB is co-planar and same facing which means it gets added to the front list. As there is only one polygon in the front list for node B (polygon pB) which has already been used as a splitter, a new leaf (leaf 2) is created down the front side of node B and polygon pB assigned to it. As we continue down the tree we see that polygons pC and pD end up getting assigned to their own leaves down the front of nodes C and D respectively. At node D however, there are no polygons in the back list so an empty leaf is created. As Figure 16.74 shows however, this empty leaf represents the area of solid space behind each of the polygons.

> **Note:** Whenever we compile a convex object with outward facing normals into a BSP tree we get a one sided tree as shown in Figure 16.74 where the nodes are all back children. If we were to reverse the plane normals so that all the polygons faced inward, empty space would be in the middle of the cube, solid space would be all around the outside of the cube, and the tree would be a one way tree down the front side instead of the back.

When we examine Figure 16.74 it starts to become clear why we can rely on a back leaf always being empty and representing solid space. When a polygon is co-planar and same facing, it is passed down the front of the tree, which means it will always end up in a leaf down the side of the tree which its normal is facing into. If the polygon is co-planar but not same facing, it is sent down the back list where it will later be used to create its own node. The polygon is obviously going to be found to be co-planar and same facing with this new node so is passed down its front. Thus, every polygon will eventually get added to a front leaf. Conversely, because this is the case, no polygons will ever be added to back leaves. Since all polygons always end up facing into the empty space of the leaf to which they are

assigned, the solid leaves represent the space behind those polygons and thus will never contain polygons of their own. Examining Figure 16.74 again, we can see that if we pass a query position through the tree that ends up in this empty back leaf, it will be located behind polygons pA, pB, pC and pD and therefore be located in center of the wall (i.e., in solid space).

Although this is probably about as simple a level as you could possibly compile, we will examine more complex levels later and show that the same holds true for our entire scene as long as we obey certain level creation rules. That is, provided we supply the BSP compiler with legal geometry, every solid region in the scene will be represented as a back leaf and empty space will always be represented as a front leaf. We will examine exactly what constitutes illegal geometry a bit later and see why it causes the solid/empty space relationship to break down.

The addition of solid and empty information to our BSP leaf tree is the primary reason behind the importance of ensuring that the on-plane case is handled correctly during construction. Recall that if a polygon is co-planar with the current node, then we add that polygon to the front list and ensure that it is not used as a splitter again. That is, we flag this polygon as used *only* if it points in the same direction. If a polygon's vertices are co-planar but its normal points in the opposite direction, then we add it to the back list, but we **do not** remove it from consideration as a future node plane candidate. This will ensure that the polygon will be selected as a split plane later, which is vitally important to the solid/empty integrity of our level

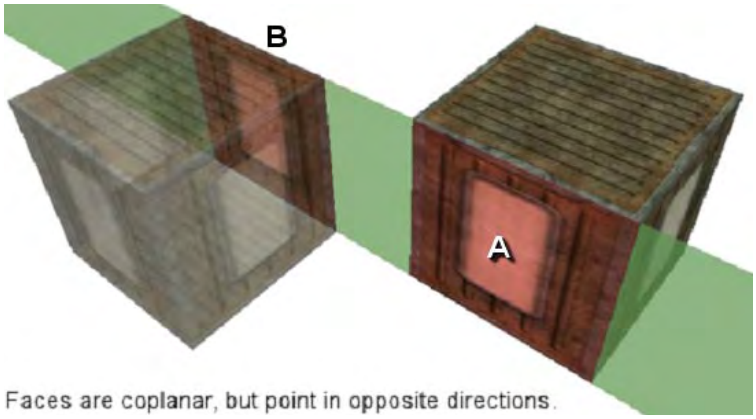

Figure 16.75

Consider the situation outlined in Figure 16.75. The example shown produces an arrangement unlike that of any of our previous test geometry. Here we have a scenario in which we find two polygons that lie on the same plane as one another but point in opposite directions. Imagine that we were to select the closest polygon as the candidate for the separating node plane depicted here. When we compare the polygon list against this plane, this candidate polygon is added to the front list as expected. Due to the fact that the co-planar polygon that is furthest away from the camera faces into the back halfspace of the node plane, it is added to the back list. As discussed in the previous section, we would not usually mark the co-planar polygon that was added to the back list as used. Yet, it may not be clear at this point exactly why this particular step is so important.

Contrary to our current building concept, if we were to remove **both** of these polygons from consideration by flagging them as used at this node, we would end up with a tree structure similar to that shown in Figure 16.77. Even though we are focusing on one particular node here and showing only the subsection of the tree that would be generated by the two cubes in the above example, we can clearly see that if *both* polygons 'A' and 'B' were flagged as used when node A was created, we would end up with a situation in which polygon 'B' has been added to a leaf that falls behind the node.

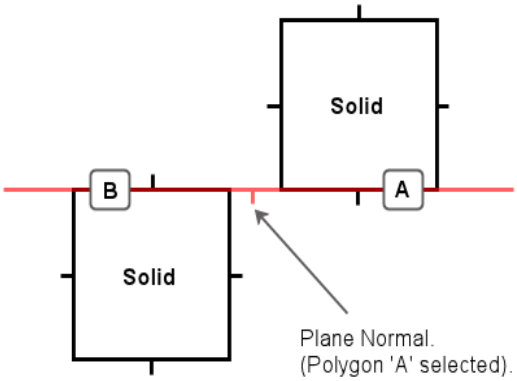

Figure 16.76

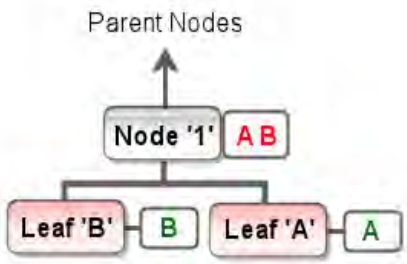

Figure 16.77

Note: Figures 16.76 and 16.77 do not represent a full and valid BSP leaf tree. These diagrams are merely intended to draw your attention to one particular portion of a larger tree.

In this particular example we can observe that the front side of polygon ‘B’ faces into a leaf contained in the back halfspace of the node. This conflicts with the key property that allows us to identify solid and empty areas in our tree because we now find that a leaf which should clearly describe empty space falls *behind* a node plane.

This is the reason why it is vital that we implement the on-plane case in the manner discussed in previous sections. By **not** marking polygon ‘B’ as ‘used’ during the classification step for the first node, we allow our compiler to select that polygon for node creation at a point further down the tree structure. As we can see in Figures 16.78 and 16.79, in this case we have allowed the compiler to generate a new node for each polygon which points in opposing directions.

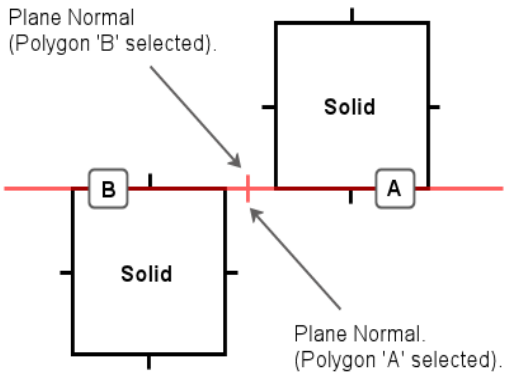

Figure 16.78

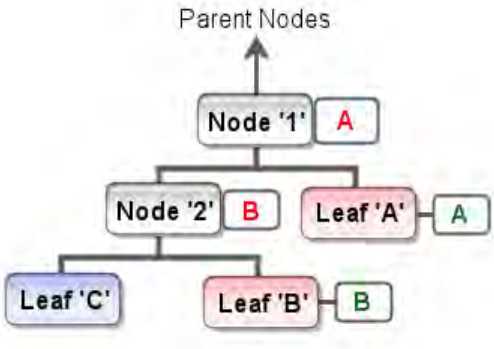

Figure 16.79

Once we allow polygon ‘B’ to create its own node, we can see that we have restored the ability to classify a leaf as solid if it is contained within the back halfspace of its parent node, or empty if it exists in front. Notice that polygons A and B both eventually end up getting assigned to front leaves.

Referring back to our single wall section example again and assuming that the wall section we have just compiled into a BSP tree is currently the only geometry in the scene, you will see that the BSP tree automatically provides us with the ability to perform line of sight tests in an extremely efficient manner.

In Figure 16.75 we show two positions that exist in empty space labeled J and K. Position J is located in leaf 1, where the wall polygon pA could be viewed. Position K is also in empty space (leaf 3) and from this position the wall polygon pC can be viewed. However, position J cannot see position K because the wall polygons are in the way.

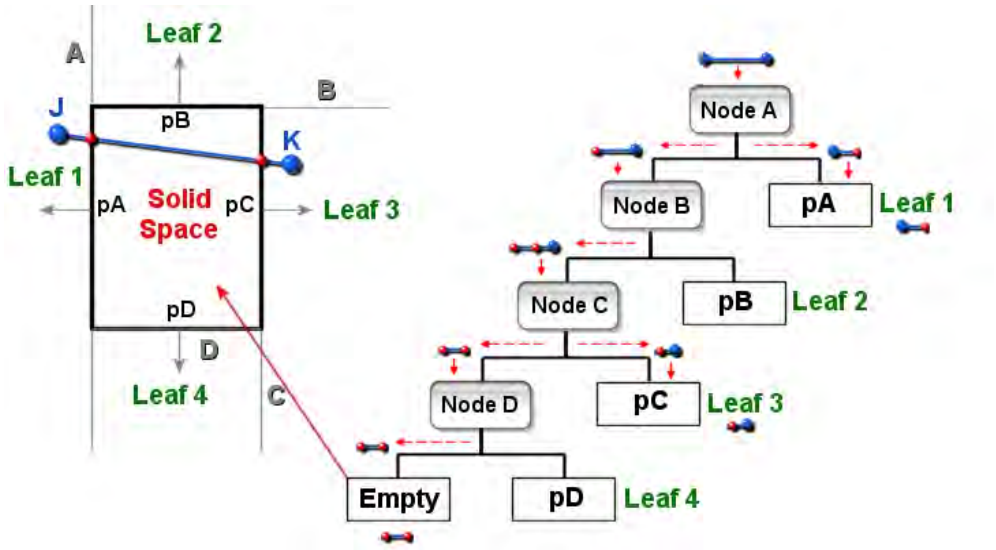

Figure 16.80

Usually, to determine if line of sight exists between points J and K we would have to perform expensive ray/polygon tests between the ray and each polygon in the vicinity of the ray. This could be a very large number of expensive tests in a complex level. However, we can see in this simple example that we can test very efficiently if line of sight exists between two points in a solid BSP tree by simply sending the ray down the tree and returning false as soon as a fragment of the ray ends up in solid space. If all fragments of the ray end up in empty space then a line of sight does exist. Note that this is determined without testing the actual polygon data.

As shown in Figure 16.80, the ray is sent in at the root node. A ray/plane test determined that the ray spans the node, so the intersection point with the plane is calculated. That ray is then split such that this intersection point becomes the end point for the child in one halfspace and the start point of the child in the other. In this example, the front split of the ray is sent down the front of node A where it arrives in Leaf 1, which is empty space. This is the section of the ray shown in Figure 16.80 between point J and the red dot on the plane of node A. The back split of the ray is passed down the back of node A where it is classified against node B. The ray fragment is completely behind node B so is passed down the back into node C. At node C the ray is found to span the plane and is split, creating two child rays. The ray fragment in the front halfspace of node C is shown in the diagram as the segment starting at the red dot on node C and ending at point K. This is sent down the front of node C where it lands in leaf 3 which is empty space. The ray fragment that was found to lie in the back space of node C can be seen in the diagram as the line that joins the two red dots on nodes A and C. This is passed down the back of node C where it arrives at node D. It is found to lay in node D's back halfspace and is passed down the back of node D into a back leaf. Since the ray has entered a back leaf this must mean that this fragment is in solid space (as we can clearly see in the top down view of the cube). Therefore, we return false from this node, and eventually the function, indicating that no line of sight exists between these two points.

It is important to understand that just because we want to have a solid BSP tree does not mean that every wall, floor or ceiling in the level has to be constructed using six sided cubes. It simply means that the geometry must be constructed such that empty space is always bounded by front facing polygons and

solid space is always bounded by back facing polygons. For example, if we were to invert the normals of the polygons in the previous example and compile a BSP tree, we would get a different, but still perfectly valid, tree.

Figure 16.81 shows the result of compiling the same polygons but with negated normals. Now the polygon normals all face into the center of the cube which creates only one empty leaf. Now, there are four back leaves behind nodes A, B, C and D which combined represent the solid space around the outside of the cube. This is still a perfectly valid solid tree. In fact, we might imagine that the inward facing polygons represent the walls of a room and leaf 1 is the empty space inside that room in which the player is allowed to walk. This is still perfectly valid because empty space is still bounded by inward facing polygons and solid space is still separated from empty space by the backs of polygons.

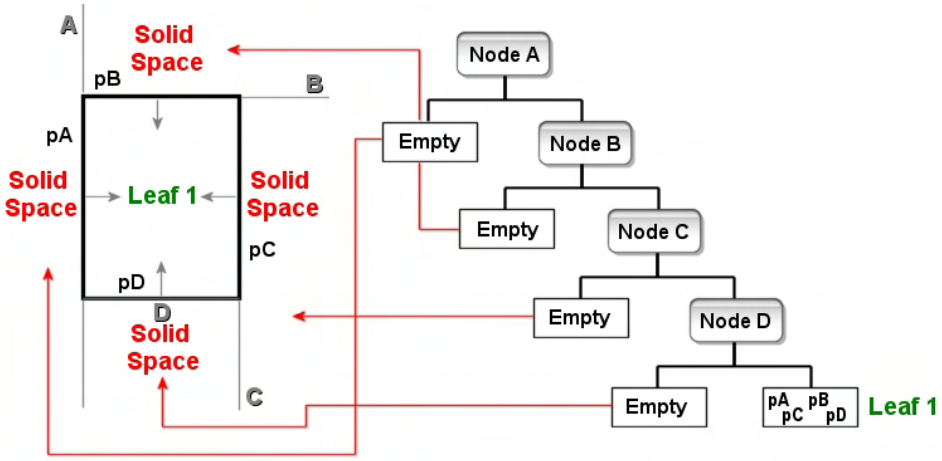

Figure 16.81

To illustrate the fact that our BSP tree code has not changed in any way, let us compile the non-convex room we looked at earlier. Remember when looking at Figure 16.82 that the walls of the room are supposed to be single inward facing polygons. In this diagram the walls have been given artificial thickness to better aid the visual demonstration. Back face culling has also been disabled so that polygon B is still rendered even though we are technically viewing it from its back side.

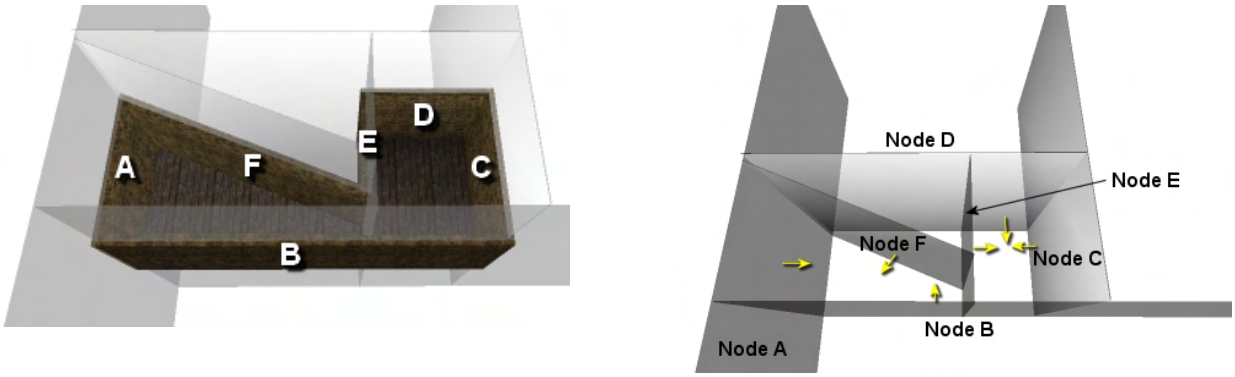

Figure 16.82

The leftmost image shows the original polygons that were used to compile the BSP tree. The letters assigned to them describes the order in which they were used to create node planes. Since we are now very familiar with the BSP tree building process, we will not show the construction process of the tree. The rightmost image shows the node planes that were created during compilation. The plane normal directions are depicted by the yellow arrows. Again, to keep the tree simple, we will pretend the floor polygon does not exist and has been rendered here only to aid with the visual component of the diagram.

Notice in the rightmost image that we have also created no node for this floor polygon (this is just a choice to keep the tree as small as possible during the examples).

Although you did not necessarily know it when we first examined this piece of geometry, this is perfectly legal geometry that will compile into a solid BSP tree. In this example, we will once again demonstrate our method using a two step approach. We will assume that the nodes of the tree were generated in an initial pass and that the polygons were then passed down the tree and collected in the leaf nodes in a second pass. The geometry depicted here obeys all the rules for keeping solid and empty space separate. The empty space is the space within the room itself and solid space is assumed to be all around the outside. Assuming that the BSP tree has already been compiled, let us now send the polygons (used to create the nodes in the first pass) into the tree and see where they end up. If this geometry is legal, we should find that all the polygons get assigned to leaves down the front of nodes and all leaves created behind nodes should represent solid space. This will also be our final example of populating the BSP tree with polygon data in a second pass. It will allow us to solidify exactly what happens to each polygon as it is passed down the tree before we merge this process into the node construction process and write our final solid BSP leaf tree compiler.

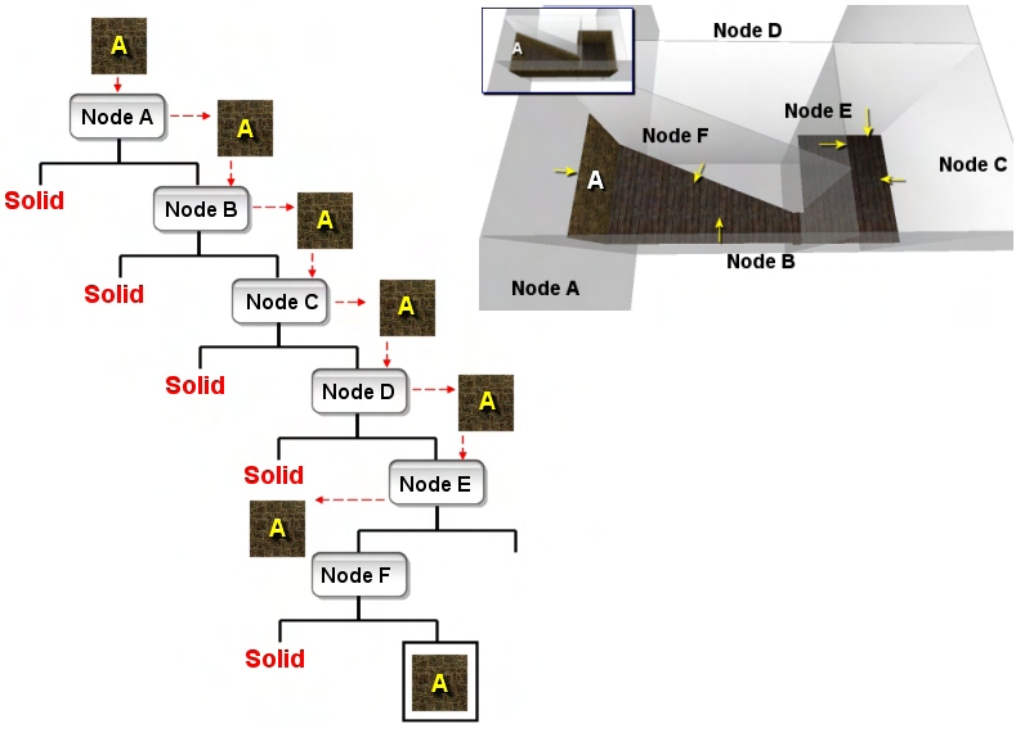

Figure 16.83

As Figure 16.83 shows, polygon A is sent into the tree first. At this point, you should be able to understand why the nodes of the tree are arranged in the order in which they are depicted. Polygon A is classified against node A where it is found to be co-planar and same facing and is therefore passed down the front into node B. We find that the polygon is also contained in the front halfspace of nodes B, C and D so it gets passed down the front at each step until it gets to node E. When classified against node E it is found to exist in its backspace and is passed down the back where it enters node F. As we can see in the diagram, polygon A is located entirely in node F's frontspace so is passed down the front of F. As no

more nodes exist down the front of node F it must mean that a leaf exists here to which polygon A is assigned.

The next polygon we pass down the tree is polygon B. At node A it is found to exist in the frontspace so is passed down the front into the node B. At node B it is obviously found to be co-planar and same facing (as this is the polygon that created this node) so is passed down the front into node C.

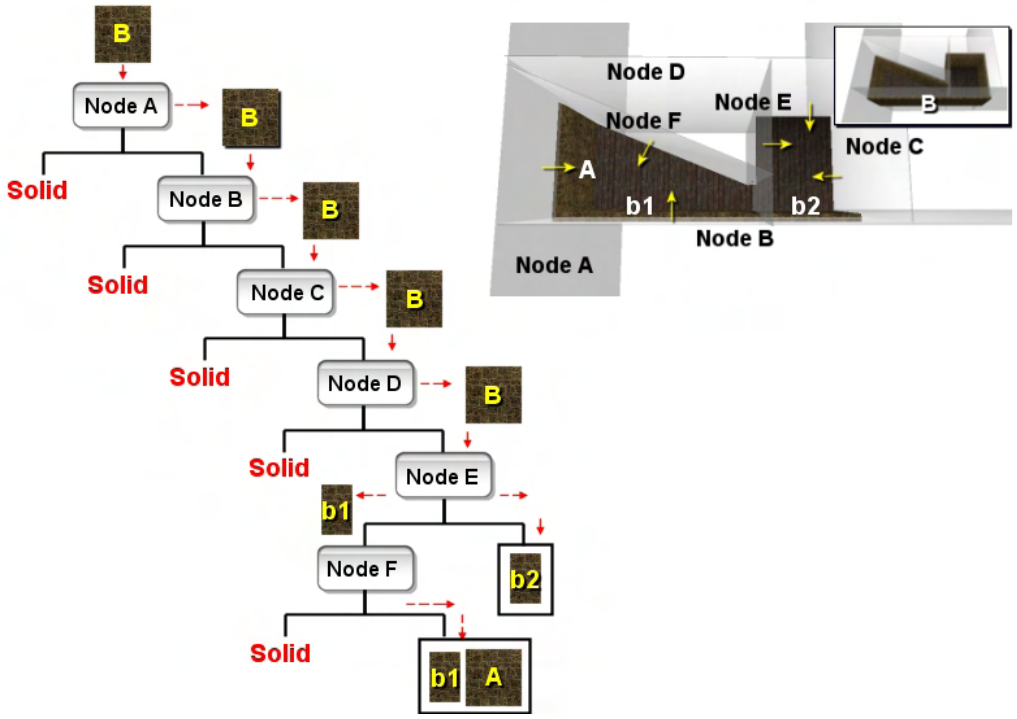

Figure 16.84

Looking at the diagram we can see that polygon B is also contained in node C's frontspace so is passed down the front into node D. Once again, node D has polygon B contained in its frontspace, so polygon B is passed into the front child of node D, which is node E.

At node E polygon B is found to be spanning the plane and is therefore split into polygon fragments b1 and b2. The original polygon B is deleted. Polygon b2 exists in the frontspace of node E so is passed into its front child. As no front child exists however this must mean that polygon b2 has entered an empty leaf attached to the front of node E. Polygon b1 is passed down the back of node E where it arrives at node F. Polygon b2, when classified against node F is found to be contains entirely in its frontspace and is therefore passed down the front of F where it gets added to the leaf that exists there. Polygons A and b1 now both exist in the empty space leaf attached to the front of node F.

Next we pass polygon C into the tree.

As Figure 16.85 clearly shows, as polygon C is passed down the tree it is found to exist in the front halfspaces of nodes A, B, D and E. This means it eventually gets added to the leaf attached to the front of node E.

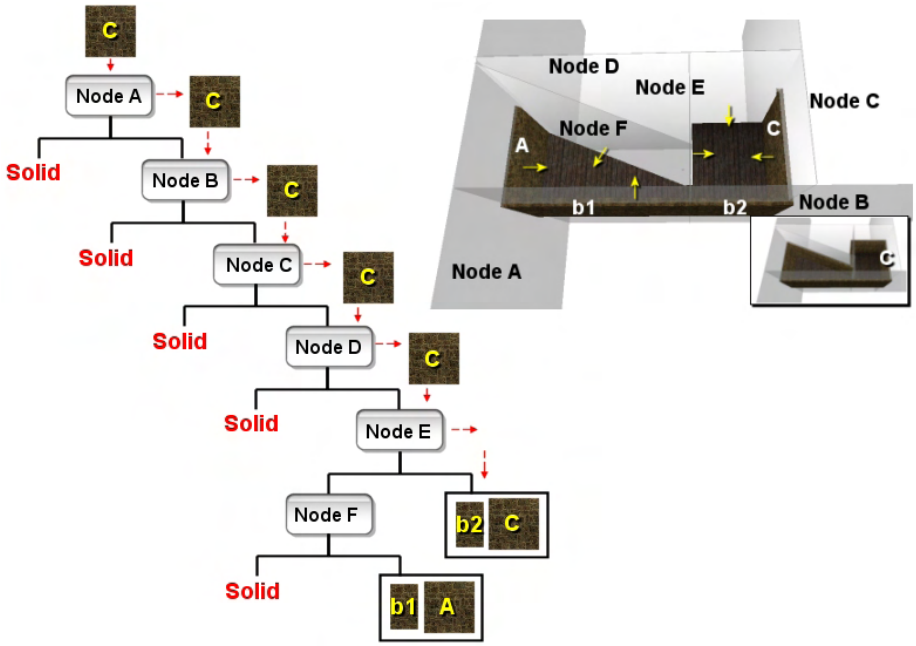

Figure 16.85

Things are looking very good at this point. No polygons have been added to back leaves and so far every polygon we have added has been added to one of two leaves. This is in keeping with what we discovered about this level when we discussed the convexity properties of the BSP tree. You will recall we used this example geometry and showed how the BSP tree would carve the geometry up into two leaves. This certainly seems to be the case. This does not mean that the tree only has two leaves; it means that it will only have two leaves that contain geometry (i.e., two leaves that are situated in front of a node).

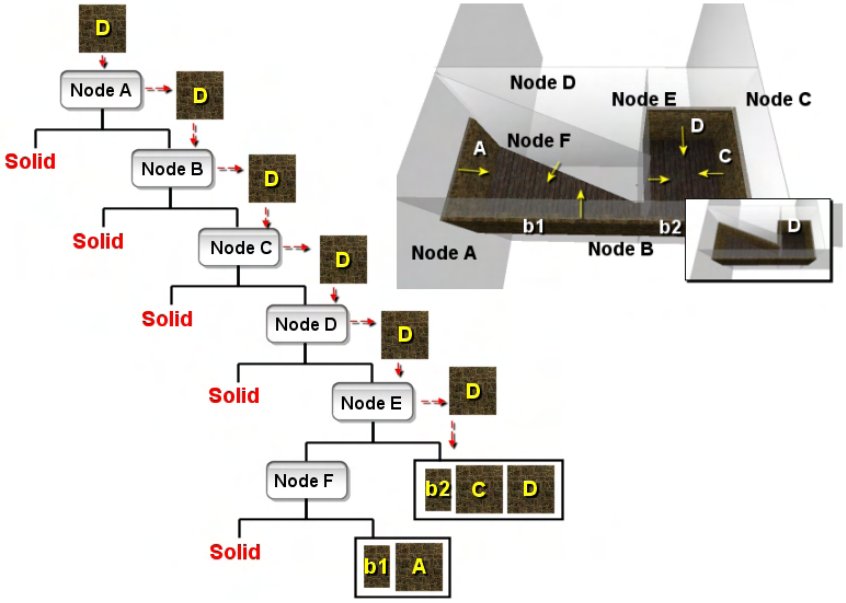

Figure 16.86

Passing polygon D down the tree we see an identical route being taken. By looking at the geometry in Figure 16.86 we can clearly see that polygon D is in the frontspace of planes A, B, C, D and E which results in the polygon being added to the leaf in the frontspace of node E. In the tree diagram we can see that this is the exact classification that happens when polygon D is passed down the tree. Polygon D is added to a front leaf which already contains polygons b2 and C.

Figure 16.87 shows the route that the penultimate polygon (E) takes though the tree. It is classified in the frontspace of nodes A, B, C, D, and E. Of course, node E is the node that was created from this polygon during the building phase and as such, we know it will get passed down the front of such a node. This also clearly demonstrates how this forces polygon E to

eventually be assigned to an empty space leaf that the node plane normal (and the polygon normal) is facing into.

We can see at this stage that the front leaf of E is complete and contains all the polygons that bound that leaf and face into it. All the polygons for this leaf are shown in the square inset in Figure 16.87.

Finally we have polygon F to send through the tree whose route and eventual leaf placement is depicted in Figure 16.88.

Polygon F is found to be in the frontspace of nodes A, B, C and D and is therefore passed down the tree into node E. At node E the polygon is found to be in the backspace of the node, so is passed down the back of E into node F.

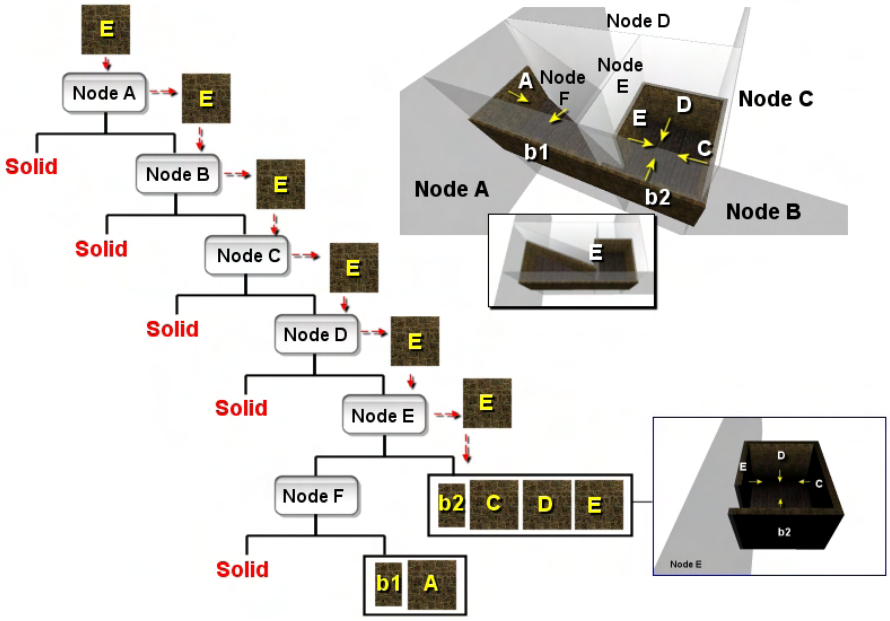

Figure 16.87

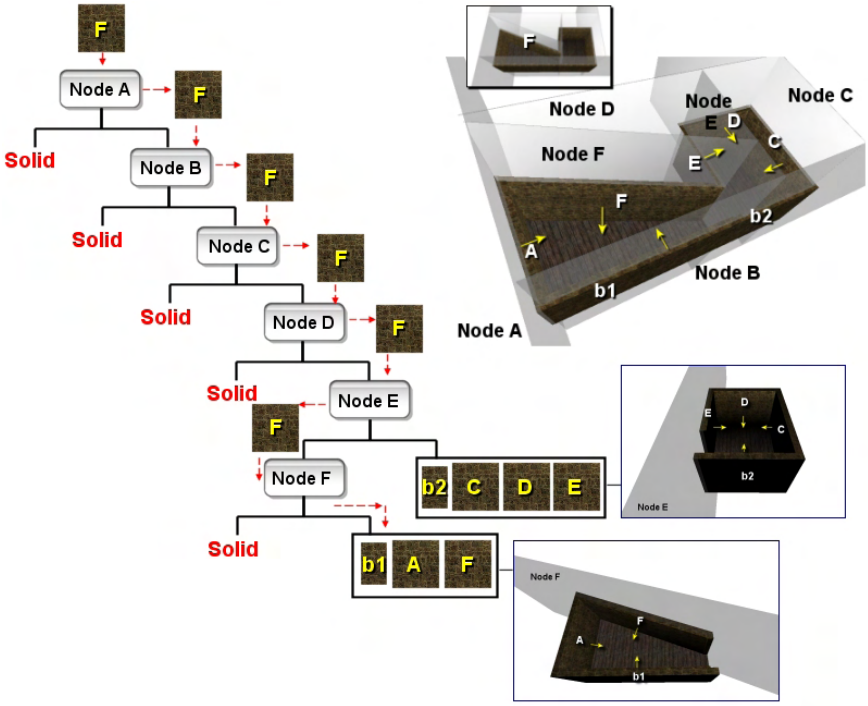

Figure 16.88

At node F, polygon F is clearly going to be found to be co-planar and same facing with the node since this was the polygon that was used to create this node. As we know, a polygon is always passed down the front of a node whose plane it was used to create, ensuring that the polygon ends up in an empty leaf which the node plane normal is facing into. We can see that this is the case in Figure 16.88. At node F, polygon F is passed down the front where it is added to the leaf that exists there. This leaf contains polygons A, b1, and now F, forming the second convex area that the non-convex geometry has been broken into.

Figure 16.88 shows our final tree which has been compiled such that if ever we traverse into a back leaf, we know we have reached solid space.

Figure 16.89 depicts our compiled tree along with three positions labeled A, B, and C. We can see in the top right image that points A and B are in solid space because they lie behind the polygons and have no line of sight with the front of any polygons in the level. Point C is in empty space as it is contained within the rightmost populated leaf. The tree diagram demonstrates what happens when we drop these three points through the tree and track their progress as they are classified against each node plane and sent down the front or back of each node depending on the classification result. As we can see, the tree gives us the correct result and verifies not only that two of these points are in solid space and one of them is in empty space, but it also tells us exactly in which solid and empty regions of the scene these points reside.

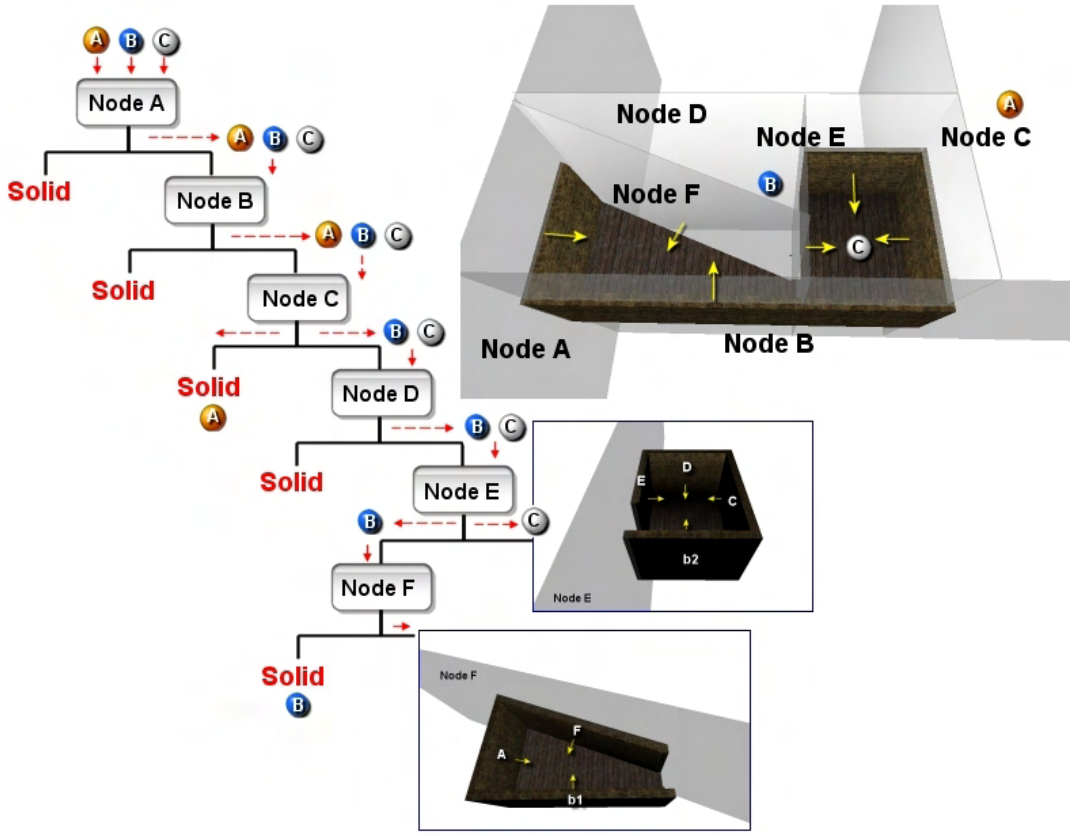

Figure 16.89

You should now be able to understand the above diagram and understand the reasons for each point's journey through the tree. As the tree shows, there are only two empty regions in this scene in which the player would normally be allowed to be located -- the empty leaf bounded by inward facing polygons b2, C, D and E (down the front of node E) and the empty leaf in front of node F bounded by inward facing polygons A, b1, and F. We can think of the polygons as providing the barrier between empty space and solid space and the means by which we stop one flooding into the other. If illegal geometry is supplied to the compiler that is exactly what will happen. We will end up with areas of space that are ambiguous because they exhibit traits that would classify them as being both solid and empty space. We

will look at some examples of illegal geometry in a short while and examine how it corrupts the solid/empty integrity of the tree.

16.3.4 Building the BSP Solid Leaf Tree Compiler

In our discussion so far we have discussed (for educational purposes) compilation of a leaf tree in two different stages. In the first stage we used the input polygon list to build the tree of nodes in the exact the same way we did when constructing our BSP node tree earlier in the lesson. However, we have assumed that once the polygon has been selected for a node it is discarded from the list. At the end of the first stage, we will have built an empty BSP tree (i.e., a BSP tree which contains no polygon data in its leaves). We then looked at how we could collect these polygons at the leaves during a second pass, where each polygon is sent down the tree and clipped to the nodes. The polygons eventually pop out at leaf nodes and these are the nodes to which the polygons are assigned. Of course, there is no reason to do this all in two separate passes as doing so would be inefficient. When constructing the tree, we have the polygon data at our disposal, so there is no reason why we cannot pass the polygons down the tree, clip them to the nodes, and collect them at the leaf nodes during construction. This allows us to implement the entire tree building process along with its static data storage in a single pass. This is how a BSP compiler usually operates and is how the BSP compiler that we will create in Lab Project 16.2 will operate.

Collecting the polygons at the leaf nodes during the build process has much in common with the way we constructed our quad-tree, oct-tree and kD-tree in the previous lessons. When constructing such trees, we generated an axis aligned split plane (or multiple split planes) at each node and divided the polygon list passed into that node into 2, 4, or 8 sub-lists depending on the type of tree being constructed. In the case of the kD-tree for example, at each node all of the polygons would be divided into two lists to be passed into the front and back child nodes. This same process continued until we reached a terminal node and all of the polygons that make it into that node were stored in a leaf structure that was attached to that node.

The same is going to be true with the BSP tree, although we have other things to consider, since the polygon list that makes it into each node is also being used to select split planes. In a nutshell, once a polygon has been selected as a splitter and a node plane created from it, it must still be passed down the tree, classified and potentially split against the remaining nodes in the tree (i.e., what was our ‘second pass’ earlier). The polygon that was used to create the root node for example, might be passed down the tree and split into multiple fragments, each assigned to a different leaf node. This is no different from how a polygon is passed down the kD-tree and repeatedly clipped to the nodes of the tree resulting in multiple fragments during the build process. However, what we must be mindful of is that once a polygon has been used as a split plane, it must never be selected as a splitter further down the tree by another node. This was not an issue in the node tree because as soon a polygon was selected to create a node plane, it was removed from the list and stored in the node. However, because we are continuing to pass the polygon data down the tree, we must make sure that it is not selected again. Furthermore, we must also make sure that if a polygon has been used as a node plane and later on down the tree it gets split by another node plane into two new child fragments, those child fragments must also not be used as splitters. This is obviously not very difficult to achieve; we can simply add a Boolean member to our

CPolygon structure called ‘BeenUsedAsSplitter’ (for example) which is set to true once the polygon has been used as a node plane. When this is passed down the tree into child nodes, each child node, when selecting a polygon from its input list to use as a split plane, will ignore any polygons in the list that have their ‘BeenUsedAsSplitter’ Booleans already set to true. This will prevent the polygon from ever being used as a split plane again until it eventually pops out in an empty leaf and is stored. If the polygon gets split further down the tree, we can simply copy the ‘BeenUsedAsSplitter’ status of the parent polygon into the two new child polygons so that they too will not be used as splitters as they continue their route down the tree. In fact, we must make sure that is the case for *all* co-planar same-facing polygons. That is, if a polygon is selected as a node plane, we must flag any polygons in the list that are co-planar and same-facing as having been used as a splitter too, so that they are not used to create additional planes down the tree. Since all co-planar polygons would generate the same split plane, it would be redundant to do otherwise.

In our final BSP compilation example we will bring these processes together to show how a piece of legal geometry can be compiled into a solid BSP leaf tree in a single pass.

In the leftmost image in Figure 16.90 we see a top down view of a simple scene (a room containing two triangular pillars). Once again, back face culling has been disabled so that we can see all the faces in the level and the yellow arrows depict the normals of each polygon and the node planes that they will create. The four outer walls form the walls of the room itself. These are facing into the room and as such, space behind these walls is considered solid space. In the center top section of the room there are two triangular constructs that are supposed to be simple pillars. These polygons all face out from the center of the pillar into the empty space of the room and as such, the areas bounded by the back faces of these pillars is naturally considered solid space. In the leftmost image we have placed a red ‘S’ to depict where solid space is assumed to be. In the rightmost image we show what this room might look like were the camera to be placed inside and we can see a portion of the two solid pillars at the far end of the room. A floor polygon has also been added in the rightmost image to give a better idea of what the room would ideally look like. However, to simplify the number of nodes we have to draw in our diagrams, we will ignore the floor and ceiling polygons and compile only the walls.

Figure 16.90

Each polygon in the leftmost image is labeled A through H, which will use to demonstrate the order in which each polygon will be selected to create a node plane at each step during the compilation process. As we have discussed, the polygons can be selected in any order and a valid tree will still be created. Of course, the number of leaves and polygons that result in the tree will be different, but the solid and

empty space will be retained and each leaf will represent a convex area described by the parent planes that intersect to form the boundary of that region.

Before looking at the tree diagram and following the compilation process step-by-step, Figure 16.91 demonstrates how the scene will be carved if the nodes are selected in the above order. It also shows where the empty leaves will be located, and can be used as a reference when we discuss the tree diagram that follows it.

Figure 16.92 depicts every step of compiling this level into a solid BSP tree and collecting the polygon data at the leaf nodes in a single phase.

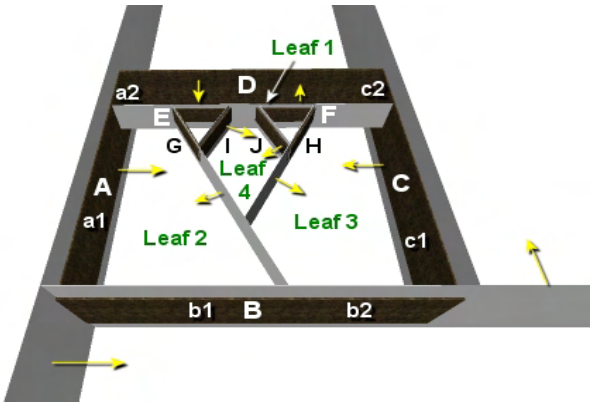

Figure 16.91

The polygon list passed into to the compiler contains polygons A through J. Polygon A is selected as the splitter first and its plane stored in the root node. Polygon A (along with any co-planar polygons) is marked as having been used as a splitter. Polygons that have already been used as splitters are highlighted red in Figure 16.92.

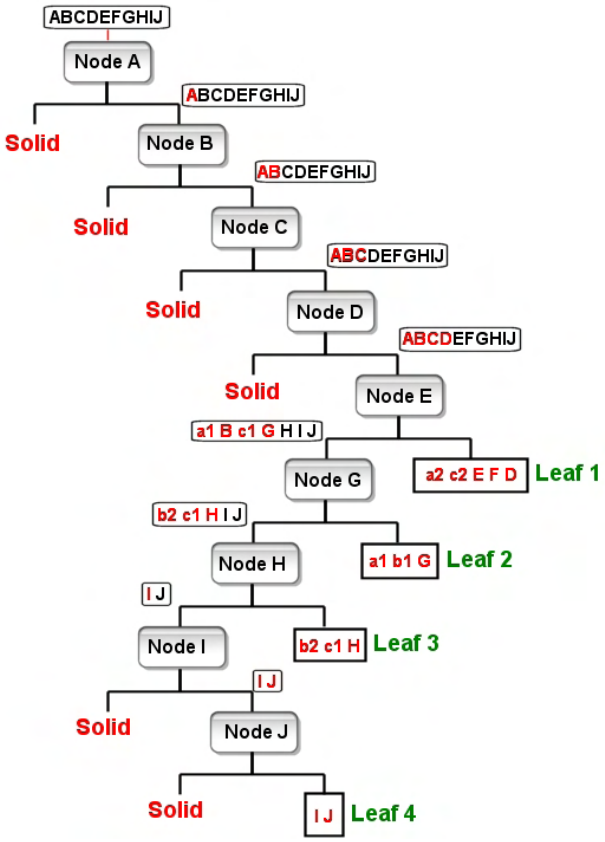

Figure 16.92

Every polygon classified against node A is found to exist in its front space, added to the front list, and passed down the front of the node. As no polygons made it into the back list of node A an empty leaf is created there, which we know will represent solid space. At the front child of A, a splitter is selected so a choice is made from polygons B through J. Polygon A is ignored by the splitter selection process as it has already been used. Polygon B is selected in this example and is marked as having been used as a splitter. All the polygons (**including A**) are classified against node B and are added to the front list. No polygons exist in the back list of node B so an empty (solid) leaf is created there. The polygons in the front list prompt a new child node to be created down the front of B and this time the selection for a splitter ignored polygons A and B as they have already been used. This process continues down to node E where we can see at this point, nodes A,B,C,D and E have been used as splitters. At node E, polygons A through J are classified against the node plane and two lists are created. Furthermore, polygons A and C span node plane E and are therefore split into polygons a1,a2 and c1,c2 respectively. The back list of node E contains polygons a1, B, c1, G, H, I and J and the front list contains polygons a2, c2, E, F, and D. Notice however that because polygons A and C have already

been used as splitters before they were split, the status of their parents is carried over into the children. Polygons a1, a2, c1 and c2 are all highlighted red, indicating they have already been used as splitters and should not be selected again. We can see in Figure 16.92 that when the front list is passed down the front of node E, every polygon in this list has already been used as a splitter and therefore, we have no more nodes to create down this side of the tree. When this is the case we know it is time to create a leaf and that every polygon in this list must lay on the boundary of a convex area. These polygons are added to Leaf 1 which is attached to the front of node E.

The back list of node E contains polygons a1, B, c1, G, H, I and J. These have not yet all been used as splitters so a new child node still needs to be created down the back this node. From this list, only polygons G, H, I, and J are considered as node plane candidates as they are the only ones that have not yet been used as splitters. In this example, node G is chosen next which splits polygon B into b1 and b2 as shown in Figure 16.94. When all the polygons are classified against G we end up with a front list containing polygons a1, b1 and G and a back list containing polygons b2, c1, H, I and J. As all the polygons in the front list have been used as splitters a new leaf is created down the front of node G and polygons a1, b1 and G are added to it.

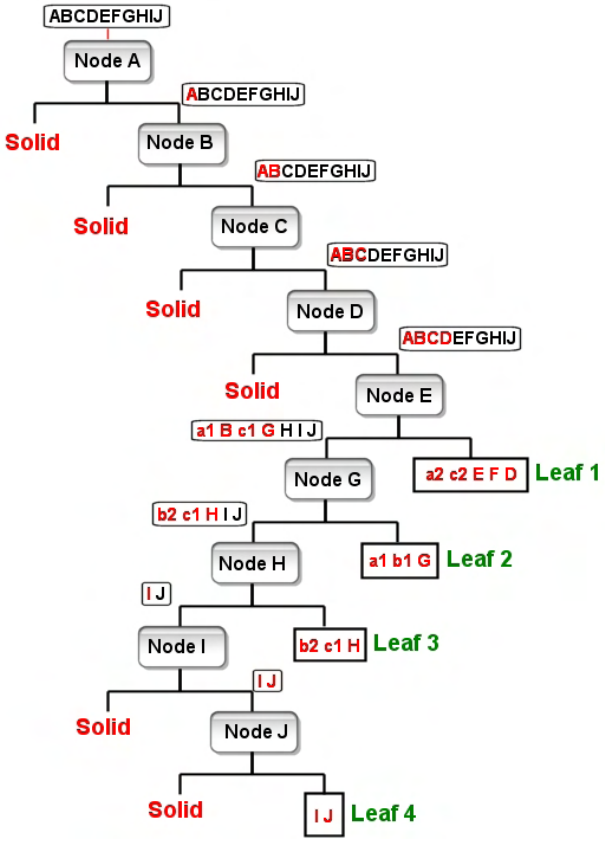

Figure 16.93

In the back list of node G we have three polygons which have not yet been used as splitters: H, I and J. Polygon H is selected next. When the remaining polygons (b2, c1, H, I and J) are classified against node H we end up with a front list containing polygons b2, c1, and H which have all been used as splitters. This means that these polygons are added to a new leaf (leaf 3 in the diagram) which is attached to the front of node H.

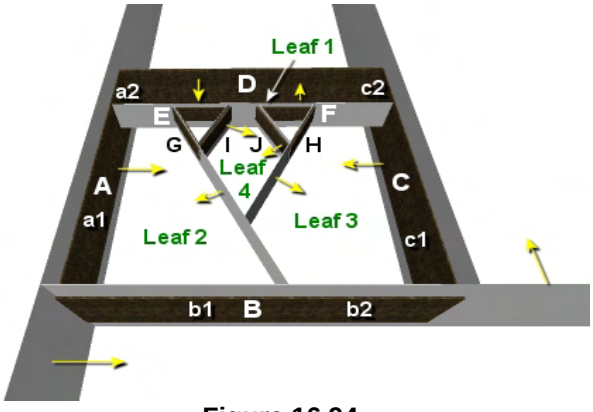

Figure 16.94

The back list of node H contains polygons I and J which have not yet been used as splitters. Polygon I is selected next to create node I. Both of these polygons exist in the frontspace of node I, so a solid leaf is created down the back of node I. The polygon list passed into the front of node I contains polygons I and J and only J has not yet been used as a splitter. Thus J is selected next and marked as having been used. These polygons are then classified against node J and both found to exist in the front halfspace. This means the creation of a solid leaf behind node J. As the polygons in the front list have now all been used as splitters we have no

more nodes to create and polygons I and J are added to a new empty leaf which is attached to the front of node J.

We have now just compiled the complete solid leaf BSP tree on paper. Before moving on, study Figures 16.93 and 16.94 and make sure you fully understand how the tree was constructed and where the solid and empty areas are. Notice how the polygons contained in the leaves in Figure 16.94 marry up with the polygons that are shown in the front leaves in Figure 16.93. Notice as well that empty space is always the region of space that has the polygon normals facing into it and how solid space is always separated from empty space by the backs of polygon along its boundaries.

Let us now examine some placeholder code that could be used to compile a BSP tree. For the exact code, please consult the accompanying workbook and lab project. The code shown here is just to demonstrate the basic concepts and logic that must be employed in a solid leaf BSP compiler.

This demonstration code assumes that a class exists called CBSPTree and that we are showing only the details of the compilation functions. It is assumed that before the CBSPTree::CompileTree function is called by the application, all static polygon data that should be compiled into the tree has been registered with the tree and added to the tree's linked list of CBSPPolygon structures pointed at by the member variable m_pFaceList. The CBSPPolygon structure is assumed to have a 'UsedAsSplitter' member that will be set to false for all input polygons prior to the commencement of the compilation process. As discussed, this Boolean member is set to true when a polygon is used as a node plane or if it is found to be co-planar and same facing as a node plane.

Finally, it should be noted that just because the leaves of the BSP tree (and the nodes) no longer represent regions that can tightly fit into an axis aligned bounding box, we can still store AABBs at each node and use the same hierarchal bounding box tests for hierarchical visibility determination and collision querying as implemented in the previous lesson. It should also be noted that because the leaves are no longer box shaped volumes, the bounding box we store at the node will no longer tightly bound the leaf in the typical case.

Imagine for example a leaf that was shaped like a view frustum (see Figure 16.95). We can see that the bounding box that was compiled for the leaf would be a loose fit. It is possible during a collision query for example, that the collision volume would intersect the bottom near corner of the leaf box (the minimum world extents corner of the leaf's bounding box). In such a case the leaf itself would not be inside the query volume (only its box would) but it would return true for a collision. In such a case, the polygons in the leaf would be tested needlessly for collision. However, this is certainly preferable to testing all the polygons in all the leaves and fits in with the visibility system and the collision querying system we have used for the other tree types.

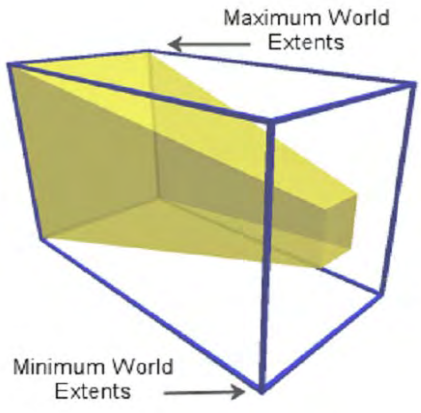

Figure 16.95

The top level function in this example is called CompileTree which simply creates the root node and invokes the recursive compilation process by calling the BuildBSPTree function. This function is passed the newly allocated root node and a pointer to the head of the polygon linked list.

```
HRESULT CBSPTree::CompileTree( )
{
    // Validate values
    if (!m_pFaceList) return BCERR_INVALIDPARAMS;

    m_pRootNode = new CBSPNode;

    // Compile the BSP Tree
    BuildBSPTree( &m_pRootNode, m_pFaceList));

    // Success
    return BC_OK;
}
```

The BuildBSP tree function has the task of populating the node with a separating plane that will be chosen from the list of polygons passed into the node. Only polygons in the list that have not yet been used as a splitter will be considered as a separating plane for this node.

```
HRESULT CBSPTree::BuildBSPTree( CBSPNode *pNode, CBSPPolygon * pFaceList )
{

    CBSPPolygon     *TestFace  = NULL, *NextFace      = NULL;
    CBSPPolygon     *FrontList = NULL, *BackList      = NULL;
    CBSPPolygon     *FrontSplit = NULL, *BackSplit    = NULL;
    CBSPPolygon     *Splitter   = NULL;
    CLASSIFY      Result;
    int           v;

    // Select the best splitter from the list of faces passed
    Splitter = SelectBestSplitter( pFaceList,
                                   DEF_SplitterSample,
                                   DEF_SplitHeuristic);

    if (!Splitter) { Error has occurred so do cleanup here }
```

We saw earlier in the node tree discussion that the SelectBestSplitter function is passed a list of polygons from which it will select one that should be used to create the node plane for the current node. The final two parameters to this function control how many polygons should be sampled in this test and the ‘splits versus balance’ heuristic that should be used when selecting the polygon. In the above code, the final two parameters to this function are assumed to be variables or #defines that you would like used for these values. The SelectBestSplitter function will have been slightly modified from the node tree version in that it must now ignore any polygons in the passed list which have previously been used as splitters (i.e., have their ‘UsedAsSplitter’ Booleans set to true). However, they will still be classified against each potential splitter candidate and contribute to the scoring of the balance versus splits heuristic. After all, just because a polygon has been used as a split plane does not mean that it will not get split into multiple fragments by node planes selected further down the tree during the building process. We will not show the modified code here to the SelectBestSplitter function as the full source

code will be discussed in the accompanying workbook. However, just know that all we have done is modified the outer polygon loop so that any polygons that have been used as splitters are not considered for a new split plane.

The function returns a polygon. In this example code we will assume that each CBSPPolygon also stores the polygon's plane and as such we can simply fetch the plane from the polygon and store it in the current node being visited, as shown below. We also set the returned polygon's (Splitter) UsedAsSplitter Boolean to true so it, or any fragments it gets split into, will never be used to create another node.

```
    // Flag as used, and store plane
    Splitter->UsedAsSplitter = true;
    pNode->Plane = Splitter->Plane;
```

Now that we have the separating plane stored at the node our next task is to loop through every polygon in the list and classify it against this plane and add it to the front or back list for this node depending on the classification result. Any polygons that span this plane will be replaced by two split fragments that exist in each halfspace and will be added to their respective lists.

In the following code we first set up a loop to iterate through each polygon in the linked list. The polygon we are current testing against the node will be stored in the local variable 'TestFace'. We also store its plane in 'Plane' for easy access. Notice that (just as we did in the node tree) we also store a temporary pointer to the next polygon in the list so that we still have access to the next polygon to be processed even when the current polygon being processed is removed from the list. This is important as currently the only access we have to the next polygon in the list is via the current polygon's next pointer (TestFace->Next). If TestFace gets deleted from the list during a split operation or a leaf assignment, we will still need to access the next polygon.

```
    // Classify faces
    for (  TestFace = pFaceList;
           TestFace != NULL; TestFace = NextFace, pFaceList = NextFace )
    {
        // Store plane for easy access
        CPlane Plane = TestFace->Plane;

        // Store next face, as 'TestFace' may be modified / deleted
        NextFace = TestFace->Next;
```

Now it is time to classify the current polygon (TestFace) against the node plane to find out whether it is in the front or back halfspace, spanning, or on-plane with the node. If the current polygon's plane is the same as the plane of the polygon that was selected as a splitter, then we know we have a polygon that is on-plane. Otherwise, we classify the polygon against the plane as we normally do by using a function called ClassifyPolygon which accepts the plane we wish to classify against (which in this case is the plane that was used as the node plane) and the vertices of the current polygon being tested.

```
        // Classify the polygon
        if ( TestFace->Plane == Splitter->Plane )
        {
            Result = CP_ONPLANE;
```

```
        } // End if uses same plane
        else
        {
            Result = ClassifyPolygon( SplitterPlane ,
                                      TestFace->Vertices,
                                      TestFace->VertexCount,
                                      sizeof(CVertex));

        } // End if differing plane
```

Now we have the classification result of TestFace stored in the Result local variable. This will contain CP_ONPLANE, CP_SPANNING, CP_FRONT, or CP_BACK. Next we will enter a switch statement and take the appropriate action in each case.

If the result is CP_ONPLANE then we know that the vertices of the test polygon lay on the node plane but we do not know yet whether this polygon faces into the same frontspace as the node or has an opposing normal. As discussed several times throughout this lesson, this is important because if the normal faces in the opposite direction, it should be added to the back list. Otherwise, it should be added to the front list. In the next section of code we assume the implementation of a function called ‘SameFacing’ which compares the two normals passed in as parameters and returns true if they are facing into the same halfspace.

```
        // Classify the polygon against the selected plane
        switch ( Result )
        {
            case CP_ONPLANE:

                // Test the direction of the face against the plane.
                if ( SameFacing( Splitter->Plane.Normal , pPlane->Normal ) )
                {
                    // Mark matching planes as used
                    if (!TestFace->UsedAsSplitter)
                    {
                        TestFace->UsedAsSplitter = true;

                    } // End if !UsedAsSplitter

                    TestFace->Next  = FrontList;
                    FrontList       = TestFace;
                }
                else
                {
                    TestFace->Next  = BackList;
                    BackList        = TestFace;
                } // End if Plane Facing
                break;
```

As you can see, we pass in the node plane normal and the normal of the test polygon and if found to be equal we know we have a co-planar same-facing polygon. When this is the case we set its

UsedAsSplitter Boolean to true since using this polygon as a splitter further down the tree would be redundant as the scene has already been divided by the same plane. We also add the polygon to the front list by assigning the test face's next pointer to point at the current head of the list and then reassign the pointer to the head of the list to point at the test face. Essentially, we are just adding the polygon to the head of the front list. Notice in the above code however that if the normals are not facing in the same direction in the on-plane case, the polygon is added to the back list and its UsedAsSplitter status is unaltered.

The CP_FRONT and CP_BACK cases are delightfully simple. If the polygon is located entirely in the frontspace of the node then we just add its pointer to the front list of polygons being compiled. If the polygon is located in the backspace of the current node then we add it to the head of the back list currently being compiled for this node.

```
            case CP_FRONT:
                      // Pass the face straight down the front list.
                      TestFace->Next            = FrontList;
                      FrontList                 = TestFace;
                      break;

            case CP_BACK:
                      // Pass the face straight down the back list.
                      TestFace->Next            = BackList;
                      BackList                  = TestFace;
                      break;
```

When a polygon is found to be spanning the node it must be split into two child fragments just as was the case with the node tree. However, after we have created the two new child fragments, we must set their 'UsedAsSplitter' Booleans equal to the parent polygon status prior to the parent polygon being deleted. This will make sure that if the parent polygon has already been used as a splitter, this state is inherited by the children so that they are not selected as splitters later. As discussed, this would be redundant and would create many unnecessary nodes. Shown below is the CP_SPANNING case and the final section of the polygon classification loop.

```
            case CP_SPANNING:

                // Allocate new front fragment
                FrontSplit          = CBSPPolygon;
                FrontSplit->Next    = Frontlist;
                FrontList           = FrontSplit;

                // Allocate new back fragment
                BackSplit           = new CBSPPolygn;
                BackSplit->Next     = BackList;
                BackList            = BackSplit;

                // Split the polygon
                TestFace->Split( Splitter->Plane, FrontSplit, BackSplit);

                // Copy over status of parent into children
                FrontSplit->UsedAsSplitter = TestFace->UsedAsSplitter;
                BackSplit->UsedAsSplitter  = TestFace->UsedAsSplitter;
```

```
                // Remove original polygon
                delete TestFace;

                      break;

            } // End Switch

      } // End while loop
```

As you can see in the above code, two new polygons are created, FrontSplit and BackSplit. These are fed into the parent polygon's Split method along with the node plane. When the split function returns, FrontSplit will contain the polygon fragment that exists in the frontspace of the node plane and BackSplit will contain the fragment that exists in the backspace. Before deleting the parent polygon, we copy the value of its UsedAsSplitter Boolean into each of the children.

When the while loop shown above exists, we will have compiled a front list and a back list of polygons describing exactly which polygons should be passed down the front and back tree of the current node.

The first thing we do is test to see if the back list has any polygons in it and whether any of them have still not yet been selected as splitters. If there are still polygons in the back list which have not been selected then all is well and we know we have to create a new back child node and keep on creating nodes from this list. If the back list has a list of polygons which have all been used as splitters then we have a real problem. Under normal circumstances (were we compiling a basic leaf tree) we would just store the polygons in a back leaf, and we could certainly do that. However, we have also discussed that if we have been passed legal geometry, this situation should never occur. That is, back leaves will always be empty and we should never be in a situation where we have a list of polygons that have all been used as splitters existing at the back of a node. When this happens, we have been given illegal geometry and we run the very real risk that the solid/empty information will be corrupt. Now, normally if the artist has created the level without regard to the technology being used, then the level will be highly illegal and there is not much you can do except modify the source level to get rid of the offending geometry (we will discuss such techniques in a moment). However, it is sometimes the case that the geometry was defined in such a way that it is technically legal but due to floating point accumulation errors or perhaps slightly sloppy object placement by the artist, a polygon's normal may face into a solid leaf. When this is the case, it often means this small sliver of polygon which has ended up in a back leaf can simply be deleted as it exists within the solid space of another object. This is the approach we take in this example. If any polygons end in back leaves, we will assume it is a floating point accumulation error and simply delete the offending fragments. However, while this works very well for compiling geometry that is essentially legal but with a few minor issues, geometry that has been assembled without any concern for solid/empty legality cannot be fixed by this simple solution. If the geometry is extremely illegal then this method could well delete half the level.

> **Note:** It is important that your project artist be aware of the rendering technology you are using and design the artwork in a compliant manner. Although we will discuss techniques for correcting illegal geometry in the next section, as well as gain a greater understanding as to what causes it, the artist must take responsibility for developing assets that can be used by the rendering solution you ultimately decide to employ.

In the following code we remove any illegal fragments that end up facing into back leaves. This assumes the implementation of a function called ‘DeletePolyList’ that, when passed the back list, will delete all the polygons contained within.

```
     // If No potential splitters remain, free the back list
     if ( BackList && CountSplitters( BackList ) == 0 )
     {
        // Remove illegal faces
        DeletePolyList (BackList);
        BackList = NULL;

     } // End if No Splitters
```

We can really not stress enough that the above section of code is absolutely no substitute for correct solid/empty level design. It fixes problems in situations where floating point inaccuracies introduced by the myriad of clipping operations that can be done on a polygon during the compile process cause its vertices to drift off the original plane and end up in solid space. But it is not a magic wand that can be thrown at any polygon soup with the expectation of compiling a perfect tree.

Now that we have the front and back lists of the current node compiled, we will construct a bounding box to be stored at that node that will bound all the polygons that exist down its front and back side. In the following code it is assumed that the CBSPNode structure has a function called CalculateBounds that, when passed two lists of polygons, will construct its bounding box to be large enough to contain the vertices of all polygons stored in those lists. Although this bounding box will not fit the geometry as tightly as the nodes of a quad-tree or an oct-tree (where the polygons have been clipped into box space regions), they can still be used to coarse cull entire branches of the tree during visibility and collision queries.

```
    // Calculate the nodes bounding box
    pNode->CalculateBounds( FrontList, BackList );
```

In the next step we test to see if any of the polygons in the front list are yet to be selected as splitters. If this is not the case then all the polygons in the front list have already been selected as splitters further up the tree and we have no more nodes to select. We also know that the polygons in this list will lie on the boundary planes of a convex region of empty space (an empty leaf). The polygons will also be facing into this empty leaf so our task is simple: create a new leaf, add the polygons to it, and attach it to the node’s leaf member. If there are still polygons in the front list that have not yet been selected as splitters then more subdivision must occur down the front of this node. When this is the case we create a new node, attach it to the current node’s Front pointer and recur into that node with the front list.

```
    // If all splitters are used in frnt list create front leaf
    if ( CountSplitters( FrontList ) == 0 )
    {
        // Add a new leaf and store the resulting faces
        CBSPLeaf * FrontLeaf = new CBSPLeaf;
        pNode->Leaf = FrontLeaf;
        CBSPLeaf->AddPolygons ( FrontList );
    }
    else
```

```
    {
        // Allocate a new node and step into it
        CBSPNode *pFrontNode  = new CBSPNode;
        pNode->Front          = pFrontNode;
        BuildBSPTree( pNode->Front, FrontList );

    } // End If FrontList

    // Front list has been passed off, we no longer own these
    FrontList = NULL;
```

When we reach the bottom of the above code, all children down the front of the node will have been created and all the polygons in this node's front list will have had their pointers stored in leaves. This means we should not delete the polygons stored in the front list since their pointers have been copied into other locations; we can simply set the front list pointer to NULL.

What may seem strange in the above code is that we assign the front leaf to a node member called 'Leaf'. As a node can have both front and back leaves, should this not be called 'FrontLeaf' instead? Well, we could, but since we know for a fact that our BSP tree will never store polygon data in back leaves, why bother creating empty leaf structures and attaching them to nodes when nothing will ever be stored in them? Instead, we will simply make the node's Back pointer, which normally points to a back child node, dual purpose. If this member is not NULL then it means there is a child node attached to the back of the current node. If this pointer is NULL, it must mean a leaf exists down the back of this node. However, all we need to know is that a solid space leaf is represented by a NULL pointer down the back of a node and we have all the information we need. Therefore, the only leaves we ever actually have to create and store information for are front leaves, which will be pointed to by the node's Leaf member. If traversing the tree we find that we need to traverse down the back of a node that has its back node pointer set to NULL, we know that we have traversed into solid space. Here is the following and final section of the compilation function.

```
    // If the back list is empty flag this as solid
    // otherwise push the back list down the back of this node
    if ( !BackList )
    {
        // Set the back as a solid leaf
        pNode->Back = BSP_SOLID_LEAF;
    }
    else
    {
            // Allocate a new node and step into it
            CBSPNode *pBackNode = new CBSPNode;
            pNode->Back = pBackNode;
            BuildBSPTree( pNode->Back, BackList);

     } // End If BackList

    // Back list has been passed off, we no longer own these
    BackList = NULL;

    // Success
    return BC_OK;
```

```
}
```

As you can see, if there are no polygons in the back list we know there must be a solid leaf behind this node so we set the back pointer to NULL. Otherwise, we need to further subdivide the space behind this node and we create a new node, attach it to the current node's Back pointer, and recur into the back child with the back list.

We have just examined everything involved in writing a solid leaf BSP compiler. This code will generate a BSP leaf tree which can be traversed like any other tree to perform visibility and collision queries. The fact that we have stored bounding boxes at each node also allows us to use the same AABB hierarchical queries on the tree as before, although we may sometimes end up traversing into leaves where the geometry does not intersect the query volume. As discussed earlier, this is because the bounding box of a node will not be a tight fit around its geometry. Therefore, it is possible that a ray for example, may be determined to intersect the bounding box of a leaf (or node) even if the ray does not intersect the convex region of the leaf. Of course, this simply means that we may end up testing polygons in a leaf that are not actually contained in the query volume in some circumstances. The same frustum culling traversal can also be performed on the tree although once again, because of the loose fitting bounding boxes around the nodes, we may find that we traverse into nodes and render some leaves that are not actually contained within the frustum.

When we consider that the polygon aligned solid leaf BSP tree will on average create much larger trees than quad-trees or kD-trees for example, one might imagine why this tree would be favored over our previous tree types. To be clear, if all we were going to do is plug our solid leaf BSP tree into the leaf bin rendering system we developed in the previous lesson, this would be a valid point. The BSP tree would be outperformed by those other trees in the typical case. However, because the BSP tree contains the solid/empty information, it makes CSG operations possible (discussed later in this lesson) and allows for very efficient line of sight tests to be carried out on large scene databases. Furthermore, and by far the most important feature, is that it allows us to construct a potential visibility set for our level which will increase the performance of our current rendering systems by an order of magnitude (in the case of a highly occluded level). Therefore, in the next lesson we will see how the BSP tree, coupled with the potential visibility set, will be our rendering technology of choice going forward and one of the core technologies that is carried forward into Module III when we start to construct our game engine.

16.4 Illegal Geometry and Hidden Surface Removal

It should be apparent at this stage that the 'solid' aspect of a solid BSP leaf tree is entirely dependant upon the geometry that is built by the artist and ultimately fed into the compiler. If the artist generates scenery in which the various different areas of the scene are not properly closed or bounded, then our ability to determine the correct nature of the space described by each leaf will be lost. While the geometry that is compiled is still a very important factor in whether or not the integrity of the solid/empty information is retained, there are solutions we can employ to ensure that this situation is less of an issue. In this section we will discuss exactly what illegal geometry is and how it can be avoided during the asset development phase. Illegal geometry is caused by a condition that can be summed up as follows:

"When the front of one or more polygons (or some part of them) can see the back of another polygon, we have illegal geometry. This means that the boundaries between solid and empty space have leaked into one another, making solid/empty space determination impossible."

Figure 16.96 shows the simplest case of illegal geometry. We have two isolated polygons positioned such that the front of polygon can 'see' the back of polygon B. If we look at the tree diagram to the right we can see that the following happens:

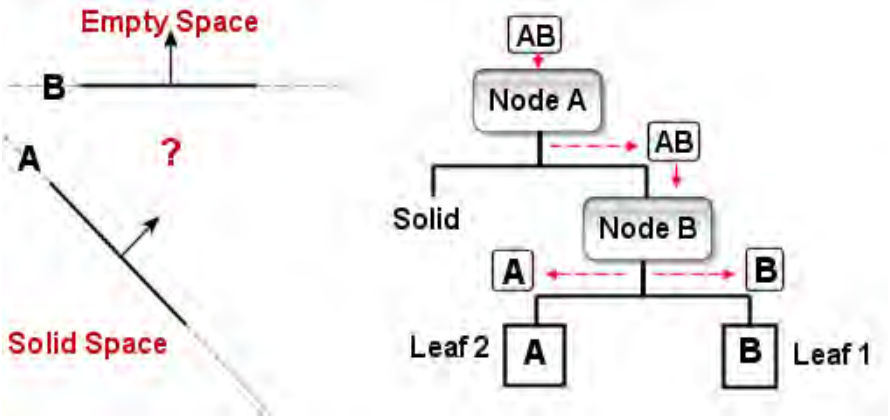

Figure 16.96

At the root node polygon A is selected as the splitter and when classified against this node plane, polygons A and B are sent down the front where B is selected as the next node. Behind node A no polygons exist in the back list so this is correctly identified as a solid leaf. Remember, solid space is the space behind the polygons. At node B we classify the polygons and find that polygon A is added to node B's back list and polygon B is added to the front list. As polygon B has already been used as a splitter this means that to the front of node B is a leaf containing polygon B. This space is correctly identified as empty space. Remember, empty space is the space located in front of the polygons. However, polygon A is passed down the back of node B but has been used as a splitter, so what should we do with it? We could delete it but that would make one of our polygons disappear and would describe the region of space between A and B as being solid space. This would be incorrect however as this space is in front of polygon A and therefore, should be empty space as it is the only space from which polygon A can be viewed. We could alternatively make this a back leaf and assign polygon B to it, but leaves with polygons assigned represent empty space therefore this would identify the region between polygons A and B as empty space. This is not correct either as in this space the viewer can see the back of polygon B, which would be removed during back face culling. The player should never be allowed inside regions of space where the backs of polygons can be seen. As you can see, this situation cannot be resolved and the region of space between polygons A and B cannot be added to any category. This is illegal geometry.

Of course, the above scenario is a little too simplistic as it is highly unlikely that any professional artist would ever construct a level which such glaring geometrical errors. However, there are ways to place geometry in a level that seem very sensible but which still cause illegal geometry, as shown next.

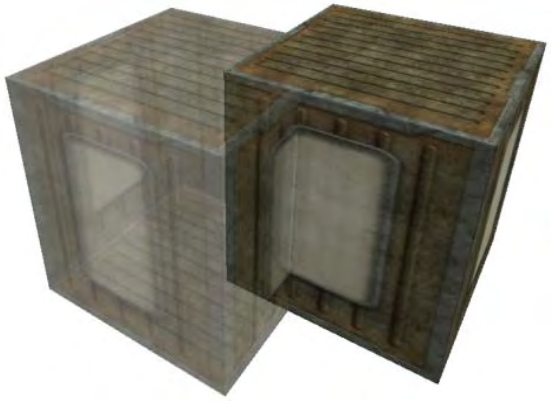

Figure 16.97

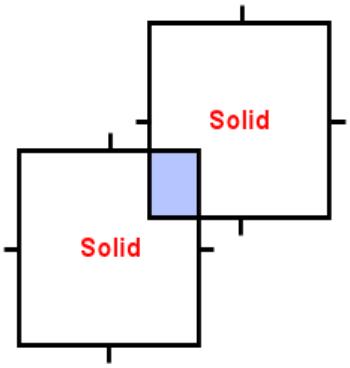

Figure 16.98

Imagine the scenario depicted in Figure 16.97 in which the artist has accidentally (or perhaps on purpose) overlapped two simple box shaped objects. The closest box has been rendered with alpha blending enabled so that we can more easily see that there are portions of the neighboring box intersecting its interior. Figure 16.98 shows the particular problem that our solid BSP leaf tree compiler would have in resolving this type of scenario during compilation. We know by experience that the space inside the two cubes should be defined as solid. However, due to the fact that some of the polygons intersect the interior space of each cube, we find a situation in which that same space which we know to be solid, exists in the front halfspace of one or more polygon fragments. That is, some portions of the polygons making up the boxes are front facing into the solid space of the other crate. This situation is one that we would commonly refer to as a *leak*. This is where solid and/or empty space – as defined by our tree and leaf layout – has 'leaked' into an area in which it should never have existed.

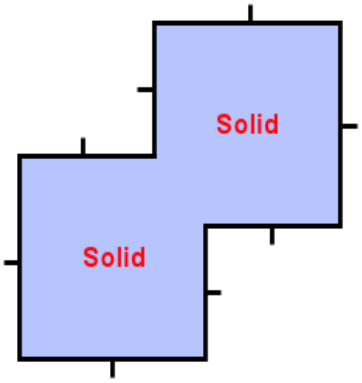

Figure 16.99

Figure 16.99 demonstrates the only possible arrangement of geometry in which this situation can be resolved. We can see here that the fragments of any polygons which are embedded in the solid space of either of the cubes have been removed. In doing, so we remove the ambiguity introduced by the erroneous front faces in solid space.

The process by which we go about removing these intersecting polygon fragments is called *hidden surface removal*. Put simply, this process is intended to remove any polygons that can never possibly be seen because they are contained within the solid space of other primitives in the scene. Not only can this remove a significant amount of overdraw in our application, it also takes care of the problematic situations outlined in this section. Something that you may have heard discussed in the past is the term 'Constructive Solid Geometry' (or 'Boolean Operations'). This term covers a multitude of topics, but in principal these techniques provide us with the means to perform various geometric operations on multiple objects. One example is the ability to merge the volumes of two primitives together in the cases where they might intersect.

In the next section we will see how we can use one of the techniques known as the 'union' operation to resolve many such types of problematic geometric situations prior to BSP compilation. This union operation is analogous to the hidden surface removal process depicted above and will help to ensure that we are able to create an accurate and very stable solid leaf BSP tree. Thus, even if the geometry does

contain such intersecting objects, the hidden surface removal techniques we will implement in this lesson will allow us to remove any polygon fragments that are found to reside in the solid space of another object. The GILES™ world editor can perform hidden surface removal on the entire level if you chose to select all brushes and then perform the union CSG operation on them. This will merge all the meshes in the scene into a single mesh, removing any polygon fragments that lie in solid space. However, if you are developing your levels in a package like 3D Studio MAX™, which does not employ the same HSR-oriented world building techniques, you may find that you create levels with many such hidden surfaces that would cause a BSP compiler to fail. Therefore, the BSP compiler we create in Lab Project 16.2 will also have an HSR processor that can be invoked as a pre-compile step to remove all such hidden surfaces and merge all meshes contained in the file into a single mesh which is then fed into the BSP compiler.

Although HSR techniques can remove hidden surfaces from within the solid space of an object, the individual meshes/brushes comprising the scene must be constructed from legal geometry. As long as all of the individual meshes comprising the scene can themselves be compiled into a solid leaf tree individually, we can perform a union operation to merge all these meshes into a single mesh with all hidden surfaces removed. However, if the individual components making up the scene contain intersecting/hidden surfaces, HSR will fail to fix the problem and the only cure is for the artist to fix this geometry manually.

Before we move into the final section of this lesson and discuss constructive solid geometry (a superset of hidden surface removal) we will look at some examples of legal geometry so that we are clear exactly how easy it is to create. Experience has shown that virtually every problem that a student has getting the BSP tree to operate and query correctly comes down to it being fed illegal geometry, and a misunderstanding of the various situations that cause illegal geometry during object placement in a level. By looking at some common examples of illegal geometry and how they can often be cured with the union CSG operation supported by many world editors and modelling packages, we will get a good feel for what to do and what not to do during the level building process.

Figure 16.100 depicts a scene created in the GILES™ world editor. It is a very simple level comprised of a room containing some pillars. It all looks pretty inoffensive until we examine how the level was created. The room itself was constructed by hollowing out a cube so that in the center of the cube we can paint the inward facing walls, floor and ceiling polygons with textures. All is well so far; the solid space of the room is contained between the polygons that form the interior and exterior sides of each wall. The outward facing polygons of the room can obviously not be seen in this image as we would have to walk outside for this to be the case, but it does not matter for this discussion. The room is perfectly valid geometry. It is a single mesh that respects the solid and empty space rules of construction.

What makes this geometry illegal is the placement of the four pillar meshes. Each pillar is constructed from three meshes: two square blocks that press against the floor and ceiling and a central cylindrical column. The cylinder is also resting up against the blocks. The blocks and the cylinder columns are closed meshes, so let us now see why this is a problem.

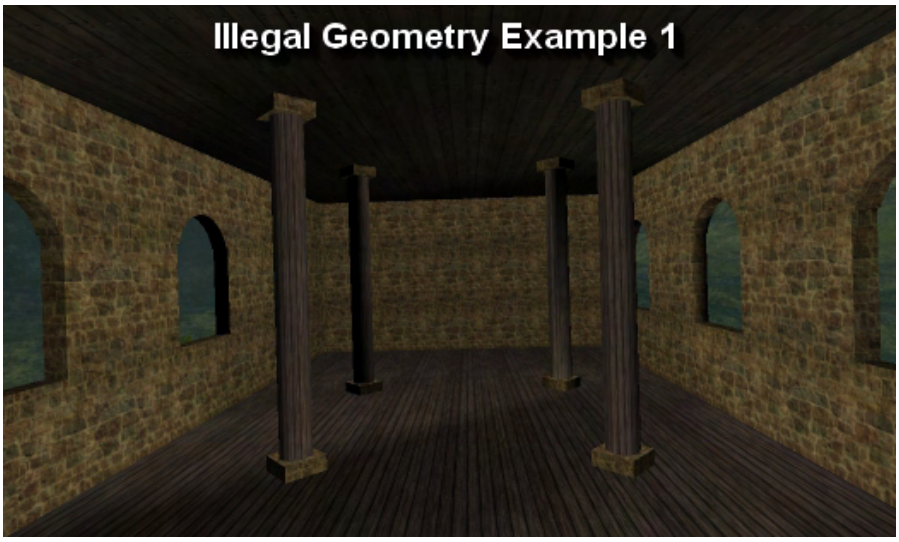

Figure 16.100

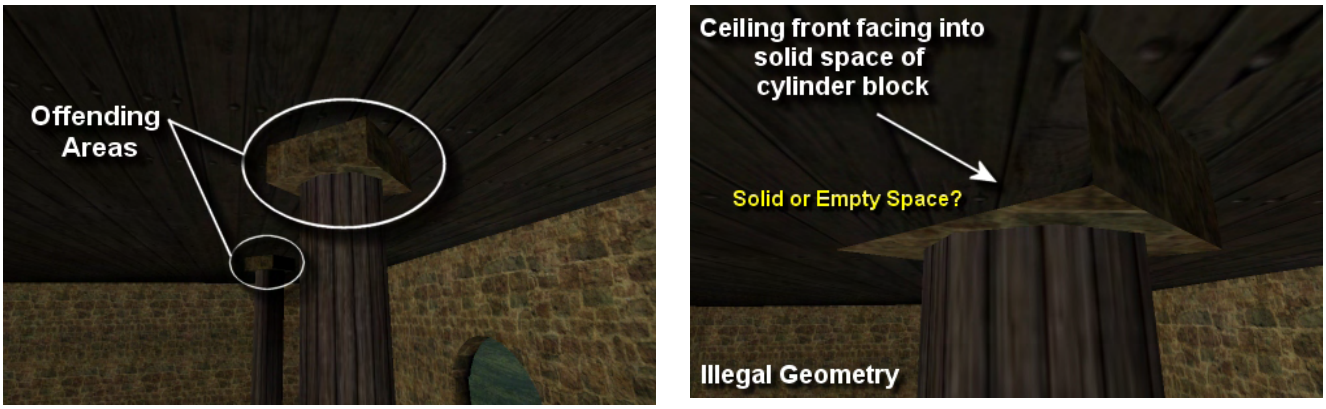

Figure 16.101

Figure 16.101 highlights the first problematic area of this scene. The pillar blocks themselves are pressed up against the ceiling, as shown in the rightmost image. As the top face of the pillar block and the roof polygons are co-planar, we have a situation where a section of the roof polygon is facing into the solid space of the pillar blocks. This is shown in the image on the right where we have removed a side face of the pillar block so that we can see what is happening inside. As you can see, the ceiling polygon is front facing into the solid space of the pillar block, which we know to be exactly what causes our solid BSP tree compiler to fail. Although it cannot be seen here, the top face of the pillar block would also be facing up into the solid space behind the ceiling polygons, so we have illegal geometry on two counts. Obviously, this will be the same situation for every cylinder block in the roof. The cylinder blocks at the bottom of each pillar will also have the same conflict with the floor polygon.

One very inelegant way to deal with this problem is to move the cylinder blocks ever so slightly away from the roof and floors so that empty space can flow between them. You may get away with this, but it certainly is not the answer we are looking for. Apart from being tedious for the artist to manually adjust everything like this, it may also happen that the user of our game will notice that the pillars are floating

in mid air. No, this definitely is not the way to go since this is a limitation we just can not live with. Luckily the hidden surface removal routines we will develop will come to the rescue by performing a union operation between the pillar block and the mesh of the room (which contains the roof polygon). The block will become part of the room mesh and the offending surfaces will be removed.

In Figure 16.102 we show the result of a union operation between the pillar block and the room mesh, which removes these hidden surfaces. As you can see, the section of the ceiling polygon that was contained inside (or co-planar) with the solid space of the pillar block has been carved away and although it cannot be seen here, so too is the top face of the pillar block that was pressed up against the ceiling.

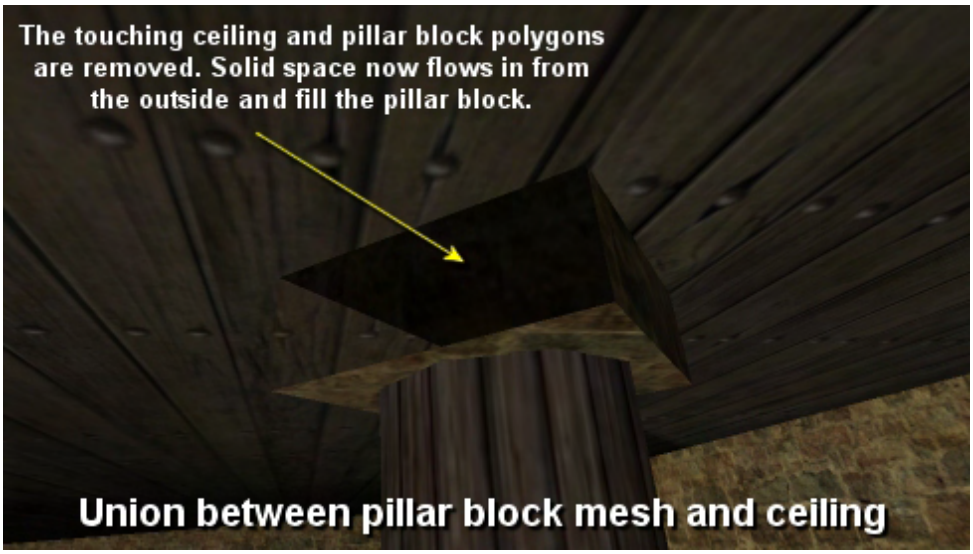

Figure 16.102

The pillar block and the room mesh have now been merged into a single mesh and the hidden surfaces have been removed. Solid space will now flow thorough this hole and fill up the inside of the block. Note that in this image we have removed the left face of the block so that we may observe what is happening inside. Obviously, if we were not to do this we would not notice any difference in the level. It is the *hidden surfaces* that have been removed by the union operation and since these polygons are hidden, we would not be able to visibly see that they have been removed.

Figure 16.103 illustrates where problems still exist. In this image, the front and back faces of the cylinder invisible so that we can see what is happening inside the solid space of the cylinder. As we can see, we have the same situation. This time, the bottom face of the block is co-planar with the top face of the cylinder (not seen here because of back face culling) which means the bottom face of the block is front facing into the solid space of the cylinder and vice versa. This problem can be resolved again by performing a union operation between the column mesh and the room mesh (which now contains the cylinder block after the previous union operation).

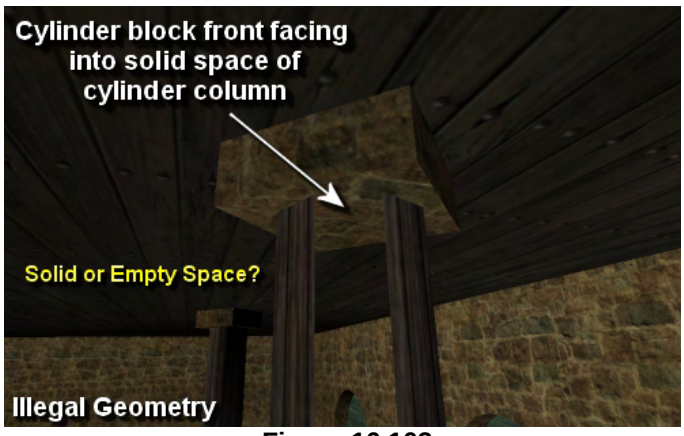

Figure 16.103

The results of this second union operation can be seen in Figure 16.104 where we note that the section of the bottom face of the pillar block that is facing into the cylinder's solid space is removed, and so too is the top face of the cylinder block. The cylinder block, the cylinder column, and the room geometry (walls, floors, ceiling, etc.) have now all been merged into one mesh with hidden surfaces removed.

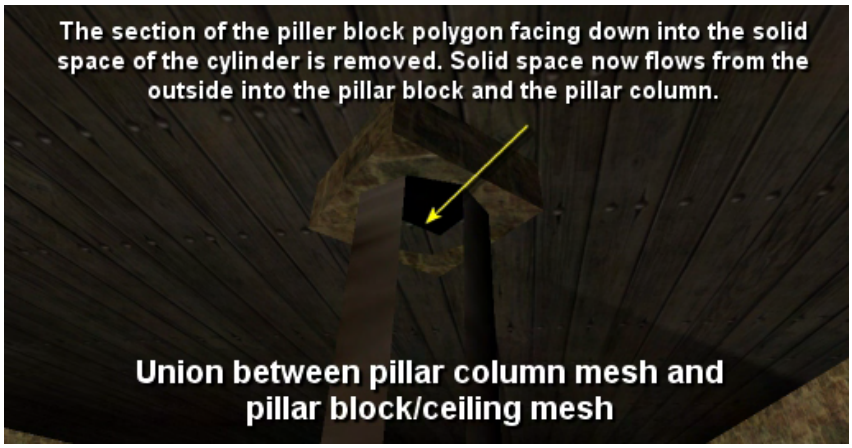

Figure 16.104

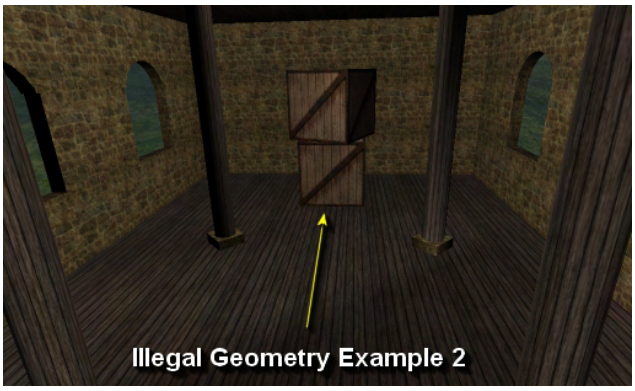
Once again we have made the front faces of the cylinder invisible so that we can see what has happened inside its solid space. Notice that the union operation has clipped a hole in the bottom face of the block which matches the dimensions of the cylinder column. Although it cannot be seen here, the top face of the cylinder has also been removed so that solid space flows from the outside, through the cylinder block and into the pillar columns. Solid space is still perfectly bounded by the backs of polygons and cannot leak out into empty space.

As Figure 16.105 shows, even if we select the all the cylinders and the room meshes and perform a union on them all to remove the hidden surfaces and correct these problems, illegal geometry can be caused by simply placing two crates in a room stacked on top of each other. This seems pretty harmless, but of course, if hidden surface removal (union) is not applied to these crates, the exact same geometry problems arise.



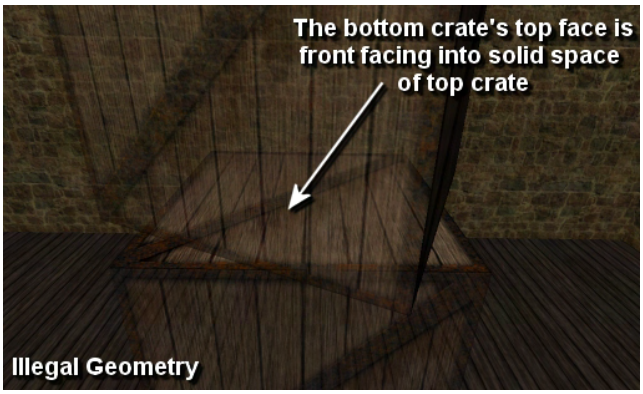


Figure 16.105

By making the polygons of the crates transparent in the rightmost image, the problem becomes immediately obvious. The top face of the bottom crate and the bottom face of the top crate are co-planar but facing in opposite directions. The top face of the bottom crate is facing into the solid space of the top crate and vice versa. Therefore, our HSR routines should also merge these two brushes/meshes together using a union operation to remove the offending hidden sections of the surfaces.

Figure 16.106 shows the result of performing a union on these two crate meshes into a single mesh.

We can see by making the faces of the top crate transparent that the entire section of the bottom crate's top face that was pointing into the solid space of the top crate has been clipped away and vice versa. These two crates are now a single mesh which is filled with solid space and whose outward facing polygons bound that solid space.

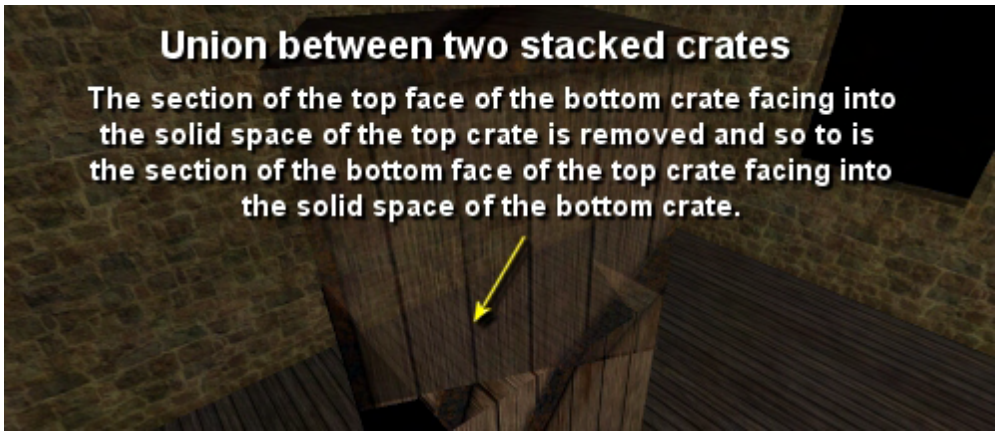

Figure 16.106

Of course, the same problem still exists between the bottom face of the bottom crate and the floor polygon of the room mesh on which it is resting. As Figure 16.107 illustrates, performing a union operation on our two crate mesh and the mesh of the room itself will remove the section of the floor that faces into the solid space of the crates and will remove the bottom face of the crate that faces into the solid space behind the floor.

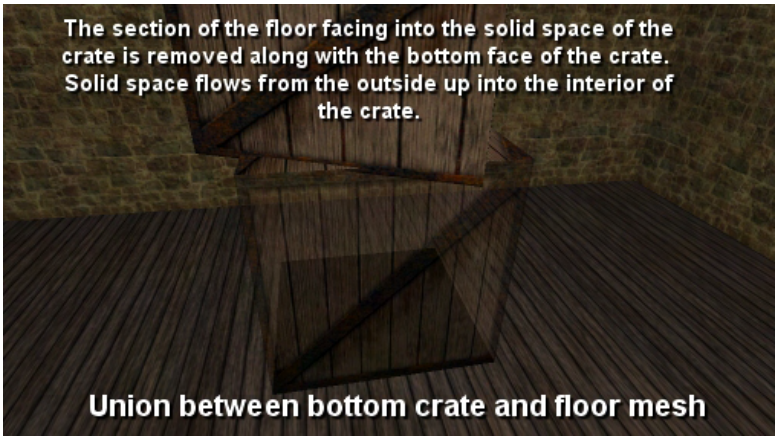

Figure 16.107

So we have seen how easy it is to create illegal geometry but we have also shown how in all these cases, HSR (union) comes to the rescue. The union operation is one of merging all the meshes that comprise the scene into a single mesh removing all hidden surfaces in the process. If the world editor/3D modeler of your choice does not support CSG and the union operation in particular, do not worry. We will discuss how to perform a union operation on your scene in the next section of this lesson and will also implement an HSR module in our BSP compiler in Lab Project 16.2. This HSR module will be invoked prior to the BSP compile to remove any hidden surfaces that exist in a multi-mesh environment.

Finally, before discussing CSG it is important to take a moment to strongly recommend that you spend a good deal of time thinking about which objects in your scene should be considered BSP geometry. Remembering that nearly every polygon you pass into the compiler will be used to create a node, we can imagine how placing a 10,000 polygon sphere in the middle of a room would create 10,000 nodes in the tree, each of which would split the polygons of the level into many tiny slivers. This would make for an extremely large tree that is slow to traverse and high on memory usage. Furthermore, it would raise the polygon count of the scene significantly.

It is quite common for only the core geometry of the level to be compiled into the BSP tree (e.g., walls, floors, ceilings, etc.) and for high polygon objects and room accessories such as furniture meshes and

décor to be assigned to the tree as dynamic/detail objects. For example, GILES™ has a property that allows you to flag a mesh as being a detail object which our BSP compiler will not compile into the tree -- it will simply write it back out to the final compiled file. When our BSP file is loaded, these detail objects can be loaded also and passed down the tree and assigned to the leaves in which they reside. This produces a much smaller and faster tree and is highly recommended in many situations.

> **Important Note:** To keep the tree small and stable, you should only be compiling your core geometry into the level. High polygon models used to populate the scene with furniture or décor should not be compiled and should be assigned to the tree as detail objects at run time.

Bearing this in mind, we might imagine how we could sidestep the entire illegal geometry problem in the previous examples by compiling only the original room meshes into a BSP tree. Once the BSP tree of the empty room has been compiled, the crate and pillar meshes could simply be assigned as detail objects to leaves in which their bounding volumes are found to reside. When these leaves are considered to be visible, the detail objects assigned to those leaves are also flagged as visible and rendered just as was the case with our previous tree types. If we were to take this approach, the only geometry from the previous example that would be compiled into the BSP tree is shown in Figure 16.108.

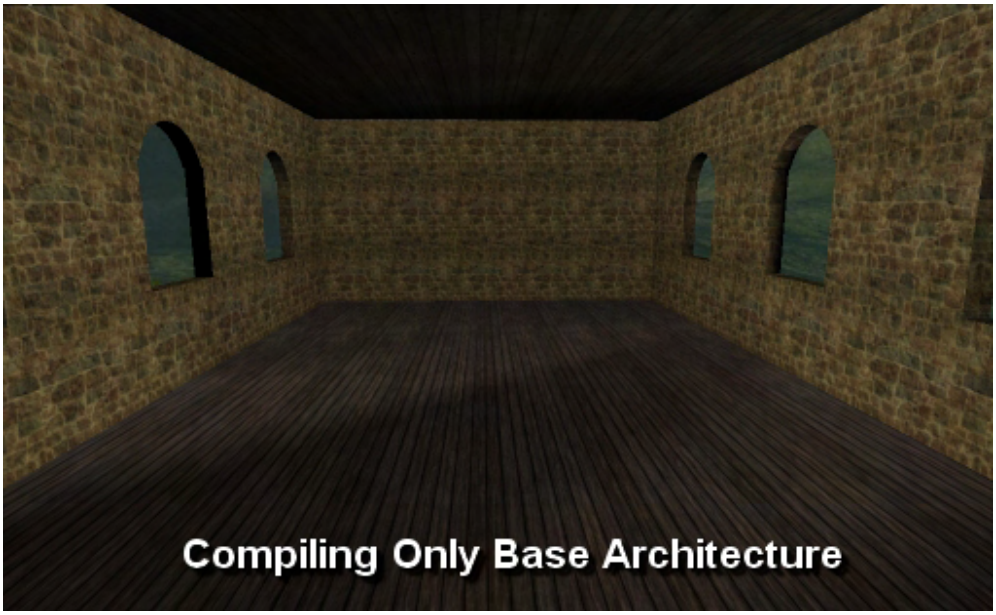

Figure 16.108

Of course, it is not always convenient or efficient to have to update the leaf assignments for objects that you know are static, so for simple static objects like crates and pillars, you may decide that you want to compile them into the tree, which means the HSR routines demonstrated above will have to be discussed and implemented. Fortunately, that is exactly what we are going to discuss in the next section.

16.5 Constructive Solid Geometry

In this section we will be examining the process known as Constructive Solid Geometry (CSG). Over the next several pages we will look at how to apply the BSP tree knowledge we have gained thus far when performing CSG and hidden surface removal (HSR). Our approach to CSG will require that the geometry we send through the compiler is *brush based*. This means that our level data must be made up of a set of enclosed hulls or primitives (e.g. cubes, cylinders, teapots, etc. – basically anything that is completely *solid*). This is the way that many of the most popular level editors work (e.g. WorldCraft™ or GILES™). As we alluded to earlier on in this chapter, hidden surface removal is used to ensure that our geometry is legal and is actually a logical extension of CSG. In fact, we basically get this support for free when we implement CSG functionality using our BSP Compiler.

There are many reasons why we would want to use CSG operations. One of the main advantages for anyone writing a BSP Compiler is the fact that we can perform Hidden Surface Removal (HSR) using the **union** operation. If you have ever tried to create a reasonably complex level using a package such as 3DStudio MAX™ and tried to compile it into a BSP tree, you will likely have learned that illegal geometry is quite commonplace. HSR takes care of most types of illegal geometry which crop up when designing a level. It simply clips away any parts of intersecting brushes which could cause the compiler to fail. The other advantage we achieve by adding support for CSG into our compiler or world editor is the ability to carve one brush from another using the **difference** operation. This allows us to easily carve doors or windows from a wall, or perhaps create other hollow objects (e.g. coffee cups, etc.) that retain their solid geometric properties.

We will discuss HSR in more detail a little later, but in order to do so we must first understand the basic principles involved in each of the 3 primary CSG operations.

16.5.1 CSG Operation Primer

Constructive Solid Geometry (often referred to as a Boolean Operation) is the process of building solid objects from other solids. The three CSG operators most often encountered are known as the Union, Intersection, and Difference operators. Each of these operators acts upon two objects and produce a single object result. By combining multiple levels of CSG operators, complex objects can be produced from any number of simple primitives. Due to the fact that we are basing our shape's 'solid' and 'empty' space on the information constructed by the BSP tree, we need not even ensure that these objects are convex to begin with.

The following set of diagrams illustrates the three CSG operations mentioned. As mentioned, although we are using simple primitives here the same principles apply with any shape we can create.

CSG Operations

We start off with our two brushes: a box and a cylinder. We can combine these two brushes in a number of ways in order to obtain various different results. You may have seen these operations elsewhere defined using their Boolean Operator names, so for future reference we have denoted these alternate names beside each operation heading.

Union (XOR)

This is the **union** of our two brushes. While it may seem as though they are simply placed on top of one another, in fact the union operation removes all polygons that fall inside the solid space of either brush. If we were to move the camera inside either of the brushes, we would see that any polygons (or fragments of polygons), which ended up in solid space are discarded. This operation represents the core of our HSR (Hidden Surface Removal) system. The **XOR** is basically the same as the Exclusive-OR operator seen in many programming languages. It simply keeps any area which does not share the same space (i.e. the parts of the box which lay outside the cylinder and the parts of the cylinder which lay outside the box).

Difference (NOT)

The **difference** operation is probably the most widely used of the three. Its purpose is to carve one brush from another. The difference (or carve) operation will result in different sets of polygons depending which brush you perform the operation with. For example, in this diagram we use the cylinder as the *cutting brush*, which basically subtracts the cylinder from the box. Only the parts of the box **NOT** inside the cylinder remain untouched. However if we turned the box into a cutting brush, it would leave behind the top half of the cylinder (since the bottom half lies inside the box, and is carved away).

Intersection (AND)

Here we see the **intersection** of our two brushes. The resulting geometry of the intersection operation describes only the area of the two brushes which were intersecting (i.e. only the parts of the box **AND** the cylinder which were intersecting remain untouched). This operation is not as widely used as the union or the difference operations, but is an alternative method of creating certain geometry if the other operations are not suitable. Some editors choose not to implement this operation at all.

16.5.2 CSG Principles

With the aid of the solid BSP leaf tree, CSG is not nearly as complicated as it may first appear. In this section we will discuss the theory behind the various CSG operators outlined above before we move on to examine how we might implement a complete CSG processor.

Figure 16.109

The first thing to realise when adding CSG to our applications, is that these methods will only work when the geometry is represented as *Brushes* (or *Solids*). What this basically means is that our level must initially be made up of various primitives such as cubes, cylinders, wedges, spikes, cones, spheres and so on. This is not as limiting as it first sounds. When we refer to brushes or solids we essentially mean anything which can be defined as having a solid space. That is, it is completely enclosed such that solid space cannot leak out into empty space. Thus any primitive that fits these criteria (such as the object shown in figure 16.109) can be a considered as valid input for each operation. The reason for this requirement will become clear when we begin to discuss how CSG actually works. It should be instantly apparent why the BSP tree is an ideal candidate for this job. Due to the fact that the very foundation of constructive solid geometry is based on the determination of solid space within any particular object, the solid / empty information provided by our BSP tree implementation will be of immense benefit to us.

As mentioned, the key to successfully implementing CSG, whether we have the aid of a BSP tree or not, is being able to determine which areas of our brush are solid and which are not. There are many problems associated with making this determination when we are not using a BSP tree, but fortunately for us, this will not be a concern.

In a short while, we will be describing how the various CSG operations actually work. But before we do this, it is vital that you understand exactly what we are describing when we talk about difference (NOT), union (XOR) and intersection (AND). So what we will do is have a brief refresher on bit manipulation which shows how the various operators (used in most programming languages) work on simple numbers. This should help us to better visualize the definitions we will be using throughout the remainder of this chapter.

Although we will be discussing the effect that these various operations have on bits and not on actual geometry at this point, it is helpful to imagine that each bit that is set to 1 is an area of space within the solid interior of the brush it is describing. The tables that follow will show how the areas of both of our brushes after the operation has been performed contributed to the construction of the final combined brush.

> **Note:** If you have any trouble understanding the bit operations, it may be helpful to start up the calculator that comes with Windows (or any scientific calculator which can handle binary numbers) and follow them through for yourself. Make sure that the calculator is running in scientific mode (View/Scientific for the Windows calculator).

The XOR (^) Operation (Union Equivalent)

Figure 16.110

The XOR operation can be a little tricky to understand at first. XOR compares each bit of the first set against the corresponding bit of the second set. Any bits that are equal in both sets (i.e. both equal to 0 or both equal to 1) will result in the corresponding bit in the output being set to 0. However, if either of the corresponding bits equals 1 while the other is 0, then the output bit will be set to 1.

The following bit tables should make this clear. We will be defining the bits as if they were areas of space occupied by a cylinder and a cube. What remains after the XOR operation will be the areas of space taken from the original brushes and used in the resulting brush (i.e. if a bit is set to 0 then the parts of either of the brushes which occupied this space will be discarded and not used in the resulting brush)

Cylinder Brush

1	**1**	**1**	**1**	**0**	**0**	**1**	**0**

XOR

Cube Brush

0	**0**	**0**	**1**	**1**	**1**	**1**	**1**

=

Resulting Brush

1	**1**	**1**	**0**	**1**	**1**	**0**	**1**

Keeping in mind that a 1 in the table above corresponds with an area of space occupied by the solid space in the brush it was describing, you can see that the areas of the cylinder which were sharing the same space as that of the cube will be removed in the resulting brush. It is important to take into account the fact that the result in these examples will describe how the two brushes are to be merged. So if the result contained a 0, then neither the section from the cube brush or the cylinder brush which occupied this particular space will be used in the final brush. This means that any part of the cube inside the cylinder and any parts of the cylinder inside the cube will not be used in the final brush (they are discarded).

Although it may not be clear at the moment, it may be worthwhile to know that this operator is the basis of the hidden surface removal techniques we will be discussing shortly.

The AND (&) Operation (Intersection Equivalent)

Figure 16.111

The AND operation is the simplest of the three. Put simply, if *both* of the corresponding bits in *both* of the sets equal 1, then the corresponding bit in the result will also equal 1. In any other case a 0 is the result. In figure 16.111 we see that only the parts of the two brushes which occupied the same space have remained.

As before, what remains after the AND op will be the parts of the original brushes used in the resulting brush.

Cylinder Brush

1	1	1	1	0	0	1	0

AND

Cube Brush

0	0	0	1	1	1	1	1

=

Resulting Brush

0	0	0	1	0	0	1	0

We can see that in the AND operation, the majority of the space described by each source brush has been discarded. Only the areas which overlapped and shared the same space now remain.

The NOT (&~) Operation (Difference Equivalent)

Figure 16.112

The NOT operator is not quite the same as the AND, OR, or XOR operators. When we use a logical NOT in a programming language it usually returns 0 if the value passed in is non-zero, and 1 if the value passed in is zero. The same logic applies to a bit-wise NOT. All of the bit values are switched from 1 to 0 and vice versa. Recall from our earlier definition of the difference operator that the resulting output of this operation depends on which brush was used as the carving brush. In this case, the space and polygons described by this brush need to be inverted such that we retain the portions of the carving brush that falls into the solid space of the opposing brush, and likewise retain the parts of the second brush that fall into the *empty* space of the carving brush. Because of this need to reverse the situation found in the intersection operation, this procedure basically performs a NOT operation on the carving brush first (but not on the brush we are carving from) and then an AND op on these two sets of bits. This means that we are essentially describing a NOT-AND operation (or NAND).

Cylinder Brush (Carving Brush)

1	1	1	1	0	0	1	0

NOT

Cylinder Brush after NOT

0	0	0	0	1	1	0	1

AND

Cube Brush (Carved Brush)

0	0	0	1	1	1	1	1

=

Resulting Brush

0	0	0	0	1	1	0	1

Here we see that the resulting brush contains only those parts of the original cube which were not occupied by the cylinder. If we wanted to carve the cube from the cylinder instead, we would apply the NOT to the cube rather than the cylinder.

Hopefully you now better understand what each of the CSG operators do. One thing that you will find about constructive solid geometry as we move forward is that that understanding what each operation does is actually harder than implementing the operators themselves. Since we will of course be working with real geometry, the 'area of space = a bit' analogy we used in the previous examples does not ultimately describe the techniques we are going to implement even though they clearly demonstrate the results we should expect.

In the next section we will begin to look specifically at how these CSG operations will function in real world situations, using physical geometry as input.

> **Note:** If you would like to see a practical demonstration of each of these operations in a real world application it is recommended that you obtain and install a copy of the GILES™ world editor from your class CD or download area. In this application you will be able to try out each of the CSG operators described above, using any manner of varying brush shapes that can be created. If you need help with using the GILES™ application, a full manual is included in the installation package, available from both the start and help menus.

16.5.3 Performing CSG with Geometry

At this point we are already well versed in BSP theory and we should know exactly how they subdivide the space within an object into solid and empty areas. Although when working with CSG we will usually be compiling only small subsets of our level at any given point, remember that the compilation principles used are exactly the same as those employed when compiling a multi-thousand polygon scene.

Before we begin to process any geometry for the purposes of our chosen operation, we first need to be able to determine which areas of space within each of the brushes in our scene (cube, cylinder, etc.) are solid and which are empty. In order to achieve this, we will first need to compile a unique BSP tree for each brush that we would like to take into consideration during the operation. Although it is not strictly necessary for us to compile each of these trees in advance – and in fact it is probably a good idea to only compile each tree as and when we need it – we must ensure that this information is available to us at some point during the procedure.

With this solid and empty spatial information to hand, we are able to implement each of our CSG operators using a simple series of clipping and removal operations.

16.5.4 Implementing the CSG Operators

As the basic principles behind the implementation of each of the CSG operators are the same, we will begin by examining the **union** (**XOR**) operation which we will use as the foundation for understanding how the other two remaining operators function.

The Union Operation

As we know, the union operator is intended for to be utilized in cases where we would like to merge two brushes together. In order to achieve this we must first clip each of the brushes' polygons to the others compiled BSP tree, and remove any fragments of those polygons that may fall into the solid areas of either brush's tree.

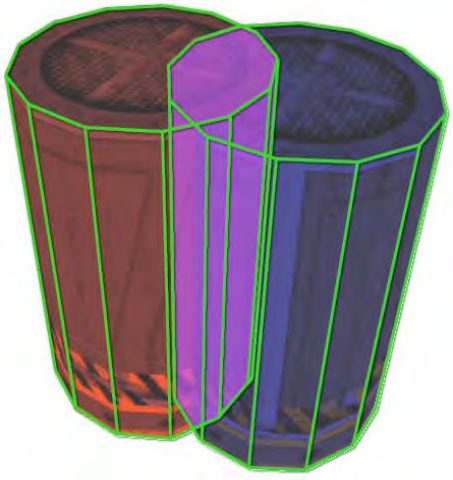

Figure 16.113

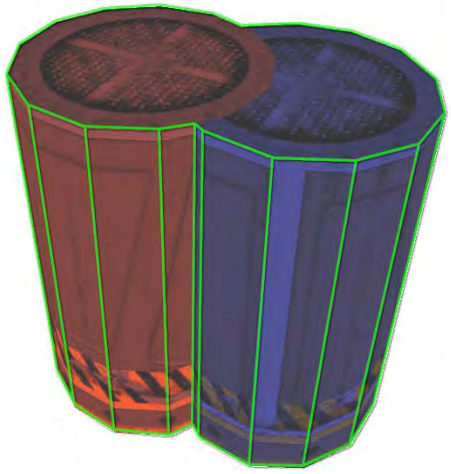

Figure 16.114

Figure 16.113 shows two intersecting cylinders. We can clearly see that we have begun this process using two separate convex hulls (the cylinders themselves) both of which have their own solid space (the red and blue areas). We can also see that where the cylinders overlap, we have an area of space that is shared by both hulls (the purple area). Figure 16.114 shows the outcome of the union operation, where the sections of each hull that lay inside the others' solid space has been removed. The result is a single solid shape which has had any and all interior polygons split and removed. One thing that you may have noticed about the resulting brush in the above figure is that the top faces of the cylinder seem to have remained untouched. Obviously if we were to remove both pieces of the top polygon that fall inside each other's solid space we would be left with a hole in our new solid. The specifics about how to handle this case are covered shortly, but for now just concentrate on how the boundaries of the objects (shown as green wire frame) have been merged together to form one continuous mesh.

Given the basic concept of this operation, let us take this background knowledge and apply it to two simple cubes using the BSP Tree. The first step is of course to build up a BSP Tree for each of the cubes (we will ignore the top and bottom polygons of this cube in order to keep the examples clear, but the same principles apply). Figure 16.115 depicts a top down view of a cube brush and figure 16.116 shows the resulting compiled solid BSP leaf tree.

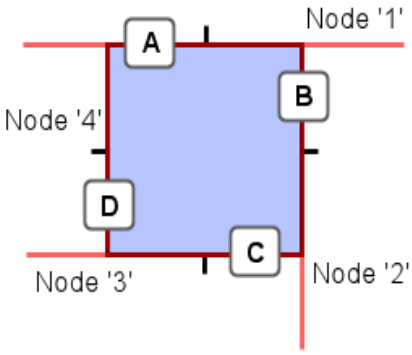

Figure 16.115

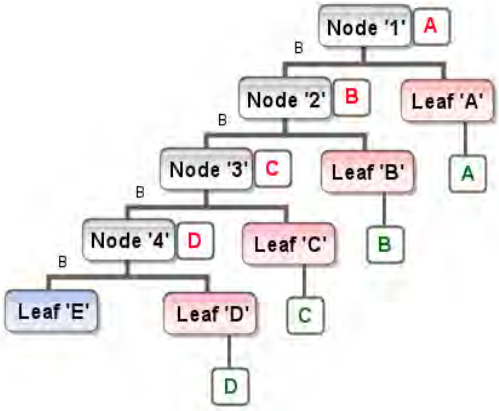

Figure 16.116

The process used to construct this tree should already be familiar at this point so we will not go into great detail about how we ended up with the hierarchy shown. This tree is quite unbalanced and certainly very simple, but it will benefit us to start small. As in each of the prior examples, the letters in figure 16.115 denote the original polygons that bound the solid space inside the cube. As illustrated in figure 16.116, we can see that we end up with just one solid leaf at the bottom of the tree with each of the remaining empty leaves attached to the front of each node. With this information available, we can start to actually perform the union operation. We will use a second identical cube to perform the op with, since the BSP tree constructed for each cube will be the same.

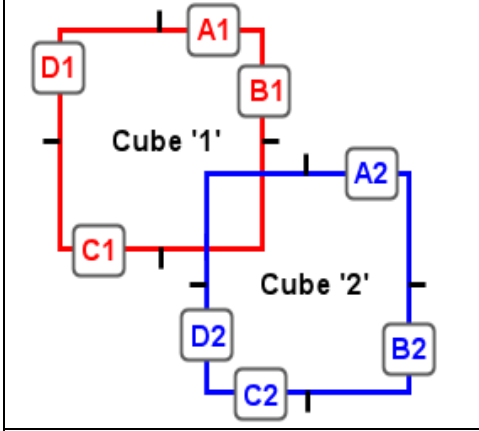

Figure 16.117

Figure 16.117 shows our two identical cubes and how they intersect. We will need to perform the same operation on both cubes (i.e. removing the areas of the first from the solid area of the second and vice versa), but we will begin by clipping cube 2's polygons against those of cube 1. To perform the union operation, we must pass every polygon contained within the first cube through the tree of the second cube, splitting the polygons against node planes as we recurse. Whenever a polygon fragment ends up in a leaf which describes solid space, it will be discarded. Once these steps have been completed for the first cube, we reverse the process and perform exactly the same operation with the second cubes polygons. Let us walk through the example step by step. We will refer to the cube 1's polygons as A1, B1, C1 and D1, and likewise the cube 2's polygons as A2, B2, C2 and D2. In the first iteration of this process we do not actually use the polygons of cube 1 at any point. This is the key to this entire process. At this point we are simply classifying and splitting the polygons of cube 2, against the nodes of the first cube's tree as we traverse.

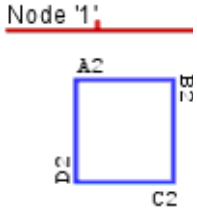

Figure 16.118

First we classify all of the polygons of cube 2 against the root node (node '1') of the tree we are clipping against. As we loop through each polygon, we can see that as we test them individually, each one is found to be completely behind this node. Just as with the actual BSP compilation process, each of these polygons should therefore be added to a *virtual* back list for this node (i.e. it is not physically attached to the node – we keep two separate lists called 'Front' and 'Back' and store each polygon in this list depending on where it lies in relation to the nodes plane. We will see why we do this in a moment). Once all of the polygons of the cube have been classified against this plane and added to the relevant list, we then step to the next node in the tree, passing the appropriate list of polygons. Since there are no polygons in the front list at this time, there is no need to step into the node/leaf indicated by node 1's front pointer. We do however have polygons stored in the back list so we pass this list down the tree to node 1's back node/leaf. (We will explain what happens if this is a leaf shortly).

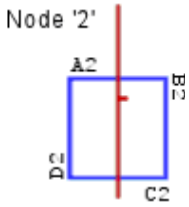

Figure 16.119

We have now passed all of our polygons to the node described by Node 1's back pointer, which happens to be node 2 in this case. As before, we start classifying polygons against the current node's plane. Starting with polygon A2, we find that this polygon is spanning the node plane and should be split. This gives us two separate polygon fragments -- one behind the plane (A2a) and one in front of the plane (A2b). We then add each respective split fragment to the relevant front or back list and discard the original polygon. Now we move on to polygon B2 which is completely in front of this node. Thus, it is added to the front list. Polygon C2, like polygon A2, is also spanning the plane and again must be split with the resulting fragments being added to the relevant list. Again, the original polygon is deleted. Finally we classify poly D2 and find that it is totally behind the plane. It is also therefore added to the back list.

At this node, we actually have polygons in both our front and back lists. We will deal with the front list first. Our front list contains part of the original A2 polygon (labelled A2b), part of the original C2 polygon (named C2b), and the complete polygon B2. As before, we need to pass this front list into

whatever node 2's front pointer contains, which in this case is an empty leaf. Because the union operation only discards polygons which end up in solid space, all of the polygons in this front list have survived the operation and as such, can be added to the final resulting brush at this point.

Our back list contains the fragments A2a, C2a and the in-tact polygon D2. This list is then passed down the back of node 2 and into node 3. We begin the process yet again. In figure 16.120, our split polygon fragments are shown in green.

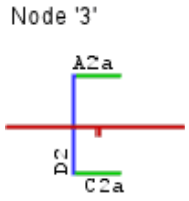

Figure 16.120

> **Note:** Remember that we are only testing against the polygons which actually survived to this point and were passed down to this node.

We start at the beginning of our list and find that the fragment A2a is completely behind the plane and is therefore added to the back list. Then C2a is added to the front list. D2 is spanning node 3's plane so it is split into two fragments (D2a and D2b) where D2a is added to the front list and D2b to the back.

As before, we have some polygons in our front list, so we pass this to whatever is in the front pointer of node 3. This happens to be an empty leaf, so whatever is in the front list has survived and can be added to the final resulting brush as before. Our back list also contains some surviving polygons, so it will be passed down the back of node 3 which directs us to node 4.

In node 4 we now have only two poly fragments that remain (A2a and D2b). We classify each of these and find they are both behind the plane and added to the back list. As in the example of node 1, we find there are no polygons in our front list, so there is no need to go recurse into the front. We do however have these two remaining polygon fragments in our back list, so we pass it down the back of node 4. However, remembering that we can distinguish solid leaves as being any attached to the back of a node this time around we find that we fall into a *solid* leaf. Since the union operation discards any polygons which make it into solid space, these polygons will *not* be added to the final brush.

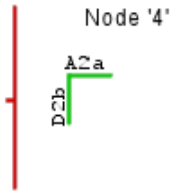

Figure 16.121

Figure 16.122 depicts the polygons that actually made it into the final brush. You will notice that the original polygon C2 has been split, and was added as two separate fragments (even though neither was deleted). Unfortunately there is no way to avoid this during the traversal process, but there are many techniques we can employ to reduce the number of splits in our final brush after processing has been completed. These will be discussed as we cover the implementation of our final CSG processor.

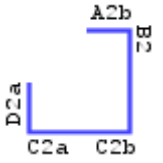

Figure 16.122

As mentioned, we have to perform this process for both brushes. So the next time around we will have to pass all of the ***second*** cube's polygons through the ***first*** cube's mini-BSP Tree in the same way as we have done with the first. But how can we do this now that we have clipped and removed most of the polygons? Actually this will not be a problem. Remember that we have already compiled the Mini-BSP trees for each brush, before the CSG process begins. This means that even though the polygons of cube 1's tree have been altered, the tree of this cube is still completely intact in its previous state. For the purposes of CSG, the polygon information that is stored in the tree is essentially irrelevant, all we need to pay attention to are the node planes, and the leaves themselves. While we will not step through the

process again for the second cube (as you should now be able to do it for yourself) the following figure illustrates the process.

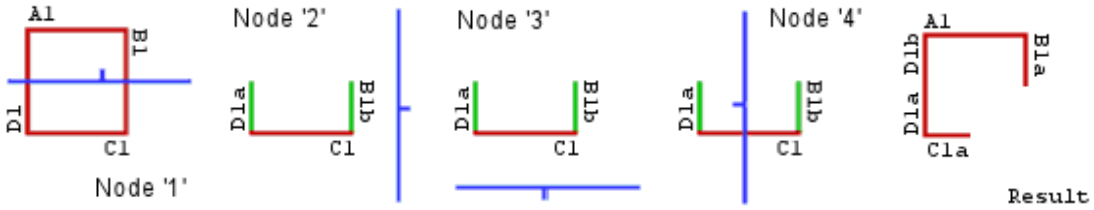

Figure 16.123

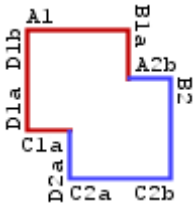

Figure 16.124

We see now that the final results of both clip operations yielded the hull shown above. We can also see exactly where each polygon came from. Although this jumble of nodes, planes and polygons may be a little confusing at first, by referring back to Figure 16.124 and following the process through step-by-step for each brush, you should start to understand exactly what is going on at each stage through the tree traversal.

We are fortunate in that we are able to reuse much of the functionality of our BSP tree code when performing CSG – for instance, our polygon classification and splitting routines. This means that with a little bit of planning, we can actually add our complete BSP tree clipping routine in just one function thanks to recursion. While some people operate under the impression that recursion is a large performance penalty, the reality is that most C++ compilers can generate much faster code than the average programmer trying to implement a manual stack. We do not really have to face the typical problems like stack overflows, because the depth of the Mini-BSP Trees will be relatively small.

One thing that we did not encounter in the previous scenario is what happens when we find a coplanar test case. As it turns out, the on-plane case does present us with a small problem when performing a CSG operation. Let us take a look at this problem now.

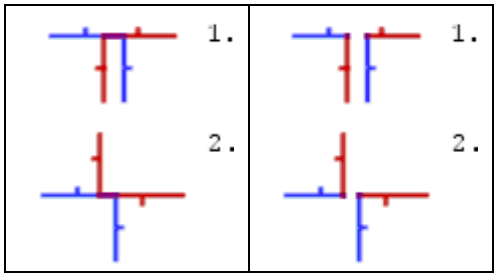

Figure 16.125 **Figure 16.126**

Figures 16.125 and 16.126 demonstrate the ‘before’ and ‘after’ of two separate cases which include polygons that are coplanar with the nodes of the tree we are testing against. In the top case (case 1), there are two polygons which share the same plane and in this case both face in the same direction. In the bottom case (case 2), the polygons are on the same plane but are this time facing in opposite directions. Let us examine case 1 first. By referring to figure 16.126, we can see the outcome if we were to automatically pass these on plane cases down the back of the node with which it is sharing a plane.

The reason this would happen is that, as we know, eventually these polygons would make their way into a solid leaf and would never be added to the final resulting brush. If you look at the colours of the polygons in case 1 in Figure 16.126, you will realise that once the CSG processor has run its course, the two lower polygons will eventually have been removed because they reside in solid space, but the gap still remains. So we end up with a hole in our hull where polygons were previously overlapping. This is clearly not a good situation, and will more than likely result in our final BSP compile failing due to illegal geometry (i.e. space leakage).

However, in case 2, we find that passing the coplanar fragments down the back of the tree is correct. If you refer back to the union operation, you will realise that the two areas of solid space have been merged and that this is still a totally valid hull (all hidden surfaces have been removed). This is a crucial part of the HSR algorithm which will take place before final BSP compilation, so we are actually fortunate in this way to be able to simply test the normal of the poly against the plane of the node. If it is facing in the opposite direction to the node, then we can simply add this poly straight into our back list as we would do for any other poly which is behind the plane. This is virtually identical to the method we used to handle the coplanar cases during the construction of both the node and leaf BSP tree earlier in this chapter. Recall that we test to see if the polygon normal is facing in the opposite direction to the node or not. This also works for the other operators (such as difference and intersection) but we will discuss those a little later in the lesson.

So the only case we have to deal with when handling the coplanar cases is that in which both the polygon normal and the node's plane are facing in the same direction.

The solution to this problem of the hole in the resulting hull is relatively simple. We already know that we perform the clipping first on one brush, and then on the other. All we have to do is to allow the clipping routine to pass these cases (where both are facing in the same direction) down the back list for one brush, but when we reverse the operation and clip the other brush, make sure that it is passed down the front list instead. Again, refer back to case 1 in Figure 16.126 where we can see the result if we were to send both fragments, from both brushes, down the back of the clipping node. In that case, both fragments are removed. But if only one of the fragments is removed, by passing only one of them down the back and the other down the front, we can see that the one sent down the front will be added to the resulting brush and the gap will be closed. Earlier in this section we demonstrated the result of the union of two cylinders in figure 16.114, in which only one of the top faces was clipped, and the other remained in-tact to fill the hole. This is an ideal demonstration of this process in action.

Fortunately, as mentioned, this same process applies to all of the CSG operators that we cover in this chapter. This is nice because it means that for these other operators we can follow exactly the same steps we have outlined here. For the most part, we need only to decide whether we want to discard the polygons which end up in solid space or those that end up in empty space.

For more information on how best to handle the on-plane case during implementation, it would be a good idea to refer to the workbook for this lesson to see the approach that we have used.

The Intersection Operation

Due to the fact that the implementation process is the same between each type of operator, we can simply now discuss how we might adapt the techniques we learned in the union operator for use with the **intersection (AND)** operation.

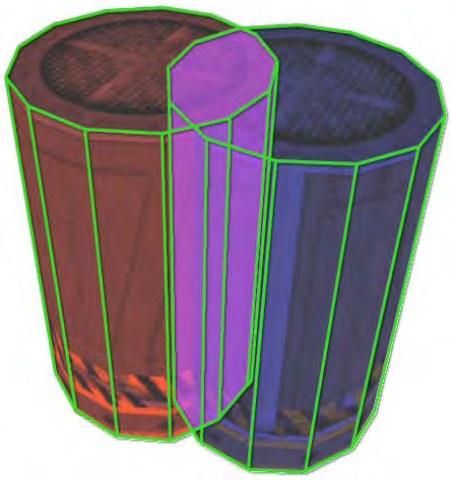

Figure 16.127

Figure 16.128

The intersection operator works in much the same way as the union operation did. In Figure 16.128 we can see that in this situation, everything that ended up in solid space has survived as opposed to being removed. There is not any significant difference in the way this works: all the on-plane cases remain the same, and everything is still split and sent down the relevant side of the clipping node as before. The only difference is that in order to produce the result we are looking for we need to discard any polygons which end up in empty space rather than in solid space as we did previously. Thus only polygons that end up in solid space are added to the resulting brush. Just as before, we perform the operation with one brush's polygons against the other brush's BSP Tree, and then reverse the process using the other brush's polygons against the first brush's BSP Tree.

For completeness the following diagram shows the result of this operation using our cube example from the last section. The step-by-step diagrams would be identical to those we saw in the union case and have therefore not been included here.

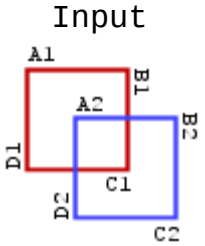

Figure 16.129

Figure 16.130

The Difference Operation

The final operator we will discuss is the **difference (NOT)** operator. It works in a slightly different manner than the other two operators, due to the fact that it is dependant on which brush we want to use to perform the operation with.

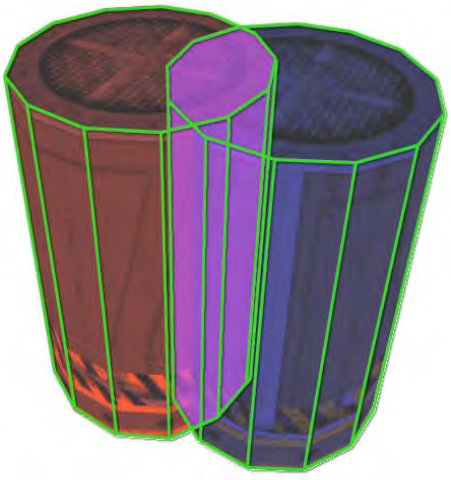

Figure 16.131

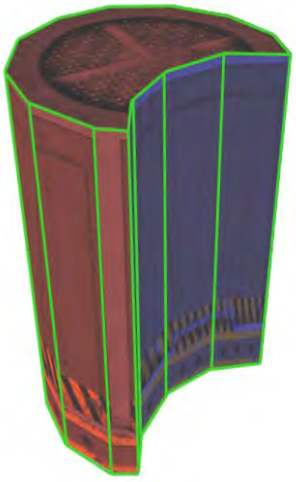

Figure 16.132

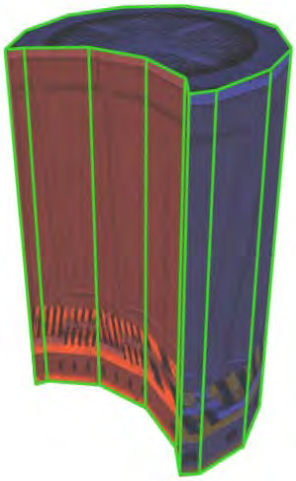

Figure 16.133

There are actually a number of aliases by which this operation is known, and you may encounter them in other contexts. Very often you will hear the difference operation referred to as a NOT, NAND, carve or subtract operation. We can see that Figure 16.132 shows the result after the blue hull from figure 16.131 has been subtracted or carved from the red hull. By the same token, Figure 16.133 shows the result after the red hull from figure 16.131 has been subtracted or carved from the blue hull.

It is clear then that the outcome of this operation does indeed depend on which brush we carve from the other. If you look back to our earlier definition of ***NOT***, we can also see that in our literal definition of the NOT / NAND operation, the outcome depended on which set of bits we swapped using the bit-wise NOT operation.

The interesting part is how we 'NOT' the brush we want to carve with, in the same way we did with the bit manipulation we performed earlier. Just as the NOT inverted the bits, we will invert all of the polygons and their normals before compiling the mini-BSP tree for this brush. In doing so, solid space becomes empty space and empty space becomes solid space. We will then perform the AND operation as shown in the intersection operation previously discussed (i.e. keep anything which ends up in solid space in either of the brushes).

Although this operation is very similar to the intersection op shown previously, we will step through the entire process as we did with the union since it is very important that you fully understand the process. Keep in mind that the BSP tree has been built in a different fashion this time around (i.e. it is inverted). To help illustrate this, the new tree which was built from the *inverted* brush polygons is shown next.

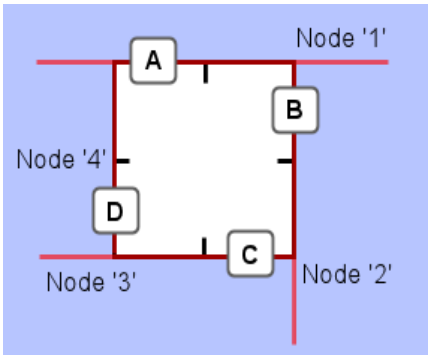

Figure 16.134

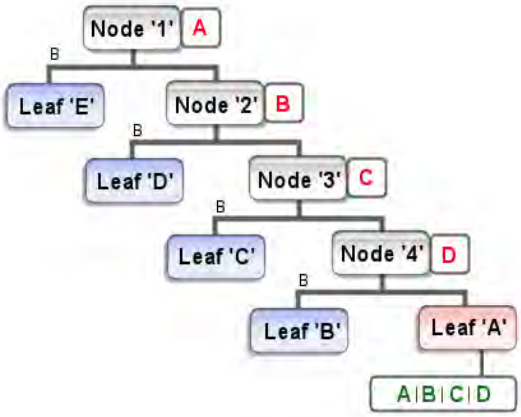

Figure 16.135

Figure 16.135 shows our inverted tree structure in which you can see that each of the brush polygons have been. Just remember that we cannot generally get away with inverting only the normal; we also have to invert the winding order of the polygons themselves if we want these polygons to render correctly when attached to the final resulting brush. We will explain how to reverse the winding order in the accompanying workbook for this chapter.

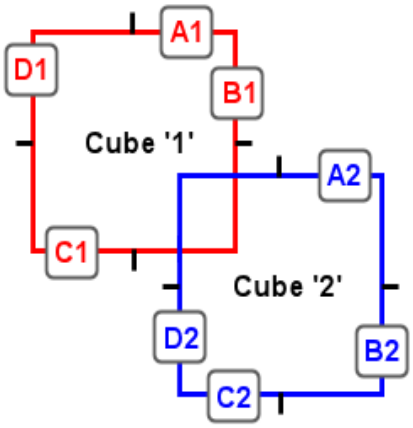

Figure 16.136

As before, we are going to use the same two cube example. In this example scenario we are going to be carving cube 1, from cube 2. Remember that cube 1 has been inverted and its mini-BSP tree has been built from the polygons in their inverted state. This means that the node planes will point in the opposite directions as shown in the figures above. Also remember that we have done nothing to the second cube just yet. We do not need to invert the polygons of any brush we are carving *from*, only the brush we are carving *with*. You can refer back to figures 16.135 and 16.136 for the definition of the second cube's tree if needed. To perform the difference operation properly, we need to do exactly the same thing as we would when performing an intersection (AND) operation assuming we have built this inverted tree. This means we will delete everything that ends up in *empty* space. This will be achieved in the same way in which we performed the clipping in our step by step union example with the exception of the differing polygon discard rules. For future reference, it does not particularly matter which brush we start with, but this example will focus only on clipping the second cube, to the tree of the inverted cube '1'. Let us now examine the rest of the process.

Looping through in alphabetical order, we find that all of our polygons which are being tested against node ‘1’ are in front of the plane, and as a result they are all added to the front list. There is nothing currently in the back list so we do not need to pass anything down the back of this node. Thus, we continue down the front, passing our newly built front list.

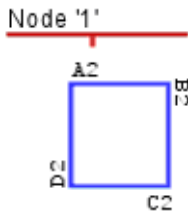

Figure 16.137

The front leads to node 2 (see figure 16.135) and we again classify our polygons against the node. We find that polygons A2 and C2 need to be split and their fragments are added to the relevant front/back lists. (Remember that we delete the original poly at this point). B2 is placed in the back list and D2 also goes in the front. Although our function would usually traverse down the front of the node before dealing with the back list, we can do it now to save confusion due to the recursive nature. The back list (containing A2b, B2 and C2b) is passed down the back of the current node and we find ourselves in a solid leaf. Since the difference operation keeps any polygons or fragments of polygons which end up in solid space, these polygons can be added to our final brush. The front list is passed down the front of the node which leads us to node 3.

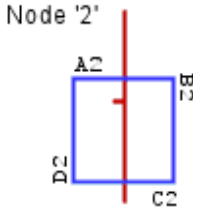

Figure 16.138

The diagram above shows the polygons that were passed to node 3. Again we classify all of the polygons and find that C2a is added to the back list and D2 is split into two fragments on either side of the plane. D2a is therefore added to the back list and D2b is added to the front list along with A2a which is also in front of the plane. As before, the back list is sent down the back, and again we find a solid leaf and add these surviving polygons from that back list to our final brush. The front list goes down the front of the node, which takes us finally to node 4.

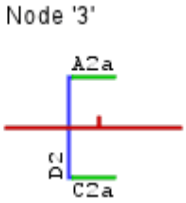

Figure 16.139

Classifying the remaining polygons, we find that no polygons are added to our back list and that both are added to the front. Our recursive function then attempts to pass this list down the front of the node, but we find that there is an empty leaf here. Since this operation discards any polygons which end up in **empty** space, these final two poly fragments are deleted.

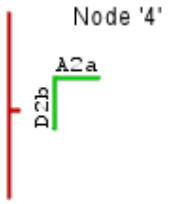

Figure 16.140

The final resulting brush is shown in the figure 16.141. We can see that, as we are clipping the second cube, this figure depicts exactly the same resulting fragments as those from cube 2 that survived during our union operation. This clearly demonstrates that swapping the rule about whether we delete what is in empty space or in solid space really does work as expected.

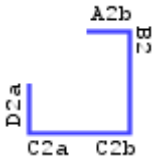

Figure 16.141

While this part of the difference operation was fairly obvious, the next bit is where the main differences lies. We can see the steps involved in clipping the first cube (the inverted brush) against cube 2 in figure 16.142. You may notice that the diagrams are identical to those we saw with the union operation. You should be able to work your way through the process with the aid of the following illustrations without much trouble. Be sure that you understand exactly why we get the results that we do.

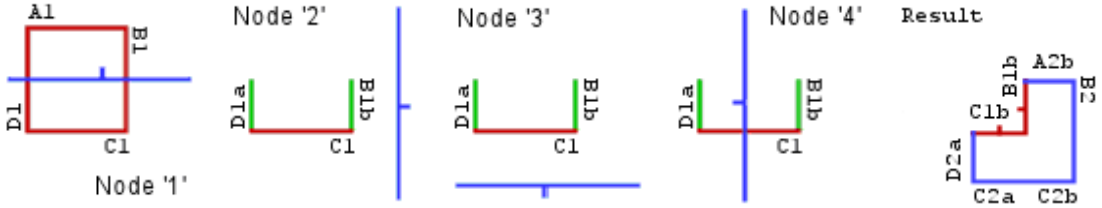

Figure 16.142

If you carried out this process on paper, you will hopefully have arrived at the result shown above. The red polygons will be all that remain of cube 1. Due to the fact that we inverted cube 1's polygons before we built the mini-BSP tree for that brush, you can see that they are now automatically pointing in the correct direction. They also close up the gap which would have been left cube 1's exterior hull.

> **Note:** Bugs in CSG processors are very difficult to track down. If there is a problem during implementation, it is very rare that the problems you see in the resulting geometry will have any bearing on the problem inherent in the code. For this reason it is important that you understand the operations completely.

Additional Notes about the Difference Operator

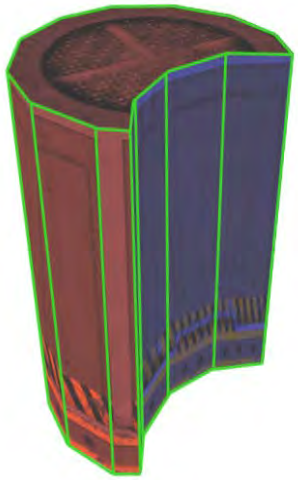

Figure 16.143

In an ideal world, the difference operator would fit neatly into the concepts we discussed in our 'area of space = a bit' examples. However, in some cases we may not be able to invert the brush data before compiling the mini-BSP tree. For future reference, we will look at one possible solution for this case. When we are performing the difference operation, we obviously still have to clip one brush to the other and vice versa in the same way we always have. For this explanation we will use Figure 16.143 as the target result we would like to obtain.

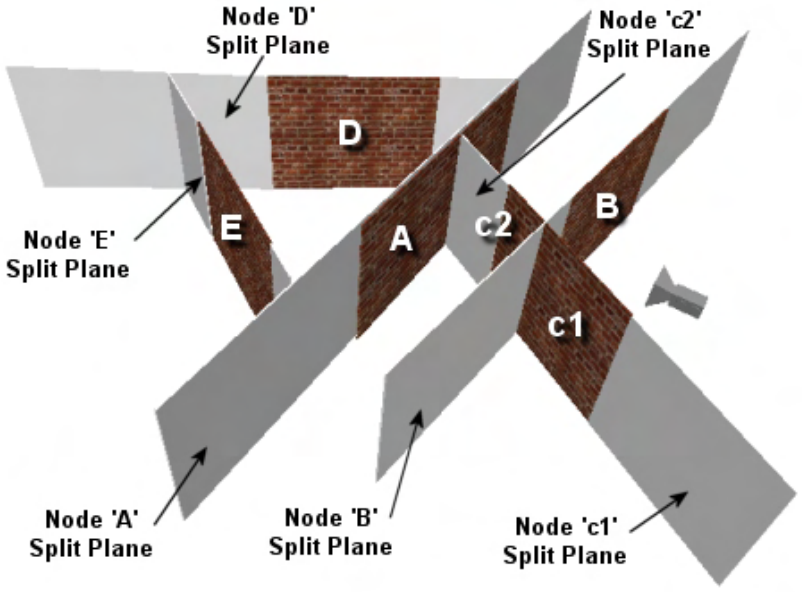
In this case we will assume that we are not able to invert the brush data before rendering, or for whatever reason, cannot invert the BSP Tree data after it is built. The solution we can employ is that when we clip the red hull's polygons using the blue hull's BSP Tree, we **delete** any polygons which end up in **solid space**. However, when we then clip the blue hull's polygons against the red hull's BSP Tree, we **retain** any polygons which end up in the red hull's **solid space**, and **delete** anything which ended up in **empty space**. There is one final step: the polygons that remained of the blue hull (which we can see in Figure 16.143) must be inverted before being added to the final brush so that they point outwards and seal up the hull. By switching the rule between the two traversal / clipping procedures in this way, we are essentially getting

the same result as inverting the tree itself. In theory however, this is not as clean as simply performing a NOT on the entire carving brush. Although either solution is a valid one, it is really more a matter of preference than necessity in many cases.

16.5.5 Conclusion

We covered a good amount of new information in this section that should be fully understood before continuing on. It would be a good idea to try some examples out on your own: perhaps an 8-sided cylinder against a cube. You can also experiment with these operations in the GILES™ world editing program. Try some of the operations on cubes, cylinders, and spheres and see what sorts of results are generated by the CSG processor under different circumstances. It will help to have a visual understanding of what it is we are aiming for as GILES™ itself uses all of the operations we have discussed here in this chapter.

Workbook Sixteen:
Binary Space Partitioning



Lab Project 16.1: Using BSP Node Trees for Alpha Rendering

The focus of this lab project will be on writing a class that will compile a BSP node tree from a list of input polygons. We will also expose methods that allow the application to render its polygon data in a back to front order with measures taken to increase efficiency where possible.

Unfortunately, although there is some degree of shared functionality, our BSP node tree class will not be derived from ISpatial tree or CBaseTree. This is mostly due to the fact that many of the methods exposed by ISpatialTree make no sense in the context of the BSP node tree. Most obviously, the node tree has no concept of leaves like the other tree types, and thus many of the ISpatialTree methods which work with leaves (e.g., ISpatialTree::CollectLeavesAABB), have no analogous concept in the BSP node tree. In the end, many of the method of ISpatialTree would have to be no-ops in the derived class if we wanted this to work. Our decision was that this was really not a good way to go. When an application sees a method exposed by an interface, it generally expects that method to do what its name describes. In the case of the BSP node tree, there are just certain methods which would make no sense due to the way it is constructed.

The rendering system in CBaseTree is also inappropriate for our BSP node tree. The CBaseTree rendering system worked by recording runs of adjacent triangles with like attributes so that we could render as many triangles as possible in the same subset with a minimum number of draw calls. We know that batch rendering in this way is always desirable for good performance. However, the last thing we want our BSP node tree to do is choose its polygon render order based on subsets. The whole point of us implementing the node tree in this lab project is so that polygons are rendered in a very specific back to front order based on view distance from the camera. Therefore, even if rendering in a back to front order means we have to change textures and materials on the device prior to rendering each polygon, there really is nothing we can do to avoid this. The polygons have to be rendered in that order for the blending to occur correctly and the whole purpose of implementing the BSP tree in this lab project is to ascertain that very order at run time.

Although the BSP node tree is a spatial tree it is being used in this lab project for a very specific purpose; it is not being used as a generic spatial manager. In fact, the BSP node tree would make a very poor choice of a spatial manager for your entire scene due to the fact that a polygon would be stored at every node in the tree, producing a large and deep tree. This is another reason we have not derived the BSP node tree from ISpatialTree. It is not to be considered as a viable alternative to our quad-tree, kD-tree and oct-tree classes for general scene management. Remember, the BSP node tree is being used to perform back to front rendering as its sole priority. As we currently have no need for this feature when rendering our opaque polygons, using the BSP node tree are our main spatial manager would result in unnecessary performance loss.

Thus, the CBSPNodeTree class is not a replacement class for our previously implemented spatial managers; it is to be used alongside them to handle only the rendering of the alpha polygon data. Our CScene object will now contain an ISpatialTree pointer and a CBSPNodeTree pointer as member variables. All polygon data will be rendered with the spatial tree, just as before. Transparent polygons will still be registered with the spatial tree as well, but their visibility status will be set to invisible. This means the spatial tree will compile the transparent polygon data into the tree, but not compile it into the vertex and index buffers used to render the tree. The transparent polygons will not be rendered by our spatial tree, but they will still be collision tested. A separate copy of the alpha polygon will then be added to the BSP tree. The BSP tree will contain all the alpha polygons after the load process is completed. Our

CScene::Render function will first ask the spatial tree to render itself (so all opaque polygons get rendered into the frame buffer with depth writing enabled) and then ask the BSP tree to render itself. The BSP tree will traverse its list of polygons in a back to front order and render its polygons with depth writing disabled and alpha blending enabled.

While it may seem that we are essentially throwing out batch rendering when it comes to rendering our BSP node tree, in practice things are not quite as bad as they first seem. For example, one might devise a render strategy for the tree that simply steps through each node in back to front order and calls IDirect3DDevice9::DrawPrimitiveUP for each polygon stored there. This would involve calling DrawPrimitiveUP for every polygon in the tree, and we already know how inefficient that would be from our discussions in previous lesson. Of course, one might assume at first that there is no better way to do it because we may end up having to switch attributes between each polygon, thus rendering a single polygon at a time anyway However, it is not uncommon for a game level to use only a handful of effects/textures for all its transparent surfaces and as such, there is a good chance that all the alpha polygons in our tree may belong to the same subset, or at the very least, collectively belong to only a small number of subsets.

This means that there is a very good chance that, as we are walking the tree in a back to front order and stepping from more distant nodes into nodes that are nearer the camera, the polygons in those nodes will share the same attribute. If we can collect the triangles in a back to front order into some temporary buffer during the traversal, the further triangles will be at the beginning of the buffer and thus will be rendered first when we send the buffer of triangles into the DrawIndexedPrimitive method. Of course, as soon as we collect a polygon during our traversal that does not share the same subset as the polygons we have previously collected in the buffer, we will have to render the buffer and then start collecting for this new subset. That is, every time we encounter the need for a subset change when collecting the triangles, the triangle buffer will have to be flushed. This system will allow us to (hopefully) get the benefit of some amount of batch rendering when adjacent nodes contain polygons with matching attributes. Ultimately, this allows us to reduce the number of draw calls.

Before we start to examine the source code to Lab Project 16.1, we will first examine the two basic components to the system. These components are the building component that compiles the tree and the render component that formats the compiled tree’s polygons data into a renderable format. The latter part will have methods to traverse the tree and render that data as efficiently as possible. Of course, these components are not new to us due to the fact that all the spatial trees we developed in the previous lesson had these same two components.

The Compilation Process

Although the CBSPNodeTree class is not derived from ISpatialTree and CBaseTree, we have tried to keep its operational flow and the names of its methods the same as their ISpatialTree counterparts. That is, the construction of the tree will be done in basically the same way.

The application will register polygons with the tree by calling the CBSPNodeTree::AddPolygon method. Our BSP node tree implementation does not need to support detail areas and dynamic objects like our previous spatial managers since there are no leaves to store this data. The focus of this class is thus very simple: compile a tree of static polygon data that can be traversed in a back to front order at run time.

After the application has registered any static transparent polygons with the CBSPNodeTree the CBSPNodeTree::Build function is called (another process that is familiar to us). This function starts the recursive process of building the BSP tree and storing the CPolygon structures in their nodes. As discussed in the accompanying textbook, each node will contain all the polygons that entered that node during the build process that were found to lay both on the node plane and that have the same frontspace.

Our previous spatial trees had the option of being constructed using polygon splitting, with the no-clipping case often being the favored approach to reduce the number of new polygons introduced by the compilation process. However, the BSP node tree will always use polygon splitting, as it is this splitting procedure that allows us to remove the ambiguous draw order situation that can arise when alpha polygons intersect each other. As discussed in the accompanying textbook, by splitting polygons that span a node, we break them into smaller pieces whose correct draw order can always be found during tree traversal.

As we are essentially building a clipped tree, we will use the same polygon storage logic used by our previous tree types when compiling a clipped tree. That is, prior to the commencement of the build process, a temporary copy of the tree's polygon database will be made. This vector will contain a list of all the polygons originally registered with the tree. The list will then be emptied and the recursive compilation process will be performed with the temporary copy. This will allow us to clip the polygons during the tree and only add them back to the tree's polygon database when they are assigned to a node in their clipped format. At the end of the build process, the tree's polygon database will contain all the polygons in the tree in their clipped format.

Every node in the tree will also be assigned an axis aligned bounding box that bounds not only the polygons stored at that node, but all the polygons in the nodes underneath it. This will allow us to construct a hierarchy of bounding boxes in our tree that can be used during the rendering traversal to reject nodes (and all their children) that lay outside the frustum. This will allow us to avoid visiting every node in the tree and make the rendering process much more efficient in the general case.

At the end of the CBSPNodeTree::Build function, prior to it returning program flow back to the application, it will issue a call to the CBSPNodeTree::PostBuild function. This is another process that we are familiar with and it will mirror the flow of our previously developed spatial trees. That is, it will call the CBSPNodeTree::CalculatePolyBounds method to calculate a bounding box for every polygon in the tree and then call the CBSPNodeTree::BuildRenderData method to copy the vertices of each CPolygon in the tree into a vertex buffer (building support structures to aid in the rendering of that data). Fortunately, the render system will not be nearly as complex as the system used to prepare and render our other spatial trees. After the BuildRenderData method returns, program flow goes back to the application and everything is ready to go. The CBSPNodeTree::Draw method can be used at any time thereafter to render the tree in a back to front order.

Finally, it is worth noting that at the moment, we are only using this tree for rendering. Thus, after the render data has been built and we have copied our vertex data into a vertex buffer, we could delete all of the CPolygon structures as we will not use them again. However, we decided to leave CPolygon structures at the node in case you ever do decide to perform some form of intersection testing on the BSP tree at a later date. We can certainly foresee situations in the future where we might want to read back the polygon vertex data stored in the tree and in that instance, we would want to have these system memory representations. However, in this lab project we do not use the CPolygons at all once the tree has been

built, so you are free to delete them after the BuildRenderData method has returned. Considering that the average game level probably only has a handful of transparent polygons (relatively speaking of course), leaving them in place in case we need them later will not increase them memory footprint of the application by any significant degree. The choice is yours.

The Render System

The rendering system for the BSP node tree will be very different from the rendering system used by CBaseTree and will require much less code. Our rendering system uses the following components:

- **The Vertex Buffer**
  The tree will have a single static vertex buffer which will be populated with the vertices of all the CPolygon structures during the BuildRenderData call. As the tree only supports a single vertex buffer this does mean that it is limited to managing a maximum of 65,535 vertices. While it may seem as if we should account for the multiple vertex buffer case, if we have 65,535 vertices whose polygons have to be rendered back to front each frame (and possibly one polygon at a time in the worst case scenario), we have bigger design problems than the need to update the code to support multiple vertex buffers. Essentially, we would have a huge tree with thousands of nodes which would slow traversal down quite a bit. Having to render this number of polygons in a back to front order (even if a BSP tree was not used and the polygons were sorted) is pretty much out of the question if we wish our frame rates to remain interactive.

- **The Dynamic Index Buffer**
  Our tree class will allocate a single dynamic index buffer that will be filled and flushed each time the tree is rendered. The BuildRenderData method will allocate this index buffer to be of the correct size, but will not initially store any data in it. The index buffer will be filled only during the recursive build procedure. As we visit each node in back to front order, we will copy the indices of each polygon stored in that node into the index buffer. If the triangles we are about to add do not have the same subset ID as those already in the index buffer (collected from prior visited nodes), the index buffer will be rendered and reset before the new polygon is added, thus starting a new collection run. This rendering logic will allow us to store multiple triangles across consecutively visited nodes in the index buffer together so that we can render them with a single draw call. We can imagine for example that if every alpha polygon in the tree had the same attribute ID (which is not so unreasonable, considering you might use a single effect for all of your glass/windows) we would actually collect the triangle data from all visited nodes into the index buffer and be able to render the entire tree dataset with a single draw call. Because we are visiting the nodes in a back to front order, the triangle will be added to the index buffer in that same order. Thus the triangles that should be rendered first are at the start of the index buffer and will be rendered first when the index buffer is submitted for rendering. As this index buffer will need to be locked and filled frequently we will need to create it with the D3DUSAGE_DYNAMIC flag so that the driver allows us to avoid stalling the pipeline.

- **Per-Polygon Index Data**
  We have already established how the rendering logic for the BSP tree should work. Every time the tree's draw function is called, a back to front traversal is done where every visible node add its

indices to a dynamic index buffer which is flushed whenever an attribute state change is encountered. The problem we have with this system however is that our CPolygon structures store convex winding N-gons and do not even store indices. Even if each CPolygon structure did store an array of indices, they would not be a lot of use to us as they would be local to the vertex array for that polygon instead of indexing into our main tree vertex buffer. This means that during the build process we are going to have to create a small index array for each polygon which will be stored in the node. So, if a node contains 5 polygons, we will also need to generate and store the corresponding 5 index arrays (one for each polygon) at that node. The index array for each polygon will describe the indices needed to render the triangles using vertices stored in the tree's vertex buffer.

The index data for each polygon at a node will be stored in a BSPRenderData structure (shown below). Note that this structure is actually contained inside the CBSPNode namespace but is shown here on its own. There will be one of these structures for each polygon stored in a node. As you can see, it contains an unsigned long pointer which will be used to point at the indices we generate for it, the triangle count that the polygon was broken into (which tells us how many triangles are in the previously described index array), and the attribute ID of the polygon that this index list is for. As we visit each node during the traversal pass, it is the indices stored in these structures that we will copy into our dynamic index buffer for eventual rendering.

```
struct BSPRenderData
 {
        USHORT * Indices;
        USHORT   TriCount;
        ULONG    AttribID;
 };
```

As there will be one BSPRenderData structure for each CPolygon stored at the node, one might well wonder why we are also storing the triangle attribute IDs in this structure when we can get the attribute ID from the corresponding polygon. After all, if there is one of these structures for each polygon stored at the node, then surely the attributes of the fourth polygon (for example) would be pNode->BSPRenderData[3].AttribID = pNode->Polygons[3].AttribID. That is, we should know that the attribute ID of the triangles stored in a BSPRenderData structure in the node's BSPRenderData array will match the attribute ID of the polygon stored in the node's polygon array at the corresponding element, right? In fact, this is not the case.

Although there will be a BSPRenderData structure allocated for each polygon at the node, we will make a small optimization in order to increase the chance of batch rendering multiple polygons stored at the same node with the same attribute ID. We will store the BSPRenderData structures in the array grouped together by subset so that when the node is encountered during the rendering traversal, we add all the polygons with the same attribute ID to that buffer first and then flush it before adding the second subset of polygons store at that node. To understand this, imagine the following polygons are all co-planar and were therefore assigned to the same node by the BSP tree compilation process. When this node is visited, the polygons A through F would have their indices collected into the dynamic index buffer and rendered.

The Node's CPolygon Array			The Node's BSPRenderData Array	
CPolygon A	:	AttribID 1	Indices A :	AttribID 1
CPolygon B	:	AttribID 2	Indices B :	AttribID 2
CPolygon C	:	AttribID 1	Indices C :	AttribID 1
CPolygon D	:	AttribID 2	Indices D :	AttribID 2
CPolygon E	:	AttribID 1	Indices E :	AttribID 1
CPolygon F	:	AttribID 2	Indices F :	AttribID 2

The above table shows how the CPolygon array stored at each node might have a 1:1 mapping with the BSPNodeRenderData array stored at that same node. That is, the first element in the BSPRenderData array stores the indices for the first element in the node's CPolygon array, and so on down the list. As we can see, it would seem pointless in this instance to store the attribute in both structures. However, look at the list of attributes in the above table and notice that the polygons that belong to same subset are not grouped at the node. We can see for example that we would first add the indices for polygon A (Indices A) to the dynamic index buffer. However, when we tried to add polygon B's indices, we would notice that the subset is different and would have to render the dynamic index buffer first before adding the second polygon. Because the polygons in this list are not stored in attribute order, and because we have to flush the index buffer every time a subset change is encountered, this would mean that although only two subsets of polygons exist at this node, every polygon would have to be rendered individually. This is extremely inefficient as it results in six draw calls. Of course, if we were to reshuffle the index arrays in the BSPRenderData array so that they are now grouped in attribute order, we would be able to render all six polygons with just two draw calls (one for each subset). Therefore, when we allocate and store the BSPRenderData structure for each CPolygon stored at a node, we will do so in subset order so that the BSPRenderData structure is essentially attribute sorted as shown below.

The Node's CPolygon Array			The Node's BSPRenderData Array	
CPolygon A	:	AttribID 1	Indices A :	AttribID 1
CPolygon B	:	AttribID 2	Indices C :	AttribID 1
CPolygon C	:	AttribID 1	Indices E :	AttribID 1
CPolygon D	:	AttribID 2	Indices B :	AttribID 2
CPolygon E	:	AttribID 1	Indices D :	AttribID 2
CPolygon F	:	AttribID 2	Indices F :	AttribID 2

Because we add the BSPRenderData structures to the array in subset order, this means there will not be a 1:1 mapping between polygons in the CPolygon array stored at that node and the index arrays in the BSPRenderData array. For example, we can see that polygon B is stored in the CPolygon array in the second position, but its indices are stored in the fourth element of the BSPRenderData array.

Looking at the second table above we can see that when this node is visited during the render traversal and the indices of each polygon are copied into the index buffer, we add the indices for polygons A, C, and B before we encounter a subset change and flush. Thus we can render these three polygons in a single draw call. We then collect the polygons B, D, and F into the index buffer and flush again the next time a subset change is encountered. We can see that when the

traversal function reaches a node, it will loop through its BSPRenderData array and copy the index arrays stored here into the dynamic index buffer, only flushing on a subset boundary. Of course, as we test and add each index array, we must know what attribute the polygon it pertains to has been assigned to. This lets us know if we can add it or if we have to flush the buffer before we do so. As the BSPRenderData array is now totally out of sync with the polygon array, we can no longer fetch it easily. That is why we also store the attribute ID in each BSPRenderData structure. It allows us to quickly detect a subset change when collecting the index arrays. Consequently, we know what subset has to be set up prior to flushing the index buffer.

- **The Attribute Callback**
  Another problem we have to overcome is that the BSP node tree essentially has to render its polygons in a self-managed fashion. With our previous tree types, we could allow the application to render the spatial tree's data batched by subset. The application would typically set the texture and material for a give subset and would then call the spatial tree's DrawSubset method to instruct the tree to render all the triangles collected into the associated render bin on the last visibility pass. The application cannot employ this same strategy when rendering the BSP node tree since the idea of rendering the scene by subset is mutually exclusive to the idea of a required back to front order, regardless of render state. Therefore, once the application calls the CBSPNodeTree::Draw function, it will not return until all of the polygons in the tree have been rendered. This leads to a very important question… where will the scene be able to set the texture and material for polygon (or batch of polygons) as it is rendered?

  The application will be able to register a callback function with the BSP tree that will be called prior to rendering a batch of triangles. That is, every time the index buffer needs to be flushed during the back to front render traversal, the registered callback function will be called by the tree and passed the attribute ID of all the triangles currently collected into the index buffer that are about to be rendered. The callback function will be responsible for setting the correct texture and material for the passed ID since the tree will have no idea what an attribute ID actually means.

  In our applications, it is the CScene class that has knowledge of what an attribute ID means (i.e., which texture and material it pertains to in the scene's attribute array). This is especially true in our application where the CScene class issues global subset IDs to all actors and meshes that are loaded. It makes sense then that is will be CScene class that will own the attribute callback function that will be registered with the BSP tree and called by that tree prior to rendering any data.

- **Lost/Reset Device Recovery**
  Because we have to use a dynamic index buffer for efficient triangle collection during the render traversal, we have an additional mechanism to implement in this tree that will actually force us to add a few small functions to CScene which will be called by CGameApp whenever the device is lost or reset.

  Up until now we have allocated all of our resources (such as index buffers, vertex buffers, and texture surfaces) in the managed resource pool (D3DPOOL_MANAGED). As we learned in Module I of this series, when we allocate a managed resource, we are allowing the Direct3D memory manager to manage our resource memory, leaving us with quite literally no work to do

after the resource has been created (other than releasing its interface when we no longer need it). The Direct3D memory manager will automatically create a system memory version of the resource data in addition to the data that may have been uploaded into video memory. This way, if the device is lost and then reset, the memory manager will automatically destroy the video memory resource and recreate and repopulate that resource with the copy of the data it has stored in the system memory version. As we know, system memory resources do not expire when the device becomes lost.

Since we now wish to create a dynamic index buffer, we will have to find another way to go because we are not allowed to create a dynamic resource in the managed resource pool (see Module I). So we will have to substitute the D3DPOOL_DEFAULT flag for the D3DPOOL_MANAGED flag during buffer allocation and use the default pool. If our device is lost, our BSP tree will have to release its index buffer and, when the device is reset, create a new one.

Destroying the index buffer and recreating it in the lost/reset device states is no hardship. Whenever the device is lost, CScene will call the CBSPNodeTree::PreReset method. This method will simply release the index buffer interface, destroying it and removing it from memory. When the device is eventually reset and ready for use by the application again, CScene will issue a call to the CBSPNodeTree::PostReset method which will simply recreate the dynamic index buffer. The problem we have with our framework so far is that the CScene class has no way of knowing when a device is in a lost state. This situation is trapped in CGameApp both during the FrameAdvance method (before we render anything) and when the user chooses to resize the window. Conversely, the CGameApp class also has no knowledge of the tree, since it is owned by the scene. Now we will need to add two new methods to CScene which can be called by CGameApp whenever it encounters a lost/reset device situation. The CGameApp class will issue a call to the CScene::PreReset method after the device has been found to be in a lost state and about to be reset. Once the device has been reset, CGameApp will call the CScene::PostReset method. These two new CScene methods simply give the scene a chance to forward the messages on to the objects it owns that need to be informed of such situations (the BSP tree as one obvious example). If we add new object types to CScene in the future that use default pool resources, we can simply let the scene call that object's PreReset and PostReset method from these two new functions.

We now have a fairly good high level understanding of the system that will be employed in order to support BSP node tree alpha rendering. From the application's perspective, the changes will be very light, as we will see shortly.

It is now time to examine the new code and any source code modifications that will be made to our demo framework. We will start by looking at the changes we will need to make to CGameApp and CScene before we study the code to the BSP node tree. This way, we can at least get an understanding of how it is ultimately going to be used in practice. Once done, we will examine the code to the node BSP tree itself.

Source Code Walkthrough - CGameApp

We will begin by examining the very small code changes that will need to be made to CGameApp in order to notify CScene about device losses and resets. No new functions or members have been added to CGameApp, but we have added two new function calls to CScene in the places where device reset detection is performed. Remember that we will generally have to reset the device when the window is resized or when it is restored after having been minimized (which always causes a lost device). Therefore, we will see calls to CScene::PreReset and CScene::PostReset inside the CGameApp::DisplayWndProc method that handles these messages. The same two functions will also be called inside the CGameApp::FrameAdvance method if it detects that the device was lost, has been recovered, and should therefore be reset. As the code added in both places is the same, we will look at only the modifications that have been made to the CGameApp::FrameAdvance method.

CGameApp::FrameAdvance (Modified)

The changes to this function are very minor, but we have shown the entire function again below (with most comments removed to compact the listing) so that we can get a feel for where the new functions are called.

The first part of the function is unchanged from previous lab projects. We increment the application counter first. Recall that the application counter is used by our spatial trees as a frame counter so that we do not test the same polygon twice during intersection tests if we are using a non-clipped spatial tree.

```
void CGameApp::FrameAdvance()
{
    static TCHAR FrameRate[ 50 ];
    static TCHAR TitleBuffer[ 255 ];

    // Increment our application counter
    IncrementAppCounter();
```

We then increment the application's timer using its (Tick method) and retrieve and print the current frame rate as calculated by the timer. We then display the current frame rate by setting it as the caption text of the render window.

```
    // Advance the timer
    m_Timer.Tick( );

    // Skip if app is inactive
    if ( !m_bActive ) return;

    if ( GetAppCounter() < 30 )
        m_Timer.SetSimulationSpeed( 0.0f );
    else
        m_Timer.SetSimulationSpeed( 1.0f );

    // Get / Display the framerate
    if ( m_LastFrameRate != m_Timer.GetFrameRate() )
    {
        m_LastFrameRate = m_Timer.GetFrameRate( FrameRate );
        _stprintf( TitleBuffer, _T("Collision Detection : %s"), FrameRate );
        SetWindowText( m_hWnd, TitleBuffer );
```

```
    } // End if Frame Rate Altered
```

This next section of code is modified. If the device is currently in a lost state and the IDirect3DDevice9::TestCooperativeLevel method is not returning D3DERR_DEVICENOTRESET, then it means the device is still lost and we can do nothing other than return. However, if we do get back an error code of D3DERR_DEVICENOTRESET then it means the device has just been recovered from a lost state and now needs to be reset before it can be used. Notice that before we reset the device (via the CD3DInitialize::Reset method -- see Chapter 2 of Module I) we first call the CScene::PreReset method. This will allow the scene to instruct the BSP node tree that it should release its index buffer since it is no longer valid. We then reset the device. After the call to the CD3DInitialize method returns, the device will have been fully recovered and non-managed resources will need to be rebuilt. We then call the CScene::PostReset method so that the scene can instruct the BSP tree that the device is now ready for rendering again and as such, it should re-create its index buffer.

```
    // Recover lost device if required
    if ( m_bLostDevice )
    {
        // Can we reset the device yet ?
        HRESULT hRet = m_pD3DDevice->TestCooperativeLevel();
        if ( hRet == D3DERR_DEVICENOTRESET )
        {
            // Restore the device
            CMyD3DInit Initialize;

            m_Scene.PreReset();

            Initialize.ResetDisplay( m_pD3DDevice, m_D3DSettings, m_hWnd );

            m_Scene.PostReset();

            SetupRenderStates( );
            m_bLostDevice = false;

        } // End if can reset
        else
        {
            return;

        } // End if cannot reset

    } // End if Device Lost
```

If the function has not returned at this point, it means we have a valid device to work with and we call all of our usual methods to fetch user input, update the player, update our animations, and render that scene. The function finally ends with the frame buffer being presented to the user.

```
  ProcessInput();
  m_Player.Update( m_Timer.GetTimeElapsed() );
  m_Scene.AnimateObjects( m_Timer );
  m_pCamera->UpdateRenderView( m_pD3DDevice );

  m_pD3DDevice->Clear( 0, NULL, D3DCLEAR_TARGET | D3DCLEAR_ZBUFFER, 0x797979, 1.0f, 0 );

  m_pD3DDevice->BeginScene();
  m_Scene.Render( *m_pCamera );
```

```
  m_pD3DDevice->EndScene();

  // Present the buffer
  if ( FAILED(m_pD3DDevice->Present( NULL, NULL, NULL, NULL )) ) m_bLostDevice = true;
}
```

Source Code Walkthrough - CScene (Modified)

As discussed in the previous section, two new methods will be added to CScene that will be called by CGameApp whenever the device has been recovered from a lost state and is about to be reset. These two new CScene methods are defined in CScene.h, as shown below.

Excerpt from CScene.h

```
void                PreReset        ( );
void                PostReset       ( );
```

We have also added a new member variable to CScene, which is a pointer to a CBSPNodeTree object. This is the object that manages our BSP node tree implementation. It is worth noting that because the BSP tree is only being used to store and render our transparent polygons, the scene will still have an ISpatialTree member just as it did in previous projects. This will make it clear that CBSPNodeTree is not a replacement for ISpatialTree derived spatial managers. Thus, below we see the two member variables in CScene that point to its tree objects.

Excerpt from CScene.h

```
ISpatialTree       *m_pSpatialTree;
CBSPNodeTree       *m_pAlphaTree;
```

The ISpatialTree derived object will still be used to contain all scene geometry for collision detection and will render all opaque geometry. The BSP tree will contain only alpha polygons and will be rendered in CScene::Render only after all other objects have been rendered (including all subsets of the ISpatialTree object).

We will now discuss the changes and additions to CScene so that we get a feel for where the BSP tree is created, where it is populated with polygon data, where it is compiled, and where and how it is rendered.

CScene::LoadSceneFromIWF (Modified)

The first function we will look at is the very familiar CScene::LoadSceneFromIWF. This is the top level function that encapsulates the entire scene loading process with respect to IWF file data. It is in this function that our ISpatialTree and CBSPNodeTree are first allocated and, at the bottom of this function, instructed to compile their polygon data that was registered during the IWF extraction process.

Since this function is getting a little lengthy, and only a few very small additions have been made to it, we will replace large sections of the function with the '….SNIP….' placeholder and a short comment describing the code we have decided not to show here in order to compact the listing on the printed

page. If you are following along with the lab project source code open in front of you (always a good idea), you will be able to see the full code to the function.

The first thing this function does is append the data path used by the application to the passed file so that the IWF file is loaded from the application's Data folder. That code has been in this section since the early days of Module I, so we will snip it from this listing. Notice that after we have constructed the full filename, we also clear the scene's collision object so that it contains no geometry or dynamic objects that might be left over from a previously loaded scene.

```
bool CScene::LoadSceneFromIWF( TCHAR * strFileName,
                               ULONG LightLimit /* = 0 */,
                               ULONG LightReservedCount /* = 0 */ )
{
    CFileIWF File;
    HRESULT  hRet;
    ULONG    i;

    ……SNIP……Append application data path to passed file name here

    // Clear our collision database
    m_Collision.Clear();
```

In this next section, which is executed before any data is loaded, we allocate both the spatial tree and the BSP node tree (called m_pAlphaTree) that will be used by our application. In this example the spatial tree allocated is of type CQuadTreeYV, but this can vary depending on the spatial tree you wish to use in your own application. The allocation of the spatial tree was here in the last two lessons as well, so all that has changed in this function is the addition of the one line that creates a new BSP node tree.

```
    // File loading may throw an exception
    try
    {
        // Allocate our spatial partitioning tree of the required type
        m_pSpatialTree = new CQuadTreeYV( m_pD3DDevice, m_bHardwareTnL, 200.0f, 100, 20 );
        m_pAlphaTree   = new CBSPNodeTree( m_pD3DDevice, m_bHardwareTnL );

        // Add our scene callback to the player.
        GetGameApp()->GetPlayer()->AddPlayerCallback( CScene::UpdatePlayer, this );
```

Notice at the bottom of the above listing that there is another familiar line. This is the call to the CGameApp owned player's AddPlayerCallback method, where the CScene::UpdatePlayer method is registered. It is this callback function that is invoked by CPlayer whenever the player is updated (this is the function that we added in our lessons on collision detection).

The next section also involves nothing new. We use the CFileIWF::Load method to load the IWF file data into its internal vectors and call a series of CScene::ProcessXX methods to extract the data and convert it into data structures useful to the application. The calls to the processing methods have been snipped as we have seen them many times before.

```
        // Attempt to load the file
        File.Load( strFileName );

        ……SNIP……Call the CScene::Process…… methods here to extract IWF data
```

```
        // Allow file loader to release any active objects
        File.ClearObjects();
```

At this point in the code both the spatial tree and the BSP tree will have had all scene polygons registered with them. This is because the CScene::ProcessMeshes is called from the above section of code (not shown) to extract the static mesh data from the IWF file. We saw in the previous lesson that for every face that we extract, we call CScene::ProcessVertices to allow our application to store the face data. As you will see in a moment, it is in this function that we create a new CPolygon structure from the passed vertices. We then test the face properties to see if it is an alpha face. If it is not an alpha face then it is simply added to the spatial tree as normal. If it is an alpha polygon, it is still registered with the spatial tree, but with the polygon's visibility Boolean set to false. This means that the polygon will be registered with the spatial tree, but will not be compiled into the render data version of the geometry. Therefore, collision queries made on the tree will correctly detect intersections with the alpha polygons, but when the tree was built, the vertices and indices of these alpha polygons would not have been added to the render data, so the polygons will not be rendered.

Of course, this is exactly what we want. We do not want the spatial tree to render our alpha polygons since they need to be rendered last and in a back to front order. Therefore, when we add an alpha polygon to the spatial tree with its visibility Booleans set to false, we make a copy of the polygon and add it to the BSP tree as well.

At this point in the LoadSceneFromIWF function then, every static polygon loaded from the IWF file will have been registered with the spatial tree and will be awaiting the build process. The BSP tree will also have had any static alpha polygons loaded from the file registered with it and is also awaiting the build process.

If the next section we set up any default lights if no lights were loaded from the file (otherwise we would not be able to see anything that we render) and instruct the spatial tree to build itself. After the build function returns, the tree will be built with all of the static polygon data loaded from the file, but its render data will contain only the opaque polygons. We then set the spatial tree as the collision system's broad phase test mechanism.

```
        // If no lights were loaded, lets default some half-way decent ones
        if ( m_nLightCount == 0 )
        {
            ……SNIP……Setup default lights here

        } // End if no lights

        // Build the spatial tree and notify the collision engine
        if ( !m_pSpatialTree->Build( ) ) return false;
        m_Collision.SetSpatialTree( m_pSpatialTree );
```

Next we instruct the BSP tree to build itself. After the compilation of this tree is complete, we set the attribute callback for later use during rendering.

```
        // Build alpha tree
        if ( !m_pAlphaTree->Build( ) ) return false;
        m_pAlphaTree->SetAttributeCallback( SetAttributes, this );
```

Notice in the above code that we set the alpha tree's attribute callback function to a CScene function called SetAttributes. We also assigned the CScene instance's pointer as the context data so that when this callback is triggered, it can use the 'this' pointer to access the CScene object's non-static data (such as its array of global attributes). The CScene::SetAttributes method will be called by the BSP tree whenever it is about to flush the index buffer and render a batch of triangles with matching attribute IDs. This function should set the correct attributes (texture and material) on the device so that the BSP tree can then render the triangles. We will look at the CScene::SetAttributes method in a moment.

In the next and final section of the code, we loop through each CTerrain object which may have been created during the load process and call the CTerrain::TreeBuildComplete. As we saw in the previous lesson, this function allows each terrain object to register each of its terrain blocks as a detail/dynamic object with the spatial tree. We then optimize the collision system, which essentially just removes any excess wasted memory that may currently exist at the end of its arrays/vectors, and allocate and initialize the CSoundManager class (which we will snip from the listing as it has not changed since it was first introduced several lessons ago).

```
        // Notify terrain that objects the spatial tree has been built
        for ( i = 0; i < m_nTerrainCount; ++i ) m_pTerrain[i]->TreeBuildComplete();

        // Optimize our collision database
        m_Collision.Optimize();

        ……SNIP……Setup CSound manager here

    } // End Try Block

    // Catch any exceptions
    catch (...)
    {
        return false;

    } // End Catch Block

    // Success!
    return true;
}
```

By the time this function returns, both of the scene's trees have been compiled and are ready for use.

CScene::SetAttributes (New)

Although this method has been has been introduced in this lesson, it really is a handy function to have around for any future objects we implement which may need to perform their own rendering with no understanding of attribute IDs. As we know, the only object that understands what the attribute ID assigned to a triangle means is the CScene class, which stores the texture/material combinations in its m_pAttribCombo array when it is requested to load an attribute. As we saw back in Chapter 8, it is the index of the texture/material in the scene's array that is actually returned as the global attribute ID.
This function has a very simple task. It will be called by the BSP node tree (or any object that may wish to use it in the future) and will be passed a void pointer to context data and an attribute ID. As we saw above, the context data registered with the callback is the instance of the CScene object that registered

the callback. When the BSP tree needs to render some triangles, it will call this callback function, passing in the context pointer and the attribute ID of the triangles it currently has collected in its index buffer. This function can then cast the context pointer to a CScene object pointer which will then give us access to the non-static data. Thus, with this pointer, the attribute array can be accessed and the correct texture and material retrieved, as shown below.

```
void CScene::SetAttributes( LPVOID pContext, ULONG nAttribID )
{
    CScene * pScene = (CScene*)pContext;

    // Retrieve indices
    long MaterialIndex = pScene->m_pAttribCombo[nAttribID].MaterialIndex;
    long TextureIndex  = pScene->m_pAttribCombo[nAttribID].TextureIndex;
```

You will recall that the scene's m_pAttribCombo array is an array of ATTRIBUTE_ITEM structures, where each item describes a texture and material combination by specifying two array indices. The first is the index of a texture in the scene's texture array and the second is the index of a material in the scene's material array. The index of an ATTRIBUTE_ITEM structure in this array also describes the attribute ID of that combination. So, in the above code you can see that we use the attribute ID to fetch the material and texture indices from the ATTRIBUTE_ITEM structure for the passed attribute ID.

Now that we have the index of the texture and material in the scene's respective arrays, we fetch the texture and material and bind them to the device. If the material index is less than zero, then it means there is no material assigned to this attribute and that the scene should use its default material.

```
    // Set the states
    if ( MaterialIndex >= 0 )
        pScene->m_pD3DDevice->SetMaterial( &pScene->m_pMaterialList[ MaterialIndex ] );
    else
        pScene->m_pD3DDevice->SetMaterial( &pScene->m_DefaultMaterial );
```

If the texture index is less than zero, then we will set NULL for the texture in texture stage 0 since it means the passed attribute has no texture assigned. If it is a valid index, we fetch the relevant element from the scene's TEXTURE_ITEM array and bind the texture pointer stored there to texture stage 0.

```
    if ( TextureIndex >= 0 && pScene->m_pTextureList[ TextureIndex ] )
        pScene->m_pD3DDevice->SetTexture( 0,
                                          pScene->m_pTextureList[ TextureIndex ]->Texture );
    else
        pScene->m_pD3DDevice->SetTexture( 0, NULL );

}
```

Although this is a simple function that requests that the scene set up the device attributes specified by the caller, we can certainly imagine how it may be used in the future by other components, not just by our BSP node tree. It is quite possible that you will develop other components down the road that for some reason or another have to render their polygons just like our BSP node tree. These components can now make a call to this function before rendering a given subset of triangles so that the scene can make sure that the correct attributes are mapped to the device prior to the commencement of rendering.

CScene::ProcessVertices (Modified)

This function has also been part of our framework since the early lessons of Module I. It is called from ProcessMeshes when a polygon needs to be processed and stored by the application. You will also recall that in the last lesson, this function was modified so that the vertices passed to this function are now used to construct a CPolygon structure that is registered with the scene's spatial tree. Now we will also add an additional piece of code that tests to see if the passed polygon is an alpha surface. If so, it will be added to the spatial tree as an invisible polygon and then copied and added to the BSP tree. The BSP tree will be the one responsible for rendering it. We will step through the first part of the function quickly as we have seen it many times before and it is unchanged from previous versions.

The function is passed the polygon as an iwfSurface pointer along with its attribute ID. The first thing we do is allocate a new CPolygon structure which we will use to store this new data. We set the attribute ID of the polygon to the attribute ID passed into the function and copy over the face normal from the passed iwfSurface. If the BackFace parameter to this function has been set to true by the caller then it means that this vertex needs its winding order flipped so that it is facing in the opposite direction. We should also negate the normal in this case as well.

```
bool CScene::ProcessVertices( iwfSurface * pFilePoly,
                              ULONG        nAttribID,
                              bool         BackFace /* = false */ )
{
    // Validate parameters
    if ( !pFilePoly ) return false;

    long      i, nOffset = 0;
    CVertex * pVertices = NULL;
    float     fScale = 1.00f;

    // Allocate a new empty polygon
    CPolygon * pPolygon = new CPolygon;
    if ( !pPolygon ) return false;

    // Set the polygon's attribute ID
    pPolygon->m_nAttribID = nAttribID;
    pPolygon->m_vecNormal = (D3DXVECTOR3&)pFilePoly->Normal;

    if ( BackFace ) pPolygon->m_vecNormal = -pPolygon->m_vecNormal;
```

In the next section we fetch the number of vertices contained in the passed iwfSurface structure and pass this value into the CPolygon::AddVertex method which will allocate the CPolygon's array of vertices to the correct size. We then fetch a pointer to the polygon's vertex array so that we can later use it to fill the vertex array with meaningful data.

```
    // Allocate enough vertices
    if ( pPolygon->AddVertex( pFilePoly->VertexCount ) < 0 ) return false;

    pVertices = pPolygon->m_pVertex;
```

In the next section we will loop through each vertex in the iwfSurface structure and copy its information into the vertex array. In the case of a normal polygon this is a simple loop that steps from 0 to N, where N is the last vertex. However, if the BackFace parameter has been set to true then it means the caller wants the passed polygon to face in the opposite direction. We have already negated the polygon normal, but as we know, that is no enough; we must also reverse the winding order such that the vertices are added in the order N to 0. We do this all in one loop by using the nOffset variable. It will be set to 0 for normal polygons and N for back facing polygons. In each iteration of the loop we will access the vertex to copy from the iwfSurface using [i+offset] which equates to [i+0] in the normal case and [i+N] in the back facing case. As *i* is increased with each iteration of the loop, nOffset is decremented by 2 (in the back face case only) such that, with each iteration of the loop [i+nOffset] will become one less. This allows us to step backwards through the winding order of the original surface and add the polygons in a counter-clockwise fashion.

Here is the code that copies over the vertices from the iwfSurface into the CPolygon's vertex array:

```
    // If we are adding a back-face, setup the offset
    if ( BackFace ) nOffset = pFilePoly->VertexCount - 1;

    // Loop through each vertex and copy required data.
    for ( i = 0; i < (signed)pFilePoly->VertexCount; i++ )
    {
        // Copy over vertex data
        pVertices[i + nOffset].x      = pFilePoly->Vertices[i].x * fScale;
        pVertices[i + nOffset].y      = pFilePoly->Vertices[i].y * fScale;
        pVertices[i + nOffset].z      = pFilePoly->Vertices[i].z * fScale;
        pVertices[i + nOffset].Normal = (D3DXVECTOR3&)pFilePoly->Vertices[i].Normal;
        if ( BackFace ) pVertices[i + nOffset].Normal = -pVertices[i + nOffset].Normal;

        // If we have any texture coordinates, set them
        if ( pFilePoly->TexChannelCount > 0 && pFilePoly->TexCoordSize[0] == 2 )
        {
            pVertices[i + nOffset].tu = pFilePoly->Vertices[i].TexCoords[0][0];
            pVertices[i + nOffset].tv = pFilePoly->Vertices[i].TexCoords[0][1];

        } // End if has tex coordinates

        // If we're adding the backface, decrement the offset
        // Remember, we decrement by two here because 'i' will increment
        if ( BackFace ) nOffset -= 2;

    } // Next Vertex
```

At this point our CPolygon has been populated with its vertex data (and texture coordinates if the passed surface had texture coordinates defined for it). We will now extract the source and destination blend modes that have been specified for this surface by the IWF creator.

> **Note:** In an IWF file, a 'Channel' can be thought of as a texture/material combination (sometimes just one of the two) and the settings describing how that channel should be rendered. If we think about a polygon that has been saved by the artist to use a blend of 3 textures, the surface would have three channels in the IWF file. Each channel describes the texture itself and any other settings required to render that texture/material correctly. If a surface has a channel count of 0, it means that it has no texture or material applied to it.

If the surface we have been passed has the SCOMPONENT_BLENDMODES flag set in its Components bitset, it means it has blend modes defined for it that can be found in the BLEND_MODE structure. This structure is defined in the file libIWF.h as shown below.

Excerpt from libIWF.h – Part of the IWF SDK

```
typedef struct _BLEND_MODE
{
    UCHAR       SrcBlendMode;               // Source Blend Mode
    UCHAR       DestBlendMode;              // Destination Blend Mode
} BLEND_MODE;
```

This structure contains two numeric values that describe the source blend and destination blend modes that should be used for this polygon. If the surface does not have this property defined, you can see at the top of the next section of code that we default the blend mode structure to contain zero in both its source and destination blend values. This basically tells us that no alpha blending is required.

```
    // Determine the blend modes we are using
    BLEND_MODE BlendMode = { 0, 0 };

    if ( (pFilePoly->Components & SCOMPONENT_BLENDMODES) && pFilePoly->ChannelCount > 0 )
          BlendMode = pFilePoly->BlendModes[0];
```

Notice that when we extract the blend modes from the surface in the above code, we extract from element zero in the surface's blend modes array. This is because the IWF file will store blend modes for each channel. Since we are not multi-texturing at the moment, we are only interested in fetching the blend modes for the first channel (the first and only texture).

Now that we have the blend modes for our polygon, we will test to see if either the source or destination blend modes are non-zero. If they are, it means that this surface should be alpha blended. In this case, we make a copy of the CPolygon (via a copy constructor) and register it with the alpha tree. The reason we create a copy of the CPolygon and do not just pass its pointer straight into the BSP tree is that we will also pass this polygon into spatial tree as well. We cannot use the same pointer for both trees because the BSP tree will most likely split the polygon during the build process, thus removing the original polygon are replacing it with two new child polygons. If the BSP tree deletes the polygon that also has a pointer stored in ISpatialTree, we are going to have significant problems. Thus, we make a copy and give each tree its own version to work with as it pleases.

Here is the code that copies the polygon and registers it with the alpha tree:

```
    // Is this using alpha blending?
    if ( BlendMode.DestBlendMode != 0 || BlendMode.SrcBlendMode !=0 )
    {
        // Make a COPY of the alpha polygon to add to the alpha tree
        CPolygon * pAlphaPoly = new CPolygon( pPolygon );
        if ( !pAlphaPoly ) { delete pPolygon; return false; }

        // Add this new polygon to the alpha tree
        if ( !m_pAlphaTree->AddPolygon( pAlphaPoly ) ) { delete pPolygon; return false; }

        // Ensure that when it's added to the spatial tree, that it's not used for rendering
        pPolygon->m_bVisible = false;
    }
```

Notice that after we added the copy of the polygon (pAlphaPoly) to the BSP tree, we set the visibility Boolean in the original polygon to false. This is because this polygon is about to be registered with the spatial tree and, although we want it added to the spatial tree for collision queries, we do not want the spatial tree to add this polygon to any of its vertex/ index buffers when it compiles its render data. This way, the polygon will not be rendered by the spatial tree and this task can be left to the BSP tree.

In the final section of code, we register the original polygon (which now has its visibility Boolean set to false) with the spatial tree, and we are done.

```
    // Add this new polygon to the spatial tree
    if ( !m_pSpatialTree->AddPolygon( pPolygon ) ) { delete pPolygon; return false; }

    // Success!
    return true;
}
```

During the loading process, this function will be called for every static polygon loaded from the IWF file. By ‘static’ we mean polygon data stored inside the IWF file (i.e., it is not called for polygons contained in external reference objects) which is defined in world space. All of these polygons will have been registered with the spatial tree and any surfaces that have been flagged by the artist as being alpha surfaces will be contained in the alpha (BSP node) tree. As we have seen, after all polygons have been processed, program flow returns to the CScene::LoadSceneFromIWF function where both trees are then instructed to compile their data.

CScene::PreReset (New)

As mentioned, the alpha tree will be using an index buffer that cannot be allocated in the managed resource pool. This means the resource will need to be rebuilt when the device is recovered from a lost state. The CGameApp object will call the CScene::PreReset method as soon as the device has been recovered, but has not yet been reset for use. This lets the scene inform any of its components to release any non-managed resources that are no longer valid. Currently, the only object in the scene that uses non-managed resources is the BSP node tree. As you can see, this function simply forwards the request to the BSP object’s function of the same name. In the BSP tree function, the dynamic index buffer will have its interface released.

```
void CScene::PreReset( )
{
    if (m_pAlphaTree) m_pAlphaTree->PreReset();
}
```

In the future we may wish to use other components that use non-managed resources and thus need to be notified of the same status. So it is a handy thing that we have now implemented a means for CGameApp to communicate the lost/reset device state to the scene.

CScene::Post Reset (New)

This function is called when the device has been reset after being recovered from a lost state. At the time this function is called, the device will have been reset and will be valid for use. This function passes the request on to any system components that need to rebuild their non-managed resources. In the case of the BSP node tree, its function of the same name creates a new dynamic index buffer which will be owned by the new recently reset device.

```
void CScene::PostReset( )
{
    if (m_pAlphaTree) m_pAlphaTree->PostReset();
}
```

We will look at the code to both the CBSPNodeTree::PreReset and CBSPNodeTree::PostReset methods in a moment when we cover the code to the BSP tree class.

CScene::Render (Modified)

The last modified function we need to look at in our framework is CScene::Render. All we have added to this function are two lines of code to render the BSP tree and set the device's world matrix to identity before doing so.

Below we show the CScene::Render function so that we can see the general flow and order in which things are done. However, as this function has hardly changed from previous versions, we have snipped out most of the code that renders the dynamic objects, sets up fog and lighting states, etc. Please consult the source code to Lab Project 16.1 if you would like to follow along with the discussion.

The first section sets up a few render states, renders the scene's sky box, and then sets any lights that the scene is currently using.

```
void CScene::Render( CCamera & Camera )
{
    ULONG i, j;
    long  MaterialIndex, TextureIndex;

    if ( !m_pD3DDevice ) return;

    ……SNIP……Set up render states

    // Render the skybox first !
    RenderSkyBox( Camera );

    ……SNIP……Set up lights

    ……SNIP……Set up fog
```

We next instruct the spatial tree to perform its visibility processing step. When this function returns, all leaves that exist inside the view frustum will be flagged as visible and any triangles that need to be rendered will be contained in their relevant leaf bins.

```
    // Allow the spatial tree to process visibility
    m_pSpatialTree->ProcessVisibility( Camera );
```

Our next task is to render the spatial tree leaf bins (one exists for each subset currently being used by the scene). As the static data contained in the spatial tree is already defined in world space, we will set the device world matrix to identity to prevent any additional transformation.

Below we see an abbreviated version of the code that loops through every subset currently being used by the scene, sets the texture and material associated with that subset (snipped), and then calls the ISpatialTree::DrawSubset method to render the polygons in the associated leaf bin.

```
    // Loop through each scene owned attribute
    D3DXMATRIX mtxIdentity;
    D3DXMatrixIdentity( &mtxIdentity );
    m_pD3DDevice->SetTransform( D3DTS_WORLD, &mtxIdentity );

    for ( j = 0; j < m_nAttribCount; j++ )
    {
        ……SNIP……Setup textures and materials on device for this subet

         m_pSpatialTree->DrawSubset( j );

    } // Next Attribute
```

With all the opaque static geometry rendered, we next loop through each CObject in the scene's CObject array and render all the subsets of any mesh/actor stored there. Once again we have snipped this section of the code as it has not been changed.

```
    // Process each object
    for ( i = 0; i < m_nObjectCount; ++i )
    {
        ……SNIP…… Render eacy dynamic object here (either actor or mesh)
    } // Next Object
```

The next section, which renders our terrain(s), is also shown using only placeholder code. Since our terrains are pre-lit in this demo, we disable lighting first, loop through each terrain, and call its Render method, before once again enabling the lighting pipeline.

```
    // Disable lighting for terrain
    m_pD3DDevice->SetRenderState( D3DRS_LIGHTING, FALSE );

    // Render each terrain
    for ( i = 0; i < m_nTerrainCount; ++i ) m_pTerrain[i]->Render( &Camera );

    // Re-Enable lighting for alpha objects
    m_pD3DDevice->SetRenderState( D3DRS_LIGHTING, TRUE );
```

In previous versions of this function the entire scene would now be rendered. Nothing more would be left to do other than call the ISpatialTree::DebugDraw method if the user has requested debug drawing of the spatial tree. However, we know that the last thing we render now should be our BSP tree. It will step through its nodes with the passed camera and render every visible polygon in a back to front order.

As the static data stored inside the BSP tree is already defined in world space, we first set the device's world matrix to identity before calling the CBSPNodeTree::Draw method.

```
    D3DXMatrixIdentity( &mtxIdentity );
    m_pD3DDevice->SetTransform( D3DTS_WORLD, &mtxIdentity );

    // Render alpha tree last
    m_pAlphaTree->Draw( Camera );

    ……SNIP……Disable Lights and Fog render states here

    // Draw the spatial tree's debug data if requested
    if ( GetGameApp()->GetDebugDraw() ) m_pSpatialTree->DebugDraw( Camera );

}
```

As you can see, after the BSP tree has been rendered we have finished rendering the entire scene. All that is left to do is disable any lighting and fog states that we used. As the final step in the function we call the ISpatialTree::DebugDraw method if the user has selected debug drawing from the menu.

We have now seen how the BSP node tree fits into our application and the few changes that were needed to accommodate it. Now that we have a feeling for how it works and where it is populated and rendered, let us have a look at the code to the CBSPNodeTree class and implement our first BSP compiler.

Source Code Walkthrough - CBSPNodeTree

Discussing the code to a BSP compiler would be fairly daunting were it not for the fact that in the previous lessons we covered a number of tree types. At this point, we are used to the recursive build process and the ways in which trees are constructed and traversed. Because of the material covered in the last two lessons, you will probably find that writing our first BSP compiler is relatively trivial. This is certainly true when you consider the extents we went to in order to devise an efficient rendering strategy for our spatial trees.

Building the BSP node tree is almost identical to building a clipped kD-tree. The main exception is that the split plane chosen at every node is selected from the polygon data that made it into that node and not calculated as one of the three axis aligned planes. Each node in the tree will have two pointers to child nodes that exist in the front and back halfspace of the node, just like the kD-tree. Of course, one other big difference with the node tree is that the polygons are stored at the nodes in the tree that they share a plane with. They are not collected at the terminal nodes (leaves), as with our previous spatial trees. Therefore, each node will also have the ability to store a list of polygons.

Before we look at the code to the CBSPNodeTree class, let us first look at the structure it uses to construct the tree and store the node information. The CBSPNode class is defined in CBSPNodeTree.h and is shown below, followed by an explanation of each of its member variables. Note that many of these members are similar to the members that we stored in the nodes/leaves of our other spatial trees.

Excerpt from CBSPNodeTree.h (CBSPNode class)

```
class CBSPNode
{
public:
    struct BSPRenderData
    {
        USHORT * Indices;
        USHORT   TriCount;
        ULONG    AttribID;
    };

    // Public Typedefs, structures and enumerators.
    typedef std::list<CPolygon*> PolygonList;

    // Constructors & Destructors for This Class.
     CBSPNode( );
    ~CBSPNode( );

    // Public Variables for This Class
    D3DXPLANE      Plane;              // Splitting plane for this node
    CBSPNode    *  Front;              // Node in front of the plane
    CBSPNode    *  Back;               // Node behind the plane
    PolygonList    Polygons;           // List of polygons assigned to this node
    BSPRenderData* PolygonData;        // One item per polygon
    D3DXVECTOR3    BoundsMin;          // Minimum bounding box extents
    D3DXVECTOR3    BoundsMax;          // Maximum bounding box extents
    signed char    LastFrustumPlane;   // The frame-to-frame coherance 'last plane' index.
};
```

D3DXPLANE Plane

This member will store the split plane that was selected when the node was constructed during the compilation process. The two child nodes will represent areas that are contained in each halfspace of this node.

When a node is first constructed during compilation, its plane is selected from the list of polygons that made it into that node. The polygon selected will be removed from the list so that it is not passed down to child nodes. Instead, it will be added to the polygon list for the node. The polygon vertices and normal will be extracted and used to create a D3DXPLANE structure representing the plane on which the polygon resides. The rest of the polygons in the list will then be classified against this plane and organized into front and back lists. Any polygons in the list that span the plane will be split and each child fragment added to the relevant list. If a polygon in the list is found to lie on the same plane, it will also be removed from the list and stored in the node's polygon list. Therefore, a node's polygon list will contain an array of all the planes whose vertices all reside on the node plane. The polygons' normals must also face into the front space of the plane.

CBSPNode * Front

This is the pointer to the node's front child. If it is not NULL, this points to a node that represents the frontspace of the current node.

CBSPNode * Back

This is the pointer to the node's back child. If it is not NULL, this points to a node that represents the backspace of the current node.

PolygonList Polygons
This is a list of polygons that are stored at the node. During the building process, any polygon that lies on the same plane as the node's split plane and faces in a matching direction will be added to this list. As the BSP tree uses plane depth to perform its back to front ordering, all polygons that lay on the same plane can be rendered together. This is why in the node tree case we store all co-planar polygons at the node. A node will always have a minimum of one polygon in its list, since a polygon was used to create the node plane. As such, at least that polygon will always be stored in this list. Typically, there are many polygons in a scene that share the same plane and in such situations, all of them would be assigned to a single node and rendered when the node is visited during the draw traversal.

BSPRenderData* PolygonData
As discussed earlier, we will be using a dynamic index buffer that is passed through the tree to collect triangles in a back to front order. For this system to work, the polygons in the tree must have indices available. Since our CPolygon structure does not store indices, this separate structure is used to store the indices of all triangles generated from a ***single*** polygon.

Excerpt from CBSPNodeTree.h (CBSPNode class)
```
struct BSPRenderData
{
       USHORT * Indices;
       USHORT   TriCount;
       ULONG    AttribID;
};
```

There will be one of these structures for each polygon stored in the node list. As you can see, each one stores an index array describing the triangles. There indices index into the main vertex buffer that is used by the tree to store the renderable version of the BSP geometry. Later we will see that after the tree has been compiled, the CBSPNodeTree::BuildRenderData function will be called. This function will copy all of the vertices in every polygon in every node into a vertex buffer and then traverse the tree building the BSPRenderData structure for each polygon at every node.

As discussed, although number of BSPRenderData structures stored at a node will naturally be equal to the number of polygons stored at that node, there is not a 1:1 mapping between the two arrays. This is due to the fact that we will create the BSPRenderData structures for each polygon stored in the node in attribute order. That is, the BSPRenderData array will be attribute sorted so that we can minimize the number of index buffer flushes that will have to be performed during the rendering traversal.

D3DXVECTOR3 BoundsMin
D3DXVECTOR3 BoundsMax
As with all of our previous tree types, each node will also store a bounding box that encompasses its polygons and the polygons stored underneath it in the tree. Although the box will generally not be nearly as good a fit as the box shaped nodes in our other spatial tree's, the end result is still a hierarchy of bounding boxes that can be used during the rendering traversal to perform hierarchical frustum culling.

signed char LastFrustumPlane
This is another member that was included in the previous lesson's nodes. It will store the index of the frustum plane that this node was rejected by in the previous traversal. This allows us to test this frustum

plane first during the next traversal so that it will hopefully be rejected again without having to test the five other frustum planes.

Now that we have an understanding of the information that will be stored at each node, let us finally begin examining the code to the BSP node tree. Our coverage will center on a class called CBSPNodeTree whose declaration can be found in CBSPNodeTree.h. We will look at the declaration one section at a time so that we can have a preliminary discussion about some of its methods and how they are used.

In order to make the node tree code feel more familiar, you will see that while the node tree is not derived from ISpatialTree (for the reasons discussed earlier), many of the methods that perform the same tasks have been given the same names. This way, we will already basically know at what point they are called in the build process and what tasks they are expected to perform. After the previous lessons, you should feel quite comfortable with most of these methods.

Excerpt from CBSPNodeTree.h

```
class CBSPNodeTree
{
public:

    // Constructors & Destructors for This Class.
    virtual ~CBSPNodeTree();
             CBSPNodeTree( LPDIRECT3DDEVICE9 pDevice, bool bHardwareTnL );

    // Public Functions for This Class.
    bool        Build               ( );
    bool        AddPolygon          ( CPolygon * pPolygon );
    void        SetAttributeCallback( void * pFunc, void * pContext );
    void        Draw                ( CCamera & Camera );

    void        PreReset            ( );
    void        PostReset           ( );
```

Above we see all the public methods exposed by this class. The Build method is called by the application after all polygon data has been registered with the tree. It is the top level function that starts the recursive build process. The AddPolygon function is called by the application prior to the tree being built to register polygon data with the tree. It is passed a pointer to a CPolygon structure that is stored in the tree's polygon vector. The SetAttributeCallback method is another method we have seen being used earlier when discussing the changes to CScene. This method is called so that the application can register a function pointer that the tree will call prior to rendering any triangles. This function will be expected to set the texture and material on the device before it returns so that when the tree flushes its dynamic index buffer, those triangles are rendered with the correct attributes. The Draw method we saw being called by the CScene::Render method. It is passed the camera that will be used to traverse the tree. It is the position of the camera which will determine the back to front traversal order. The PreReset and PostReset methods are called by the scene when the device has been lost and then restored. These two functions will be responsible for destroying the current index buffer and recreating it, respectively.

Now we will look at the private methods which will be invoked either directly or indirectly by the public methods discussed above.

Excerpt from CBSPNodeTree.h

```
private:

    // Private Typedefs, structures and enumerators.
       typedef std::list<CPolygon*> PolygonList;

    // Private Functions for This Class

    bool        BuildTree           ( CBSPNode * pNode, PolygonList PolyList );

    CPolygon *  SelectBestSplitter  ( PolygonList PolyList,
                                      unsigned long SplitterSample,
                                      float SplitHeuristic );

    void        DrawRecurse         ( CBSPNode * pNode,
                                      CCamera & Camera,
                                      UCHAR FrustumBits = 0x0,
                                      bool bAutoVisible = false );
```

The BuildTree method is called from the Build method and is the function that performs the recursive compilation of the tree. Each time the BuildTree method is called, it constructs and populates a node and then calls itself to create the children.

The SelectBestSplitter method will be called by the BuildTree method when it needs to select a polygon from the list passed into that node to be used as the split plane. As discussed in the accompanying textbook, this function will use an algorithm that will select a polygon that strives for the smallest number of splits while still factoring in tree balance as a key concern.

The DrawRecurse method is invoked by the Draw method to recursively walk the tree in a back to front order with respect to the passed camera position. Any node that is outside the frustum will not have its children visited and any node that is visited will have its polygons collected into the dynamic index buffer and rendered each time an attribute change is encountered.

Below we see the final set of private methods. Most of them should be recognizable by name, due to our coverage of CBaseTree.

```
    bool        Repair              ( );
    void        RepairTJunctions    ( CPolygon * pPoly1, CPolygon * pPoly2 );
    bool        PostBuild           ( );
    void        CalculatePolyBounds ( );
    bool        BuildRenderData     ( );
    bool        PopulateNodeData    ( CBSPNode * pNode, USHORT *& pIndices );
```

The PostBuild method is called from the Build method after the tree has been compiled. It first calls the CalculatePolyBounds method so that each CPolygon has a bounding box calculated for it. Although we never use the polygon bounding boxes in our lab project, it does not mean that you will not want to run intersection tests on the BSP node tree in your own application. In that case, the polygon bounding boxes are very useful to have to speed up these processes. After the CalculatePolyBounds methods returns, PostBuild then calls the BuildRenderData method to instruct the tree to compile the vertex data of the tree into vertex buffers, build the index array for each polygon at the nodes, and create a dynamic index buffer.

Before the BuildRenderData method starts to compile its data, it will call the Repair method to remove any T-junctions from the geometry that may have been introduced by the clipping process. This method calls the RepairTJunctions method as a helper function to mend the T junctions between a pair of polygons. These methods are just simplified versions of the repair methods that were in CBaseTree. As such, the code to these functions should be instantly understood.

After the BuildRenderData method has removed any T-junctions and collected all the vertices in the tree, it will then issue a call to the PopulateNodeData method, passing in the root node. This recursive method will traverse the tree and, at each node, build the index arrays for each polygon in attribute order.

Finally, now that we have a feel for the function layout and where in the process each will be called (most of which should be very familiar after the previous lesson), we will now discuss the member variables of CBSPNodeTree.

Excerpt from CBSPNodeTree.h

```
    // Private Variables for This Class
    CBSPNode               * m_pRootNode;       // The root node of the tree
    LPDIRECT3DDEVICE9        m_pD3DDevice;      // The Direct3D Device
    bool                     m_bHardwareTnL;    // Use hardware transformation and lighting?.
    LPDIRECT3DVERTEXBUFFER9  m_pVertexBuffer;   // Vertex buffer for storage of polygon data
    LPDIRECT3DINDEXBUFFER9   m_pIndexBuffer;    // Dynamic index buffer used for rendering.
    ULONG                    m_nVertexCount;    // Number of vertices stored in VB
    ULONG                    m_nFaceCount;      // Number of faces we need to store in IB.
    PolygonList              m_Polygons;        // LIST of Stored polygon data.
    CALLBACK_FUNC            m_AttribCallback;  // Callback function pointer
}
```

CBSPNode * m_pRootNode

After the tree has been compiled (i.e., after Build has been called by the application) this member will point to the root node of the BSP node tree.

LPDIRECT3DDEVICE9 m_pD3DDevice

This member will store a pointer to the device interface on which the BSP tree data will be rendered. This is the device that will own the vertex and index buffers for this tree.

bool m_bHardwareTnL

This Boolean signifies whether the device supports hardware accelerated transformation and lighting. If it is set to false, then software vertex processing will be needed and the tree will have to create its index and vertex buffers in system memory.

LPDIRECT3DVERTEXBUFFER9 m_pVertexBuffer

This is a pointer to the vertex buffer that will be created in the BuildRenderData method. It will contain all the vertex data for all triangles stored in the BSP tree.

LPDIRECT3DINDEXBUFFER9 m_pIndexBuffer

This is a pointer to the dynamic index buffer that will be created in the BuildRenderData call. This index buffer will not initially be filled with any data; it will be repeatedly filled and flushed during the rendering traversal.

ULONG m_nVertexCount;
This member describes the number of vertices in the tree's vertex buffer.

ULONG m_nFaceCount
This is the number of triangles in the entire tree. If we think of the vertex buffer as being a single mesh represented as an indexed triangle list, this value will be the number of triangles in that mesh. We obviously need to store this value and have it easily accessible whenever we need to create (or recreate in the case of a lost device) the index buffer since our index buffer must be large enough to collect this many vertices. Of course, it is probably rare that we would ever collect all of the triangles into the index buffer at once (considering frustum culling and buffer flushing on subset changes). However, it is still within the realm of possibility that the alpha polygons in this tree may belong to the same subset and may all be inside the frustum simultaneously. In such a situation, the render traversal would collect every single triangle stored in the tree and render the whole batch at once. Therefore, by allocating the index buffer large enough to contain every triangle, we can rest assured that we will always have enough room, regardless of the circumstances.

PolygonList m_Polygons
This is an STL list of CPolygon structures that will contain all the polygons currently registered with the tree (via the CBSPNodeTree::AddPolygon method). Pre-compilation, this list will contain all the polygon data that the scene has registered. Post-compilation, it will contain the data in its split format, just list the other tree types we developed with splitting enabled. In the BSP tree, not splitting is not an option. It is necessary for the algorithm to work correctly.

CALLBACK_FUNC m_AttribCallback
This structure has been used by several of our objects in the past to store callback functions and their context data. This structure contains two void pointers. The first stores a pointer to the callback function that was registered with the tree by the application, and the second is the context data that should be passed into the callback function when it is triggered. As usual, we will use the context data to pass the CScene object's pointer back to the scene's static callback function so that it has access to the non-static variables.

With all member variable discussions out of the way, let us start to study the functions to the BSP tree class in an order that most closely follows the flow of when they are called during the building and rendering process.

CBSPNodeTree::SetAttributeCallback

As we saw earlier, this method is called by CScene::LoadSceneFromIWF file just after the BSP tree has been created. It is passed a pointer to a static CScene function called SetAttributes which is called during rendering to set the texture and material for a given subset of triangles that the tree is about to draw. The second parameter passed to this function is the context pointer (the CScene instance that registered the callback) which will be passed to the callback function.

```
void CBSPNodeTree::SetAttributeCallback( void * pFunc, void * pContext )
{
    // Store details
```

```
    m_AttribCallback.pFunction = pFunc;
    m_AttribCallback.pContext  = pContext;
}
```

CBSPNodeTree::AddPolygon

This function is called by the application during the loading process when it wishes to register a polygon with the tree. As you can see, this function simply adds the passed CPolygon pointer to the back of the tree's m_Polygons STL list of polygons. It is this polygon list that will be the input data for the root node at the start of compilation process.

```
bool CBSPNodeTree::AddPolygon( CPolygon * pPolygon )
{
    try
    {
        // Add to the polygon list
        m_Polygons.push_back( pPolygon );

    } // End Try Block

    catch ( ... )
    {
        return false;

    } // End Catch Block

    // Success!
    return true;
}
```

CBSPNodeTree::Build

The Build function is called by the application to start the compilation process. The function first allocates the root node as shown below.

```
bool CBSPNodeTree::Build( )
{
    PolygonList::iterator       PolyIterator = m_Polygons.begin();
    PolygonList                 PolyList;

    // Nothing to build?
    if ( m_Polygons.size() == 0 ) return true;

    // Allocate a new root node
    m_pRootNode = new CBSPNode;
    if ( !m_pRootNode ) return false;
```

What it does next is not new to us as we employed the same strategy in all of the Build functions encountered for our other tree types when a splitting tree was being built. We make a copy of the tree's polygon list that currently contains all the registered polygons. The temporary list will be input into the recursive process and the original polygon list of the tree is emptied. This is done because many of these polygons will be split during the build process and we want the m_Polygons list to contain the split

geometry (the actual geometry) after the compilation process is completed. Therefore, having emptied this list, polygons will only be added back to this list when they get assigned to the nodes in the tree. These polygons may have been split several times along the way, so we will only be adding the final clipped polygon pieces back to the list. After the compile is complete, the temporary copy of the list we made will be empty (because polygons are removed as each node is constructed) and the m_Polygons list will contain the new polygon data in its split form.

```
    // Loop through all of the initial polygons
    for ( ; PolyIterator != m_Polygons.end(); ++PolyIterator )
    {
        // Retrieve the polygon
        CPolygon * pPoly = *PolyIterator;
        if ( !pPoly ) continue;

        // Store this polygon in the top polygon list
        PolyList.push_back( pPoly );

    } // Next Polygon

    // Clear the initial polygon list as this will eventually
    // become storage for whatever gets built
    m_Polygons.clear();
```

At this point we have made a copy of the entire polygon set (TreeList) that was registered with the tree and cleared the member variable list m_Polygons.

Next we kick start the build process by calling the recursive BuildTree method. It will call itself repeatedly until every node in the tree has been constructed. By the time this function returns, the entire tree will be compiled and the polygon list we just cleared will be filled with the final clipped polygon set. We pass in a pointer to the root node we just created (which will be populated by this function) and the list of polygons that are to be input into that node. For the root node, this is obviously going to be the complete set of registered polygons.

```
    // Build the tree itself
    if ( !BuildTree( m_pRootNode, PolyList ) ) return false;

    // Perform the post build steps
    return PostBuild( );
}
```

Notice also the familiar call to the CBSPNodeTree::PostBuild method after the BuildTree method returns. The PostBuild method will calculate the bounding boxes for each polygon and call the BuildRenderData method to construct the renderable versions of the data.

CBSPNodeTree::BuildTree

This is the recursive function that populates the input node. A split plane is going to be selected from the input polygon list and we will classify the remaining polygons in the list into front and back lists. Any polygons that span the plane will be split at the plane and the two child fragments added to the front and back lists appropriately. Any polygon that is found to reside on the same plane as the node (facing in the same direction) will be removed from the list and stored at the node.

The first thing this function does is select a polygon from the list that will be used to construct the node's split plane. For this task, it calls the CBSPNodeTree::SelectBestSplitter method. This function is passed the polygon list that was passed into the function and will return a pointer to a polygon that it considers the best choice for the node. We store the result in the local pointer Splitter.

```
bool CBSPNodeTree::BuildTree( CBSPNode * pNode, PolygonList PolyList )
{
    CPolygon            * CurrentPoly, * FrontSplit, * BackSplit, * Splitter;
    D3DXVECTOR3           Normal, BoundsMin, BoundsMax;
    PolygonList           FrontList, BackList;
    PolygonList::iterator PolyIterator;
    ULONG                 i;

    // Select a good splitter polygon
    Splitter = SelectBestSplitter( PolyList, 60, 3.0 );
    if ( !Splitter ) return false;
```

As you can see, the splitter selection function accepts three parameters. The first is the polygon list from which a splitter should be chosen. The second will be discussed a little later when we see the code to the SelectBestSplitter method, but essentially it allows us to control how thoroughly the passed polygon is tested for node plane candidacy. Lowering this value allows us to reduce the number of polygons in the passed list that are tested (to speed up compile times). The third parameter is a weight value that is used to bias the importance of splits when calculating the score for a polygon (described in the accompanying textbook). The higher this value, the more priority will be given to finding a polygon that creates the least number of splits; a lower priority will thus be given to finding a node that evenly divides the remaining data set into two subsets. We will look at the code to this function next, so for now just be aware that it returns a pointer to one of the polygons in the list that should be used as the node plane.

Now that we have the splitter for this node, the first thing we will do is add its pointer to the node's polygon list so that this polygon will be rendered when this node is rendered. As each node will also store a bounding box, we will also initialize two extents vectors to default values. They will be used to record the AABB of all polygons in the passed list. Keep in mind that this is the list of all polygons stored either at the node or beneath it in the tree.

```
    // Add the splitter to the node polygon list and our final list
    pNode->Polygons.push_back( Splitter );
    m_Polygons.push_back( Splitter );

    // Reset the bounding box properties
    BoundsMin = D3DXVECTOR3( FLT_MAX, FLT_MAX, FLT_MAX );
    BoundsMax = D3DXVECTOR3( -FLT_MAX, -FLT_MAX, -FLT_MAX );
```

We have the splitter polygon stored at the node but we have not yet stored the node plane itself. However, we do know what the plane normal is as it is the same as the splitter polygon's. We also know a point on that plane -- any vertex in the polygon will do. If we have a point known to be on the plane we can just dot it with the plane normal to get the distance D to the plane from the origin of the coordinate system. Since the plane normal is described in the plane equation as ABC, we now have all four plane components we need. The D3DXPlaneFromPointNormal function takes a point known to be on the plane and a plane normal and will return the <ABCD> properties in a D3DXPlane structure which we store in the node (in the CBSPNode::Plane member).

```
    // Generate the actual plane from the splitter
    D3DXPlaneFromPointNormal( &pNode->Plane,
                              (D3DXVECTOR3*)&Splitter->m_pVertex[0],
                              &Splitter->m_vecNormal );
```

We now have both the node plane and the polygon used to create it stored in the node. Our next task will be to loop through every polygon in the list and add them to either the front or back lists depending on their classification against the plane. We deliberately skip the test if the current polygon being tested is the splitter polygon as we do not want it added to any child list. Essentially, this means we have taken it out of the recursive process now that it is stored at the node. If we find any other polygons in the list that also lie on the node plane and have normals that face in the same direction, they too will be stored in the current node's polygon list. Any polygon that is spanning the node plane is split, the original polygon is deleted, and the two split fragments are added to the front and back lists.

In the first section we set up the loop to iterate through the polygon list passed into the function. If the current entry in the list is set to NULL we continue. Then, we loop through each vertex in the polygon and compare its position vector against our currently recorded minimum and maximum extents.

```
    // Classify all polygons
    for ( PolyIterator = PolyList.begin(); PolyIterator != PolyList.end(); ++PolyIterator )
    {
        // Store current poly
        CurrentPoly = *PolyIterator;
        if ( !CurrentPoly ) continue;

        // Calculate node bounding box while we're here.
        for ( i = 0; i < CurrentPoly->m_nVertexCount; ++i )
        {
            // Store info
            CVertex * pVertex = &CurrentPoly->m_pVertex[i];
            if ( pVertex->x < BoundsMin.x ) BoundsMin.x = pVertex->x;
            if ( pVertex->y < BoundsMin.y ) BoundsMin.y = pVertex->y;
            if ( pVertex->z < BoundsMin.z ) BoundsMin.z = pVertex->z;
            if ( pVertex->x > BoundsMax.x ) BoundsMax.x = pVertex->x;
            if ( pVertex->y > BoundsMax.y ) BoundsMax.y = pVertex->y;
            if ( pVertex->z > BoundsMax.z ) BoundsMax.z = pVertex->z;

        } // Next Vertex
```

At this point we have tested the vertices and adjusted the box extents vectors to contain every polygon in the list we have tested so far. Now it is time to classify the current polygon against the plane. If the current polygon is the same polygon that we used as a splitter (the same one that was returned from the SelectBestSplitter function), we skip it and continue.

```
        // Skip if this is the same as the splitter
        if ( CurrentPoly == Splitter ) continue;

        // Classify the poly against the plane
        CCollision::CLASSIFYTYPE Location =
                   CCollision::PolyClassifyPlane( CurrentPoly->m_pVertex,
                                                  CurrentPoly->m_nVertexCount,
                                                  sizeof(CVertex),
                                                  (D3DXVECTOR3&)pNode->Plane,
                                                  pNode->Plane.d );
```

At this point the local variable Location stores the classification result for the plane test. Now we enter a switch statement that handles the different cases, starting with the on-plane case.

```
        // Decide what to do
        switch ( Location )
        {
            case CCollision::CLASSIFY_ONPLANE:

                // Does the poly point in the same direction as the node?
                if ( D3DXVec3Dot( (D3DXVECTOR3*)&pNode->Plane,
                                  &CurrentPoly->m_vecNormal ) > 0 )
                {
                    // Add to node list and final list
                    pNode->Polygons.push_back( CurrentPoly );
                    m_Polygons.push_back( CurrentPoly );

                } // End if facing in the same direction
                else
                {
                    // Add straight to the back list
                    BackList.push_back( CurrentPoly );

                } // End if facing in the opposite direction
                break;
```

If the result of the classification is on-plane, this does not necessarily mean we should just store the polygon in the node. While the vertices might all share the same (node) plane, the normal of the current polygon must also be tested to see if it faces in the same direction as the node plane. We will only store polygons at the nodes when the polygon normal matches the direction of the node plane normal. Therefore, in the on-plane case we first perform a dot product between the polygon normal and the node plane normal. If the result is greater than zero then it must mean that the normal is facing in the same direction and the polygon can be added to the node. Notice that we also add its pointer to the tree's polygon list, which was emptied prior to the build process commencing. We said earlier that we only add polygons back to the main polygon list once they get assigned to a node. This is where that happens. If the polygon normal is facing in the opposing direction, we add it to the back list where it will be passed into the back child node in the next recursion. We discussed why this is the case in the accompanying textbook.

If we determine that the polygon is behind the plane or in front of the plane, it is simply added to the back or front list, respectively

```
            case CCollision::CLASSIFY_BEHIND:

                // Add straight to the back list
                BackList.push_back( CurrentPoly );
                break;

            case CCollision::CLASSIFY_INFRONT:

                // Add straight to the front list
                FrontList.push_back( CurrentPoly );
                break;
```

If the current polygon is spanning the plane then we split the polygon to the node plane using the CPolygon::Split method. This returns the two child splits in the output variables FrontSplit and BackSplit. The original polygon is then deleted from the list since it will no longer be needed and we add the front and back split fragments to the relevant lists.

```
            case CCollision::CLASSIFY_SPANNING:

                // Split the current poly against the plane and delete it
                CurrentPoly->Split( pNode->Plane, &FrontSplit, &BackSplit );
                delete CurrentPoly;

                // Add the fragments (if any survived) to the appropriate lists
                if ( BackSplit  ) BackList.push_back( BackSplit );
                if ( FrontSplit ) FrontList.push_back( FrontSplit );
                break;

        } // End Switch

    } // Next Triangle

    // Store the bounding box properties in the node
    pNode->BoundsMin = BoundsMin;
    pNode->BoundsMax = BoundsMax;
```

That ends the polygon processing loop. After the above loop exits, the front and back child lists will have been constructed and are ready to be passed into the front and back child nodes. Any polygons that were found to have matching planes with the node will not have been added to any of these lists. They will be stored at the node so that they will not be processed further down the tree. In the bottom two lines of the above code, we record the AABB extents for the polygons that made it into this node.

With the front and back lists compiled it is now time to create the child nodes, attach them to the current node and traverse into those nodes with their respective lists. In the next section of code, we begin with the front list.

```
    // Anything in front?
    if ( FrontList.size() > 0 )
    {
        // Allocate child node
        pNode->Front = new CBSPNode;
        if ( !pNode->Front ) return false;

        // Recurs into this new node
        BuildTree( pNode->Front, FrontList );

        // Clean up
        FrontList.clear();

    } // End if anything in front
```

When the recursive call to the BuildTree method returns, the entire front tree of this node will have been created. We can then clean up by clearing the front list.

Next we do the same for the back list.

```
    // Anything behind ?
```

```
    if ( BackList.size() > 0 )
    {
        // Allocate child node
        pNode->Back = new CBSPNode;
        if ( !pNode->Back ) return false;

        // Recurs into this new node
        BuildTree( pNode->Back, BackList );

        // Clean up
        BackList.clear();

    } // End if anything behind

    // Success!
    return true;
}
```

We have now seen the function that builds the entire BSP tree. Hopefully you have been pleasantly surprised by how small and familiar it is due to our coverage of the other tree types in the previous lesson. Of course, there was one function called in the above code that we have not yet covered, the SelectBestSplitter function. We will cover that next.

CBSPNodeTree::SelectBestSplitter

The CBSPNodeTree::SelectBestSplitter function is called by the recursive BuildTree function every time it needs to select a splitter polygon from the list of polygons passed into that node. In the textbook we learned that the basic algorithm to be performed is looping through every polygon and classifying its plane against all the other polygons in the list. We will record the number of polygons in the list that were found both behind and in front of the plane, which tells us the level of imbalance that will be introduced at this node should this candidate actually be chosen as the node plane. We also record the number of spanning cases that occur, which tells us how many other polygons in the current list will be split should this polygon be chosen as the splitter.

We also mentioned that the score recorded for each candidate polygon will be calculated as follows:

```
Score = (long)abs( (long)(FrontFaces - BackFaces) ) + (long)((float)Splits * SplitHeuristic);
```

FrontFaces and BackFaces hold the number of polygons that were found to be in the front and back spaces of the candidate plane, and Splits stores the number of polygons in the list that were found to be spanning that plane. SplitHeuristic is a simple scalar value that will be used to weight the importance of splits. The higher this values is, the greater the score will be with the occurrence of each split. Since it is the polygon with the lowest score at the end of the process that gets chosen as the splitter, we can see that raising this value will bias the procedure towards selecting the polygon that causes the least number of splits and lowering this value more strongly factors in the imbalance that will be caused by the candidate plane, should it be chosen. The split heuristic is a parameter to the function (we saw that we passed 3.0f in the above function) which can be tweaked during development to help you achieve a more efficient tree.

This function also takes a second parameter not discussed in the accompanying textbook, called SplitterSample. This value serves as a means for speeding up the computation of the tree by instructing the SelectBestSplitter function to only test a certain number of polygons in the list for node plane candidacy. This is very useful during debugging. For example, if this value is set to 60, then even if there are 1000 polygons in the list, only the first 60 will be tested as node plane candidates. This significantly speeds up compilation at the expense of a less efficient tree.

To understand why this feature is important you have to keep in mind that if the scene contained 50,000 polygons, when choosing the splitter at the root node we would have to test each of these polygons against all the other polygons. This would take a dreadfully long time. The children of the root (assuming a perfectly balanced tree) would then typically have somewhere in the region of 25,000 polygons, each to test against the other, and so on down the tree. We can imagine that testing every polygon that enters a node against every other polygon that enters that node is going to make the compilation process very slow on large levels. While the tree generated by sampling only a small number might be less efficient and create deeper trees, during the development cycle, we often want to run our programs as quickly as possible as we may have to test run our application many times in a single day. We really do not want to be sitting around for 15 minutes every time we run our application just because the BSP compiler is trying to choose the best possible splitter at every node. In general, we only care about getting the best tree possible when the time comes to save that data out for the release build. Therefore, the SplitterSample parameter will aid you in more rapid development. If the SplitterSample parameter is passed a value of 0, it means we wish the function to do a full test of every polygon in the passed list.

The first thing the function does is set up an iterator to step through every polygon in the passed list. Each polygon in this list will be tested as a node plane candidate. Inside this loop we fetch the pointer to the current polygon (in the pSplitter local variable) and create a plane from it.

```
CPolygon * CBSPNodeTree::SelectBestSplitter( PolygonList PolyList,
                                             unsigned long SplitterSample,
                                             float SplitHeuristic )
{
    CPolygon            * pSplitter = NULL, * pCurrentPoly = NULL, * pSelectedFace = NULL;
    long                  Score, Splits, BackFaces, FrontFaces;
    long                  BestScore = 10000000, SplitterCount = 0;
    PolygonList::iterator SrcIterator, DestIterator;
    D3DXPLANE             SplitterPlane;

    // Iterate through the face list
    for ( SrcIterator = PolyList.begin(); SrcIterator != PolyList.end(); ++SrcIterator )
    {
        // Extract the polygon we're going to test as a potential splitter
        pSplitter = *SrcIterator;
        if ( !pSplitter ) continue;

        // Create testing splitter plane
        D3DXPlaneFromPointNormal( &SplitterPlane,
                                  (D3DXVECTOR3*)&pSplitter->m_pVertex[0],
                                  &pSplitter->m_vecNormal );
```

Now that we have the node plane candidate, we will set the score variables to zero before iterating through every polygon in the list (except the one we are currently testing) and classifying them against the candidate plane.

```
        // Test against the other poly's and count the score
        Score = Splits = BackFaces = FrontFaces = 0;

        for (DestIterator=PolyList.begin(); DestIterator != PolyList.end(); ++DestIterator )
        {
            // Extract the polygon we're going to test against the splitter
            pCurrentPoly = *DestIterator;
            if ( !pCurrentPoly || pSplitter == pCurrentPoly ) continue;

            // Classify against the splitter plane
            CCollision::CLASSIFYTYPE Result =
                        CCollision::PolyClassifyPlane( pCurrentPoly->m_pVertex,
                                                       pCurrentPoly->m_nVertexCount,
                                                       sizeof(CVertex),
                                                       (D3DXVECTOR3&)SplitterPlane,
                                                       SplitterPlane.d );
            switch ( Result )
            {
                case CCollision::CLASSIFY_INFRONT:
                    FrontFaces++;
                    break;

                case CCollision::CLASSIFY_BEHIND:
                    BackFaces++;
                    break;

                case CCollision::CLASSIFY_SPANNING:
                    Splits++;
                    break;

                default:
                    break;

            } // switch

        } // Next Test Polygon
```

When the inner loop exits, we will have tested every polygon in the list against the candidate plane and recorded the number of splits that will occur and the number of polygons that will live in its front and back halfspaces. With this information, we now calculate the score for the candidate plane using the passed SplitHeuristic parameter as a weight. If the score of the polygon turns out to be lower than the lowest score we have found so far, then we record this score and the polygon. If no lower score is found, we have this information at the end of the function to return to the build process.

```
        // Tally the score (modify the splits * n )
        Score = (long)abs( (long)(FrontFaces - BackFaces) )
              + (long)((float)Splits * SplitHeuristic);

        // Is this the best score ?
        if ( Score < BestScore )
        {
            BestScore       = Score;
            pSelectedFace = pSplitter;

        } // End if better score
```

After calculating and possibly storing the score, we increment the local SplitterCount variable such that it is updated for each candidate plane we test. If the SplitterSample parameter was not set to zero (which

means we should test all polygons as node plane candidates), and if SplitterCount is greater than or equal to SplitterSample, then we have tested the number of polygons that the caller required and we break from the loop. The polygon that was recorded with the lowest score will then have its pointer returned back to the build process where it will be stored in the node and used to create the node plane.

```
        SplitterCount++;

        // Break if we reached our splitter sample limit.
        if ( SplitterSample != 0 &&
             SplitterCount >= (long)SplitterSample &&
             pSelectedFace ) break;

    } // Next Splitter Polygon

    // This will be NULL if no faces remained to be used
    return pSelectedFace;
}
```

CBSPNodeTree::PostBuild

The CBSPNodeTree::PostBuild method is called at the very bottom of the CBSPNodeTree::Build method after the tree has been fully compiled. It calls the CBSPNodeTree::CalculatePolyBounds method to calculate and store the bounding boxes for every CPolygon stored in the tree. This function is just a straight cut and paste from the CBaseTree version. The second function it calls is the CBSPNodeTree::BuildRenderData method which builds the vertex and index buffers that will be used for rendering.

```
bool CBSPNodeTree::PostBuild(  )
{
    // Calculate the polygon bounding boxes
    CalculatePolyBounds( );

    // Build the render data
    return BuildRenderData( );
}
```

When this function returns, the BSP tree will be built and all the data will be compiled into a renderable format ready for use by the application. Let us look at the CBSPNodeTree::BuildRenderData method next.

CBSPNodeTree::BuildRenderData

The BuildRenderData method is called by the PostBuild method after the tree has been constructed. Its job is to collect the vertex data stored at each node and compile it into a single vertex buffer. First it will copy all the vertex data into a D3DXMesh so that we can use its welding functionality to remove any redundant vertices in the mesh data. After the weld, the vertex data will be copied into the tree's vertex buffer and the mesh will be released. After all the vertex data has been created, this function will also allocate the dynamic index buffer that will be used by the tree during the render traversal. Finally, it will also call the recursive PopulateNodeData method which recursively walks the tree, generating the index

arrays for each polygon store at each node (in the node's CBSPRenderData structures discussed earlier). These are the indices that will be copied into the dynamic index buffer during the render traversal.

The first section of the function tests whether the device being used is capable of supporting hardware transformation and lighting. If not, the ulUsage local variable will have the D3DUSAGE_SOFTWAREPROCESSING flag set. This will be the usage parameter we use to create the vertex buffer. Notice that ulUsage is initialized at the top of the function to include the D3DUSAGE_WRITEONLY flag. This way, whether the device has hardware support or not, the buffer will be allocated optimally for write-only operations. If the device is set to NULL, we also return as it obviously means that this tree is not intended to be used for rendering and therefore no render data should be built. We also return immediately if the root node has not yet been constructed as it indicates that this function has somehow been called before the tree has been compiled.

Assuming that everything is valid up to this point, we call the CBSPNodeTree::Repair method. Although we will not cover the code to that function in this workbook (it is just a simplified version of the one used by CBaseTree), you will recall that this method removes any T-junctions that may have been introduced into the geometry by the clipping process (or perhaps unwittingly by the artist).

```
bool CBSPNodeTree::BuildRenderData(  )
{
    ULONG       nTotalTris, nTotalVertices;
    ULONG       ulUsage = D3DUSAGE_WRITEONLY;
    CVertex    *pDestVertices, *pSrcVertices;
    ULONG      *pAttributes;
    USHORT     *pIndices;
    USHORT      nCounter;
    ULONG       i, j;
    LPD3DXMESH  pMesh;
    HRESULT     hRet;

    // Should we use software vertex processing ?
    if ( !m_bHardwareTnL ) ulUsage |= D3DUSAGE_SOFTWAREPROCESSING;

    // Instructed not to build data?
    if ( !m_pD3DDevice ) return true;

    // Anything to do ?
    if ( !m_pRootNode ) return false;

    // First thing we need to do is repair any T-Junctions created during the build
    Repair( );
```

We wish to create a D3DX mesh object into which we will copy all the vertices currently stored in the tree so that we can use its weld functionality on that vertex data. Before we allocate this mesh, we need to know how big its vertex and index buffers need to be, so we will first loop through every polygon currently stored in the tree and keep a running sum of the vertices from all polygons to eventually pass into the mesh creation function. We do not have to traverse the tree to collect the polygon counts as the CBSPNodeTree::m_Polygons vector also contains a list of all the polygons pointers stored at the nodes. For each polygon, we will also add up the number of triangles it will add to the mesh since this will also be required information for the mesh creation function. Because our CPolygon structures are convex winding polygons, we can find out how many triangles we will need to create for each one simply subtracting 2 from the vertex count for that polygon. At the end of the loop shown in the next section of

code, we will have recorded the total number of vertices stored in the tree and the total number of triangles that we will need to generate indices for.

```
    // Iterate through all of the polygons in the tree and count the vertices
    // and triangles for the purposes of correctly sizing our vertex / indexbuffer.
    nTotalVertices = 0; nTotalTris = 0;
    PolygonList::iterator Iterator = m_Polygons.begin();
    for ( ; Iterator!= m_Polygons.end(); ++Iterator )
    {
        CPolygon * pPoly = *Iterator;

        // Skip if it's invalid
        if ( !pPoly || pPoly->m_nVertexCount < 3 ) continue;

        // Total up vertices and triangles
        nTotalVertices += pPoly->m_nVertexCount;
        nTotalTris     += pPoly->m_nVertexCount - 2;

    } // Next Polygon
```

With this information we can now create a D3DXMesh of the correct size. Notice that because this mesh is only being used temporarily to store data that we intend to read back from, we allocate this mesh in system memory. If the mesh is created successfully, we lock its vertex, index, and attribute buffers so that we have pointer to each for mesh population.

```
    // Create a mesh to perform a weld
    hRet = D3DXCreateMeshFVF( nTotalTris,
                              nTotalVertices,
                              D3DXMESH_SYSTEMMEM | D3DXMESH_SOFTWAREPROCESSING,
                              VERTEX_FVF,
                              m_pD3DDevice,
                              &pMesh );

    if ( FAILED( hRet ) ) return false;

    // Lock the vertex, index and attribute buffers ready for population
    if ( FAILED( pMesh->LockIndexBuffer( 0, (void**)&pIndices ) ))
       { pMesh->Release();
         return false; }

    if ( FAILED( pMesh->LockVertexBuffer( 0, (void**)&pDestVertices ) ))
       { pMesh->UnlockIndexBuffer();
         pMesh->Release();
         return false; };

    if ( FAILED( pMesh->LockAttributeBuffer( 0, &pAttributes ) ))
       { pMesh->UnlockIndexBuffer();
         pMesh->UnlockVertexBuffer();
         pMesh->Release();
         return false; }

        // Attributes should all 0 to ensure  no face remapping occurs during the weld!!!!
        ZeroMemory( pAttributes, nTotalTris * sizeof(ULONG) );
```

At the bottom of the above code, we set the attribute of every triangle in this mesh to zero so that the D3DXWeldVertices function will assume that this mesh contains a single subset. In this case we can circumvent any aggressive weld optimizations on the index data that we wish not to be altered by the process.

With our mesh now created and with pointers to its index and vertex buffers, we can loop through each polygon again and add the vertices to the vertex buffer and generate the indices for each triangle as they pertain to the vertex buffer. In the first section of the loop shown below we can see that for the current polygon being processed, we memory copy its vertex array into the destination pointed to by pDestVertices. After the vertices for each polygon have been copied, the vertex buffer pointer (pDestVertices) is incremented by the number of vertices just added such that, in the next iteration of the loop the vertices will be added immediately after the vertices of the polygon we have just added.

> **Note**: During the compilation phase, we add polygons to the tree's master polygon list at the same time we add them to the nodes. This means that the order in which the polygons are stored in the tree's master list is identical to the order in which we would visit these polygons were we to traverse the tree and process the polygons at each node. Therefore, while we are just looping through the tree's master polygon list, we are adding them to the vertex buffer in the exact order they will be visited during node traversal. This will become significant when we have to walk through the tree and calculate the index arrays of each polygon stored at the nodes, as we will see later.

```
    // Loop through each polygon
    nCounter = 0;
    for ( Iterator = m_Polygons.begin(); Iterator!= m_Polygons.end(); ++Iterator )
    {
        CPolygon * pPoly = *Iterator;

        // Skip if it's invalid
        if ( !pPoly || pPoly->m_nVertexCount < 3 ) continue;

        // Copy over the vertices
        memcpy( pDestVertices, pPoly->m_pVertex, pPoly->m_nVertexCount * sizeof(CVertex));
        pDestVertices += pPoly->m_nVertexCount;
```

Wit the vertices of the current polygon having been added to the vertex buffer it is time to generate the indices for its triangles. Recall from previous lessons that we generate the triangle indices for a convex winding polygon by stepping around its vertices in the order 0,1,2: 0,2,3: 0,3,4, etc.. Of course, since we are indexing into a global array rather than a local vertex list, the indices need to be offset to reflect prior vertices that came earlier in the global buffer. The local variable nCounter is used for this task. It will be zero for the first polygon and at the end of this loop will be incremented by the polygon's vertex count so that in the next iteration it contains the location of where the next polygon's first vertex will be placed, and so on. Here is the loop that generates the indices for the current polygon.

```
        // Build indices and attributes
        for ( j = 0; j < (unsigned)(pPoly->m_nVertexCount - 2); ++j )
        {
            // Build indices
            *pIndices++ = nCounter;
            *pIndices++ = nCounter + (USHORT)j + 1;
            *pIndices++ = nCounter + (USHORT)j + 2;

        } // Next Triangle

        // Increment counter
        nCounter += pPoly->m_nVertexCount;

    } // Next Polygon
```

At this point, the vertex buffer contains every vertex that was contained in the tree and the index buffer contains the indices of all the triangles that vertex buffer describes. In a moment, you will see that we will pass this index buffer into a recursive method that will visit each node and copy the indices for each polygon from this index buffer into the BSPRenderData structure stored at the node (in attribute order). For the moment, we have the mesh populated, so it is time to unlock the mesh buffers in preparation for the weld.

```
    // Unlock the buffers
    pMesh->UnlockIndexBuffer();
    pMesh->UnlockVertexBuffer();
    pMesh->UnlockAttributeBuffer();
```

Our mesh is ready to be welded, so we allocate a D3DXWELDEPSILONS structure and initialize all its members to have a compare tolerance of 0.001. We then pass this information along with the mesh into the D3DXWeldVertices function.

```
    // Set all epsilons to 0.001;
    D3DXWELDEPSILONS WeldEpsilons;
    float * pFloats = (float*)&WeldEpsilons;
    for ( i = 0; i < sizeof(D3DXWELDEPSILONS) / sizeof(float); i++ ) *pFloats++ = 1e-3f;

    // Weld the vertex data
    hRet = D3DXWeldVertices( pMesh,
                             D3DXWELDEPSILONS_WELDPARTIALMATCHES |
                             D3DXWELDEPSILONS_DONOTSPLIT,
                              &WeldEpsilons, NULL, NULL, NULL, NULL );

    if ( FAILED(hRet) ) { pMesh->Release(); return false; }
```

Now our vertex data will have hopefully been compacted by some amount and the indices in the index buffer will have also been updated to reflect the new positions of the post-weld vertices.

The next step is creating the vertex buffer that will be used to store the post-weld data since the mesh will be discarded shortly. In order to allocate the tree's vertex buffer we need to know how many vertices it needs to hold. We cannot use the vertex total that we calculated earlier in the function since the number of vertices may have changed due to the weld. So we will call the ID3DXMesh::GetNumVertices method to fetch the current number of vertices in the mesh and then allocate our vertex buffer.

```
    // Create the actual vertex and index buffers ready to store the data
    m_nVertexCount = pMesh->GetNumVertices();
    hRet = m_pD3DDevice->CreateVertexBuffer( m_nVertexCount * sizeof(CVertex),
                                             ulUsage,
                                             VERTEX_FVF,
                                             D3DPOOL_MANAGED,
                                             &m_pVertexBuffer, NULL );
    if ( FAILED(hRet) ) return false;
```

We will also retrieve the number of triangles in the mesh and use that to allocate the tree's dynamic index buffer. Note that we will use the D3DUSAGE_DYNAMIC flag during index buffer creation to allow later locking and filling during tree traversals without stalling the pipeline. Also notice our request for the D3DPOOL_DEFAULT resource pool. A dynamic buffer will fail to create if we ask for the

managed resource pool, which is why we will also have to manage releasing and re-allocating this buffer ourselves when the device is lost and then reset.

```
    m_nFaceCount = pMesh->GetNumFaces();
    hRet = m_pD3DDevice->CreateIndexBuffer( (m_nFaceCount * 3) * sizeof(USHORT),
                                            ulUsage | D3DUSAGE_DYNAMIC,
                                            D3DFMT_INDEX16,
                                            D3DPOOL_DEFAULT,
                                            &m_pIndexBuffer, NULL );
    if ( FAILED(hRet) ) return false;
```

We will now lock our new vertex buffer and the mesh vertex buffer and copy over the data. At this point, the vertices are in their final renderable state in the tree's vertex buffer.

```
    // Lock the vertex buffers ready for extraction
    if ( FAILED( m_pVertexBuffer->Lock( 0, 0, (void**)&pDestVertices, 0 )))
       { pMesh->Release(); return false; }

    if ( FAILED( pMesh->LockVertexBuffer( 0, (void**)&pSrcVertices )))
       { m_pVertexBuffer->Unlock(); pMesh->Release(); return false; }

    // Copy over the vertices
    memcpy( pDestVertices, pSrcVertices, pMesh->GetNumVertices() * sizeof(CVertex) );

    // Unlock Both Buffers
    pMesh->UnlockVertexBuffer( );
    m_pVertexBuffer->Unlock( );
```

With the vertex data prepared it is now time to generate the indices for each triangle. We already have the indices generated and stored in the mesh's index buffer but our render system requires that the indices of the each polygon are stored in system memory arrays at the nodes as described earlier. That way, when a node is visited during the rendering traversal, we can copy the indices into the dynamic index buffer. Because the mesh's index buffer currently contains the information we need, we will lock and pass a pointer to this index buffer's data into the recursive CBSPNodeTree::PopulateNodeData method. It will traverse the tree, starting from the root, and at each node, copy the indices from the mesh's index buffer into system memory arrays at each node. So if a node contains five polygons in its list, we will have to store five index arrays at that node. The index arrays for each polygon will be stored in a BSPRenderData array at the node and there may not be a 1:1 mapping between the polygon array and the BSPRenderData array. This is because the PopulateNodeData method will extract the indices from the mesh's index buffer in attribute order so that during the rendering traversal, we minimize the need to flush the index buffer when collecting triangles that may be spread over a range of attributes.

```
    // Lock the index buffer ready for extraction
    if ( FAILED( pMesh->LockIndexBuffer( 0, (void**)&pIndices )))
       { pMesh->Release(); return false; }

    // Populate the node's polygon data items
    bool bResult = PopulateNodeData( m_pRootNode, pIndices );

    // Unlock the buffer and release the mesh
    pMesh->UnlockIndexBuffer();
    pMesh->Release();

    // Success?
    return bResult;
```

```
}
```

Our job is now done and we can return to the caller (PostBuild function) which will essentially return program flow back to the application. At this point, the tree will be ready to render via its Draw method.

CBSPNodeTree::PopulateNodeData

This function is actually very small as it has a very simple task to perform. For each node it visits, it has to allocate an array of BSPRenderData structures at that node large enough so that there is one element for each polygon stored at that node. Because the tree's master polygon list was iterated through in order to generate the indices in the mesh's index buffer (passed into this function), this means the triangles are ordered in the passed index buffer in the exact order we would generate them if we were to walk the tree and generate the indices on a per polygon basis. Since we pass the index buffer pointer by reference, this means we can extract the indices for the current node we are visiting and then increment the pointer by the number of triangles stored at that node so that when we recurs into the next node, the indices pointer is now pointing at the index information for the polygons that are stored at that node. In short, at the start of any instance of this function, the pIndices parameter will point to the section of the index buffer that contains the triangles that were generated by the polygons stored at this node. This function relies on that fact.

We will essentially loop through each polygon stored at the node, record its vertex count, and then use this to calculate the number of triangles the polygon will generate. We will then copy over the indices from the index buffer into a BSPRenderData structure stored at the node so that at the end of this function, all the indices generated from the polygons stored at this node will have been copied from the passed index buffer into the corresponding BSPRenderData structures. As we copy over the indices for each polygon, we also total up the number of triangles we have copied into this node (nTriCount). Before we recur into the children, we can increment the passed pIndices pointer by this amount so that when this pointer is passed to the children, it points to the region of the index buffer where their triangles start, and so on.

If all we were going to do was loop through each polygon stored at the node, extract its indices from the index buffer, and copy them into the corresponding BSPRenderData structure, the function would be very simple. However, what we wish to do is copy the indices in subset order. For example, imagine that we have 50 triangles stored at the node and 20 of them use attribute 1, another twenty use attribute 2, and the other 10 use attribute 3 but that they are arranged in no particular order. We want to copy all the indices that use attribute 1 first, followed by all the indices that use attribute 2, and finally the indices that use attribute 3. So while there will still be a BSPRenderData structure in the node's array for each polygon stored at the node, there will no longer be a 1:1 mapping between the BSPRenderData array and the CPolygon list. The first section of the BSPRenderData array will store the triangles in the node that use attribute 1, followed by the triangles that use attribute 2, and so on. During the render traversal, we will then be able to collect the polygons stored at that node in subset order, minimizing the number of draw calls that have to be performed. In this example, all the polygons at the node could be rendered in three draw calls, one for each subset. If the BSPRenderData structures were not ordered by subset however, we may require many more subset changes, perhaps one for every polygon.

Therefore, our basic system will work like this. We will allocate an STL map that stores an attribute ID as the key and a Boolean as its value. Remembering that the passed index buffer pointer (pIndices) will point to the section of the index buffer where this node's regions of triangles are stored, this is what we will do:

- Fetch the number of polygons stored at the node and allocate the BSPRenderData array to store an element for each polygon.

- Loop through each BSPRenderData structure stored at the node (nBSPDataCount)

    - Loop through each polygon stored in the node and try to find an attribute ID we have not yet processed by searching the map. We skip any that we have processed already because as you will see, once we find an attribute ID we have not processed yet, we copy over the indices of all the polygons that use it.

    - At this point we have an attribute ID (AttribID) that we have not yet processed, so we add it to the map and set its value to true so that we know it has been processed and that we should not process it again.

    - We now make a temporary copy of the passed index buffer pointer (pTempIndexBuffer) so that we can repeatedly search though the section of the index buffer that pertains to this node and extract the indices for the current attribute we are processing.

    - Loop through each polygon in the node (pTest)

        - If pTest->AttribID does not equal AttribID
            - This means the current polygon we are testing does not belong to the attribute we are current trying to copy indices for.
            - Increment pTempIndexBuffer by the triangle count of pTest so that we step past the section of indices in the index buffer that were added for this polygon. We are not interested in copying over the indices of this polygon as it does not belong to the subset we are currently processing.
        - Else
            - Store AttribID in BSPRenderData structure (pBSPData[nBSPDataCount])
            - Calculate triangle count of polygon pTest and store in pBSPData[nBSPDataCount]
            - Copy over vertices from pTempIndexBuffer into pBSPData[nBSPDataCount]
            - Increment pTempIndexBuffer by ptest->TriangleCount * 3 so that it points at the indices of the next triangle in the node
            - Increase variable nTriCount which will be eventually incremented by each polygon we process. At the end of the function it stores the number of triangles generated by the node's polygons.
            - Increment outer loop variable nBSPDataCount since we have just filled out a new BSPRenderData structure.

- pIndices still points to the beginning of the section of the index buffer where this node's triangle data starts, so increment by nTriCount so that it now points at the next block of triangle data for the first child node.

- Traverse into front child with pIndices
- Traverse into back child with pIndices

Although this might seem pretty confusing at first, we are essentially just making a pass through the passed section of the index array once for each BSPRenderData structure so that we extract the triangles one subset at a time.

The first section of the code retrieves the number of polygons stored at the node currently being visited. Assuming that there is some polygon data stored at the node (in the BSP node tree case there always should be) we enter the main section of the function. The first thing we do inside this section is allocate the node's BSPRenderData array so there is one element for each polygon stored in the node. Notice at the head of the function that we instantiate an STL map called **ProcessedAttributes.** This is empty at the head of the function but will be populated by an attribute ID and a boolean set to true for each subset that is processed.

```
bool CBSPNodeTree::PopulateNodeData( CBSPNode * pNode, USHORT *& pIndices )
{
    CBSPNode::PolygonList::iterator Iterator;
    std::map<ULONG,bool>            ProcessedAttributes;
    ULONG                           nPolyCount = 0, nAttribID  = 0, nTriCount = 0;
    ULONG                           nDestPoly;
    CPolygon *                      pSrcPoly;
    USHORT   *                      pBuffer;

    // Validate parameters
    if ( !pNode ) return true;
    if ( !pIndices ) return false;

    // Get the poly count
    nPolyCount = pNode->Polygons.size();

    // Is there anything here?
    if ( nPolyCount > 0 )
    {
        // Allocate our rendering data
        pNode->PolygonData = new CBSPNode::BSPRenderData[ nPolyCount ];
        if ( !pNode->PolygonData ) return false;
```

We will now loop through each BSPRenderData structure in the array we have just allocated which forms the main outer loop of the process. Although there might seem quite a lot of code inside this loop, it is simply trying to find the next polygon we should process and thus, the next section of indices that should be copied from the passed index buffer pointer into the current BSPRenderData array.

```
        // Keep looping till we're done
        for ( nDestPoly = 0; nDestPoly < nPolyCount ; )
        {
            // First find an attribute we haven't used yet
            pSrcPoly = NULL;
```

Inside this loop we will execute a small loop through every polygon contained at the node to test their attribute IDs against the STL map. As soon as we find an attribute ID which has not yet been stored in the map we know we have encountered a polygon that belongs to a subset we have not processed yet, so we will process it next.

> **Note**: Loop variable nDestPoly contains the index of the current BSPRenderData structure we are extracting information for. You will see later how this is incremented elsewhere in the loop, so this does not mean that the number of loop iterations will be equal to the number of elements in the array. You will see how inside the loop we extract triangles on a per-subset basis and as such, if there are five polygons that use this subset, inside this loop five BSPRenderData structures will be populated and nDestPoly will be incremented by five. This loop is really to make sure that we at least loop once for every BSPRenderData structure in the worst case where every polygon in the node belongs to a different subset.

```
            for ( Iterator = pNode->Polygons.begin();
                  Iterator != pNode->Polygons.end(); ++Iterator )
            {
                // Get the polygon
                pSrcPoly = *Iterator;
                if ( !pSrcPoly ) continue;

                // Has this been used?
                if ( ProcessedAttributes.find( pSrcPoly->m_nAttribID )
                     == ProcessedAttributes.end() ) break;

            } // Next Polygon

            // Retrieve the current attribute ID and add it to the processed list
            nAttribID = pSrcPoly->m_nAttribID;
            ProcessedAttributes[ nAttribID ] = true;
```

Note the use of the STL::Map.find method which searches the map for an entry that has the passed key (attribute ID). As soon as we find an attribute that is not already in the map, we break from the loop so that we can copy the attribute ID for this polygon into the local variable nAttribID and enter its row into the map with a Boolean status of true.

We have found the next attribute we wish to extract triangle data for so we will now need to make a pass through the indices pointed at by pIndices to search for indices that belong to polygons with a matching attribute. We make a copy of the pIndices pointer in pBuffer which we can increment to step through the index array without losing our starting place.

```
            // Process all polys with this matching attribute
            pBuffer = pIndices;
            for ( Iterator = pNode->Polygons.begin();
                  Iterator != pNode->Polygons.end(); ++Iterator )
            {
                // Get the polygon
                pSrcPoly = *Iterator;
                if ( !pSrcPoly ) continue;
```

If the attribute ID for the current polygon being tested does not match the attribute ID for triangles we are looking to extract, we will just fetch the number of indices that were generated by the current polygon (VertexCount-2) * 3 and use this to increment pBuffer. This will advance us past the section of the index buffer that contains indices for the current polygon being tested.

```
                // Attribute matches?
                if ( pSrcPoly->m_nAttribID != nAttribID )
                {
                    // Just Skip over the index data for this polygon
                    pBuffer += (pSrcPoly->m_nVertexCount - 2) * 3;

                } // End if attribute does not match
```

If the attribute of the test polygon does match the attribute ID we are looking for, pBuffer will currently point to the first index in the run of triangles that were generated by this polygon. It is this section of indices we wish to extract and store in the current BSPRenderData structure we are processing.

First we get a pointer to the BSPRenderData structure in the node's array we wish to populate and then we set the attribute ID of this structure equal to the attribute ID of the polygon whose triangles we intend to store there. We also calculate the triangle count of the current polygon (VertexCount-2) and store that in the BSPRenderData structure since we will need this information when collecting the indices from this structure during the render traversal. Then we allocate the CBSPRenderData structure's index array to be large enough to store the indices of all the triangles generated by this polygon.

```
                else
                {
                    // Store pointer for easy access
                    CBSPNode::BSPRenderData * pData = &pNode->PolygonData[ nDestPoly ];

                    // Store current attribute ID, and allocate indices
                    pData->AttribID = nAttribID;
                    pData->TriCount = pSrcPoly->m_nVertexCount - 2;
                    pData->Indices  = new USHORT[ pData->TriCount * 3 ];
                    if ( !pData->Indices ) return false;
```

Next we copy over the index data from pBuffer into the BSPRenderData's Indices array before incrementing the pBuffer pointer to step past the indices we have just copied to the start of the next polygon we will process in the next iteration of the loop. We also increment the outermost loop variable nDestPoly which keeps track of the number of BSPRenderData structures we have populated so far since many may be populated in this inner polygon loop. This is the case if there are multiple polygons in the node that share the same subset. As such, if we have populated multiple BSPRenderData structures in this inner loop, the outer loop variables should be adjusted to reflect this so that we do not try to collect index data for the same structures again. We also increment the local variable nTriCount by the number of triangles generated by the current polygon we just processed. When we finally break from all the loops, this will contain the total number of triangles stored at the current node. When multiplied by three, this value describes how much we need to advance the pIndices pointer to step past the index data for this node and point at the start of the data for the front child node.

```
                    // Copy over the index data and move the buffer on
                    memcpy( pData->Indices, pBuffer, (pData->TriCount * 3) *sizeof(USHORT));
                    pBuffer += pData->TriCount * 3;

                    // We've processed this polygon data item
                    nDestPoly++;
                    nTriCount += pData->TriCount;

                } // End if attribute matches
```

```
            } // Next Polygon

        } // Keep processing

    } // End if any polys exist
```

At this point we have built all the BSPRenderData structures at this node, so we just increment the pIndices pointer to point to the start of the front child's index data. We then recurs into the front child and then the back child before returning.

```
    // Shift the indices past this block in the index buffer
    pIndices += nTriCount * 3;

    // Traverse down the front of the tree, then the back
    if ( pNode->Front ) PopulateNodeData( pNode->Front, pIndices );
    if ( pNode->Back  ) PopulateNodeData( pNode->Back, pIndices );

    // Success!
    return true;
}
```

We have now covered the entire render data build process for the BSP tree and thus are ready to examine the methods that are called to perform a back to front render traversal through the tree.

CBSPNodeTree::Draw

The CBSPNodeTree::Draw method is called by the application to set up and call the recursive process. That is, it calls the recursive CBSPNodeTree::DrawRecurse method to start the traversal at the root node. This function takes a single parameter, a reference to a CCamera class. It is this camera that will be passed through the tree and used to draw the scene into the frame buffer in back to front order. The camera class also exposes the BoundsInFrustum method that will be used by our tree to perform hierarchical frustum culling.

This function's main job is to set up the render states for the rendering of the alpha polygons and restore those states after the traversal function has returned. It also must bind the tree's index and vertex buffers to the device. Remember, this is a dynamic index buffer and it will be empty at this point.

Below we see the entire function in one block as it is very small. It enables alpha blending and sets the source and destination blend states on the device to D3DBLEND_SRCALPHA and D3DBLEND_INVSRCALPHA, respectively. As discussed in Chapter 7 of Module I these are the standard states for color blending with the frame buffer using an alpha value. We also set up the first texture stage so that its alpha pipeline modulates the texture alpha with the vertex alpha (the alpha component of the diffuse color) so that the alpha value can be extracted from either of these two sources. This is important because some of our scene's geometry may store alpha components at the vertices while others might use a texture with an alpha channel. We also disable Z writing since this is the last set of triangles that should be rendered in this scene and we know that the alpha polygons will be rendered in a perfect back to front order. Recording their per-pixel depths in the depth buffer is unnecessary work. We then bind the vertex and index buffers to the device before passing in the camera and the root node pointer to the recursive draw process.

```
void CBSPNodeTree::Draw( CCamera & Camera )
{
    // Anything to do?
    if ( !m_pD3DDevice || !m_pIndexBuffer || !m_pRootNode ) return;

    // Setup States
    m_pD3DDevice->SetFVF( VERTEX_FVF );
    m_pD3DDevice->SetRenderState( D3DRS_ALPHABLENDENABLE, TRUE );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_ALPHAOP, D3DTOP_MODULATE );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_ALPHAARG1, D3DTA_TEXTURE );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_ALPHAARG2, D3DTA_DIFFUSE );
    m_pD3DDevice->SetRenderState( D3DRS_SRCBLEND, D3DBLEND_SRCALPHA );
    m_pD3DDevice->SetRenderState( D3DRS_DESTBLEND, D3DBLEND_INVSRCALPHA );
    m_pD3DDevice->SetRenderstate( D3DRS_ZWRITEENABLE , FALSE);

    // Setup the index / vertex buffers
    m_pD3DDevice->SetIndices( m_pIndexBuffer );
    m_pD3DDevice->SetStreamSource( 0, m_pVertexBuffer, 0, sizeof(CVertex) );

    // Render
    DrawRecurse( m_pRootNode, Camera );

    // Restore critical states
    m_pD3DDevice->SetRenderState( D3DRS_ALPHABLENDENABLE, FALSE );
    m_pD3DDevice->SetTextureStageState( 0, D3DTSS_ALPHAOP, D3DTOP_DISABLE );
    m_pD3DDevice->SetRenderstate( D3DRS_ZWRITEENABLE , TRUE);
}
```

When the DrawRecurse method returns, all the polygons stored in the tree will have been rendered in a back to front order, so we can once again disable alpha blending, disable the alpha pipeline in texture stage 0 and re-enable depth writes. Of course, it is in the DrawRecurse method where all the real work happens, so we will look at that next.

CBSPNodeTree::DrawRecurse

Many elements of this function will look familiar to you from our coverage of our other trees' recursive functions. Notice that the parameter list is the same with the FrustumBits unsigned char initially set to zero at the root node and the bAutoVisible Boolean set to false. Please refer back to our last lesson if you do not recall the purpose of these values.

In the first section of the function you can see that if the bAutoVisible Boolean is set to true, then one of its parent nodes must have been completely contained inside the frustum and therefore, this node must be too. When this is the case, we skip the frustum test. If it is set to false however, we perform the frustum test and return from the node immediately if the node's bounding volume is found to be completely outside the frustum.

```
void CBSPNodeTree::DrawRecurse( CBSPNode * pNode,
                                CCamera & Camera,
                                UCHAR FrustumBits /* = 0x0 */,
                                bool bAutoVisible /* = false */ )
{
    ULONG                     i, nPolyCount = pNode->Polygons.size();
    CBSPNode::BSPRenderData * pRenderData;
```

```
    USHORT                  nTriCount = 0, *pIndices = NULL;

    // Perform frustum test if applicable
    if ( !bAutoVisible )
    {
        CCamera::FRUSTUM_COLLIDE FrustumResult;
        FrustumResult = Camera.BoundsInFrustum( pNode->BoundsMin,
                                                pNode->BoundsMax,
                                                NULL,
                                                &FrustumBits,
                                                &pNode->LastFrustumPlane );

        if ( FrustumResult == CCamera::FRUSTUM_OUTSIDE ) return;
        if ( FrustumResult == CCamera::FRUSTUM_INSIDE  ) bAutoVisible = true;

    } // End if
```

If we get to this point in the function, we have found that the node we are visiting is inside the frustum, so we first must classify the camera position against the node plane to determine in which halfspace it is located. If the camera position is found to be in the front half space of the node plane then it means the polygons stored at this node are facing the camera position. Therefore, as discussed in the textbook, we must first traverse into the back child to draw the sections of the tree that are furthest away from us first, then render the polygons stored at the node, and then step into the front child. If the camera position is found to be in the backspace of the plane, then we simply visit the front child first and then visit the back child. We do not have to render the polygons stored at the node in this case as it means they are facing away from us and would ultimately be back face culled in the D3D pipeline.

```
    // Classify the camera against the node plane
    CCollision::CLASSIFYTYPE Result =
                CCollision::PointClassifyPlane( Camera.GetPosition(),
                                               (D3DXVECTOR3&)pNode->Plane,
                                                pNode->Plane.d );
```

Let us now test the results of the classification of the camera position against the node plane. We will start with the case where the camera is in the front space of the plane. First we recurs into the back child.

```
    // What was the result of the classification
    if ( Result == CCollision::CLASSIFY_INFRONT || Result == CCollision::CLASSIFY_ONPLANE)
    {
        // Traverse down the back of the tree
        if ( pNode->Back ) DrawRecurse( pNode->Back, Camera, FrustumBits, bAutoVisible );
```

After the above function call returns, the entire back sub-tree of the current node will have been rendered. Now it is time to render the polygons stored at this node before we traverse into the front child.

The first thing we do is initialize a local variable called nLastAttributeID will be used to store the ID of the last triangle we added to the dynamic index buffer. As soon as we reach a point where the attribute ID of the BSPRenderData structure we are about to copy the indices from is different from this last attribute ID values, we know we have reached the subset boundary and we should render the current contents of the dynamic index buffer. So we set up a loop that will iterate for each BSPRenderData structure stored in the node and fetch a pointer to the current structure inside the loop.

```
        // Loop through the polygon data stored at this node
        ULONG nLastAttribID = INT_MAX;
        for ( i = 0; i < nPolyCount; ++i )
        {
            pRenderData = &pNode->PolygonData[i];
            if ( !pRenderData ) continue;
```

Now that we have a pointer to the current render data structure that we wish to extract the indices from into our dynamic index buffer, we must first test that its attribute ID is the same as the last render data structure we just added triangles from. If not, then it means we have to flush the current contents of the index buffer which will contain the triangles of the previous subset. So in the next section of code we examine what happens when a new subset is encountered.

Notice that the first thing we do (assuming we have already added some triangles to the index buffer) is retrieve the pointer to the attribute callback function. This is the CScene function that is called to set the texture and material on the device for the triangles we are about to render. The typedef SETATTRIBUTES is defined in CBSPNodeTree.h and is defined as a pointer to a function that takes two parameters, a void context pointer and an attribute ID. As the first parameter to the callback function we pass the context data that was registered by the scene (a pointer to the CScene object that registered the callback). The callback function will use this to access the texture and material data from its non-static array. As you can see, the inner conditional code will only be executed if we have added triangles to the index buffer, so it will never be called during the first iteration. You will see in a moment a little further down in the listing that we increment the nTriCount member every time we copy triangles into the dynamic index buffer.

```
            // Is this attribute different?
            if ( pRenderData->AttribID != nLastAttribID )
            {
                // If we have any data built so far, we must unlock the index buffer
                // and render it
                if ( nTriCount > 0 )
                {
                  // Execute the callback in order to set texture / material details etc
                  SETATTRIBUTES SetAttributes = (SETATTRIBUTES)m_AttribCallback.pFunction;

                  if ( SetAttributes )
                  SetAttributes( m_AttribCallback.pContext, nLastAttribID );

                    m_pIndexBuffer->Unlock();
                    m_pD3DDevice->DrawIndexedPrimitive( D3DPT_TRIANGLELIST,
                                                        0,
                                                        0,
                                                         m_nVertexCount,
                                                         0,
                                                         nTriCount );

                    // Clear pIndices var so we know we need to lock again
                    pIndices  = NULL;
                    nTriCount = 0;

                } // End if renderable data
```

Looking at the above code it is important to realize that the inner conditional will only ever be executed if we have added triangles. In this case the dynamic index buffer will have been locked and pIndices will

point to the last place in the index buffer where we added triangles. Since the index buffer is already bound to the device (that was done in the Draw method), we can simply unlock the buffer and call the DrawIndexedPrimitive method to draw everything we have collected in the index buffer so far to the frame buffer. pIndices is then set back to NULL which we will see in a moment causes the buffer to be locked again and a new collection process started. The nTriCount member which was used to record how many triangles we have added so far will be set back to zero as the buffer has been flushed. So we can see in this section of code that the index buffer is only emptied once a subset change occurs. It is fortunate then that we have the BSPRenderData structures ordered by attribute in the node's array.

In the next section of code we can see that if pIndices is set to NULL, this is either the first time through the loop or we have just locked and flushed the index buffer. In this case, it means we wish to unlock the index buffer to be ready for another collection process. Notice that when the buffer is locked, we store the returned pointer in pIndices. It is this pointer we will use to add the indices to the index buffer.

```
                // Lock the IB?
                if ( pIndices == NULL )
                {
                    // It is very important that we test for failure here.
                    // In a lost device situation we
                    // may not have yet fully restored it before getting here.
                    if ( FAILED(m_pIndexBuffer->Lock( 0,
                                                      0,
                                                      (void**)&pIndices,
                                                       D3DLOCK_DISCARD ))) return;

                } // End if IB requires locking

            } // End if attribute has changed
```

All of the above code is only executed if the attribute ID of the current BSPRenderData structure we are processing has a different attribute ID to the last one we collected the indices from.
In the next section loop we can see that we update nLastAttribID to contain the attribute ID of the current BSPRenderData structure we are processing so that the buffer will not be flushed again until we encounter another BSPRenderData structure that has been assigned a different attribute ID. Thus we copy over the indices stored in the current BSPRenderData structure's index array into the index buffer. Notice that the location we copy the indices into is described by offsetting pIndices (which points to the beginning of the index array) by nTriCount * 3. This describes the number of indices we have added so far for the current attribute being collected.

```
            // Update last attribute ID
            nLastAttribID = pRenderData->AttribID;

            // Copy over index data and increment our renderable data count
            memcpy( &pIndices[ nTriCount * 3 ],
                     pRenderData->Indices,
                    (pRenderData->TriCount * 3) * sizeof(USHORT) );

            nTriCount += pRenderData->TriCount;

        } // Next Polygon
```

After copying the index data, we increase nTriCount by the number of triangles that were copied from the BSPRenderData structure. That ends the outer loop which is executed for all BSPRenderData structures stored in the node.

Outside the loop we unlock the index buffer and test to see if TriCount is larger than zero. If it is, then it means there are triangles in the index buffer that still need to be flushed. These will be the triangles collected for the last subset encountered in the BSPRenderData array (i.e., the triangles for the last subset stored in the BSPRenderData array) which have not have been flushed in the normal flow of the loop. This is because the buffer only gets flushed when an attribute change occurs, which for the final subset in a node, will never occur.

```
        // Unlock the indexbuffer if it was locked
        if ( pIndices ) m_pIndexBuffer->Unlock();

        // Render any remaining data
        if ( nTriCount > 0 )
        {
             // Execute the callback in order to set texture / material details etc
             SETATTRIBUTES SetAttributes = (SETATTRIBUTES)m_AttribCallback.pFunction;

             if ( SetAttributes )
             SetAttributes( m_AttribCallback.pContext, nLastAttribID );

             m_pD3DDevice->DrawIndexedPrimitive( D3DPT_TRIANGLELIST,
                                                 0,
                                                 0,
                                                 m_nVertexCount,
                                                 0,
                                                 nTriCount );

         }
```

Having rendered all the polygons stored at the node we then step into the front child. That concludes the case handler for the camera existing in the node's front space.

```
        // Traverse down the front of the tree
        if ( pNode->Front ) DrawRecurse( pNode->Front, Camera, FrustumBits, bAutoVisible );

    } // End if camera is infront
```

Of course, we still have to handle the case where the camera position is classified as being in the back space of the node plane. This case is easier to handle since we do not have to render the polygons stored at the node because they are facing away from us. Therefore, all we have to do is recurs into the front child and then into the back child which renders all polygons down both sides of this node.

```
    else
    {
        // Traverse down the front of the tree, then the back
        if ( pNode->Front ) DrawRecurse( pNode->Front, Camera, FrustumBits, bAutoVisible );
        if ( pNode->Back  ) DrawRecurse( pNode->Back, Camera, FrustumBits, bAutoVisible );

    } // End if camera is behind or onplane

}
```

We have now covered all the building and rendering functions of the BSP node compiler. Next we will look at the PreReset and PostReset methods of this class which as we have seen are called from the CScene namesakes when the device has been recovered from a lost state.

CBSPNodeTree::PreReset

This function is called from CScene when the device used by our BSP tree has just recovered from a lost state but has not yet been reset. This instructs our tree that any default pool resources will need to be released as they are no longer valid. As you can see, this method simply releases the index buffer interface and sets the tree's index buffer pointer to NULL.

```
void CBSPNodeTree::PreReset( )
{
    if (m_pIndexBuffer) m_pIndexBuffer->Release();
    m_pIndexBuffer = NULL;
}
```

CBSPNodeTree::PostReset

This method will be called from its CScene namesake when the device has been recovered from a lost state, has been reset, and is once again ready for use. This method will always be called after its PreReset counterpart so the index buffer of the tree will not exist at this point.

This function simply recreates the dynamic index buffer in exactly the same way that it was initially built. Once again, special attention is paid to the fact that we wish to create a dynamic index buffer which must be allocated in the default resource pool.

```
void CBSPNodeTree::PostReset( )
{
    if ( !m_pD3DDevice ) return;

    // Release previous index buffer (just in case)
    if (m_pIndexBuffer) m_pIndexBuffer->Release();
    m_pIndexBuffer = NULL;

    ULONG  ulUsage = D3DUSAGE_WRITEONLY;

    // Should we use software vertex processing ?
    if ( !m_bHardwareTnL ) ulUsage |= D3DUSAGE_SOFTWAREPROCESSING;

    // Re-Create the index buffer
    m_pD3DDevice->CreateIndexBuffer( (m_nFaceCount * 3) * sizeof(USHORT),
                                     ulUsage | D3DUSAGE_DYNAMIC,
                                     D3DFMT_INDEX16,
                                     D3DPOOL_DEFAULT,
                                     &m_pIndexBuffer, NULL );
}
```

Lab Project 16.1 Conclusion

We have now fully implemented a BSP node tree compiler and renderer. Along the way we noticed that it shares very similar qualities to the trees we developed in the previous lessons. Of course, it also has some very distinct differences, such as the polygons being stored at the nodes instead of at the terminal nodes (the leaves) of the tree. We have also had a chance to see a different type of traversal logic that can be used to render the tree in a specific order. In our example we were rendering alpha polygons and needed the back to front rendering. But by simply changing the order in which the children are traversed in the DrawRecurse method, we can easily convert it into a front to back renderer instead.

Lab Project 16.2: Solid Leaf BSP Compiler

As we move forward with the development of our graphics engine and framework, certain processes will become much more expensive for us to perform. For instance, many of the techniques employed in providing accurate scene visibility and occlusion culling schemes can involve extremely lengthy computations which cannot possibly be done in real time. In order to prevent these computations from introducing a significant delay, which could destroy the gaming experience for the player, it is important that load times remain as brief as possible. As a result, it is very often necessary to find ways to remove or optimize any processes or calculations which may need to be performed while a level is being loaded. Even in common situations, such as the compilation of a relatively simple oct-tree or kD-tree, these additional computations can easily add several seconds or more to a level's loading time. This is of course on top of the many other load-time tasks that have to be undertaken such as the reading of files, loading and potential compressing of textures, building of animation data and so on. For this reason, it will become of much greater importance that we begin to remove as much of the burden of computing such complex information from the runtime portion of our application.

Throughout the previous chapters we have introduced several new concepts and techniques which can introduce a significant delay in load time execution if we were to use a scene with a high level of geometric complexity. Constructing a spatial hierarchy from our level is by no means a trivial task as we have already discovered. In the next chapter we will be introducing the foundation of our visibility determination scheme. The operations involved in such a scheme can often take anywhere from several minutes to many *hours* to execute. To perform such lengthy operations at runtime is, as a result, unfeasible at best. One method by which we can reduce the time that it takes to load and construct our level data is to try and move as many processes and calculations as is possible from our application altogether.

As we know, most everything that we have implemented in these spatial partitioning lessons is intended to build information that allows our application to more easily manage scene data. With the exception of those processes which rely on information only available on the end user's computer hardware – such as how much data can be stored in a single vertex buffer for instance – most of the data that is constructed is based on information that does not change. As an example, during the construction of an oct-tree, kD-tree or quad-tree, the input geometry is used to define how the tree is constructed. This means that we can fully expect identical tree structures to be built on any computer system as long as they each use the same input geometry and construction parameters. Furthermore, each of these tree building classes is fundamentally assembling a series of simple data structures that are used by the application in some manner after the main game loop has commenced.

So, we know that the structure of the tree will not change irrespective of the end-user system on which it is built. As a result, it makes sense that this same information can just as easily and accurately be constructed on the developer or artist's hardware. We also know that once the game play portion of our application has begun we are simply making use of information that was built during the compilation stage. It should be possible therefore to simplify this problem by having the developer or artist save this information out to a file alongside the scene itself. This reduces our application's involvement in this process to one of simply loading and reconstructing the original data structures, rather than having to compile it on the fly. This type of operation is often referred to as a pre-process. Three such operations that exemplify such pre-process tasks – and those that will be discussed in this chapter's workbook – are

Hidden Surface Removal, *Spatial Partitioning* (of any kind) and *T-Junction Repair*. Due to the focused nature of these individual compilation tasks, it is often desirable to build a tool that is completely separate from our game application and whose sole purpose is to perform these potentially lengthy processes in advance of runtime.

With lab project 16.2, we will begin developing such a tool that will perform the brunt of our scene processing and compilation tasks. By using a relatively modular design, we will also be able to provide a level of extendibility that will be to our great benefit as we introduce additional pre-process tasks in the future.

In this section will cover the following:

- The concepts involved in building a reusable tool.
- A series of new math utility classes that will be used by this application.
- Adapting our application structures for use in a file based system.
- Building a portable pre-processing core.
- Designing a modular system for the compilation processes.
- Compilation of a polygon-aligned BSP leaf tree with solid / empty leaf information.
- Implementation of the hidden surface removal process.
- Porting the T-Junction repair system to the pre-processing tool.

Building a Reusable Tool

One of the first things that should be apparent when initially examining the source code to our new solid leaf BSP compilation tool is how different the compiler portion may appear when compared to everything we have encountered in our lab projects to date. One such difference is the implementation of several new math support classes that have been introduced in order to remove a specific reliance on the third party D3DX library provided by the DirectX™ SDK. Whilst this may seem a little superfluous to begin with, it is important to bear in mind that when we are developing a generic tool such as this we will often want to ensure that it is as portable and **re-usable** as possible.

In contrast to our game application – which is generally targeted at a specific platform / API combination – the broad applicability of the types of compilation process implemented in such tools make their re-usability highly desirable. By developing our pre-processing application in such a way that it has as few unnecessary API and platform dependencies as possible will allow this same tool to be adapted and applied to almost any project you may undertake in the future, regardless of the target platform or API. If you plan to license your toolset to third party developers, this can also be of great importance to them.

One other important benefit gained by developing our compilation toolset in this way is that it greatly increases its longevity. This is due to the fact that it will remain unaffected by any future changes made to any API on which it is dependant. Finally, by substituting the game-centric D3DX library with that of our own design we will be able to write code in a manner which best suits the specific application we are building.

The Replacement Math Classes

As a direct result of removing the dependency on the DirectX™ and associated APIs, we have introduced five new support classes which provide the math library functionality that will be required when building our compilation toolset. These include a plane class similar to D3DXPLANE, a matrix class which replaces D3DXMATRIX, two vector classes analogous to D3DXVECTOR3 and D3DXVECTOR4, and finally a new and more easily manageable axis aligned bounding box class. Each of these classes exposes member functions which provide the functionality previously accessed via calls to global D3DX functions such as D3DXMatrixMultiply in addition to other common functions that will be required.

The following list outlines each of the new math classes we will be introducing in the new compilation toolset. We will use the ‘CVector3’ class as the means by which we discuss the general design concepts used throughout our new supporting math tools. As a result we will discuss this class in greater detail than those which follow. In each case however, we will provide a summary of that class along with its intended purpose.

- **CVector3**

  This new class is designed to replace the D3DXVECTOR3 structure and associated support routines that we have been using within our run-time lab projects to date. There are many uses to

which this has been put in the past and all of the same D3DX functionality has been included here in the form of member functions. As an example of this, when performing a dot product between two D3DX vector types, we have previously made use of the 'D3DXVec3Dot' global function. With this new vector class, the dot product function has been included within the class itself via the 'CVector3::Dot' member.

In our previous implementations we have performed a dot product operation between two vectors using code similar to that shown below:

```
D3DXVECTOR3 Vector1( 1.0f, 0.0f, 0.0f );
D3DXVECTOR3 Vector2( 0.0f, 1.0f, 0.0f );

// Perform the dot product
float fDot = D3DXVec3Dot( &Vector1, &Vector2 );
```

This code should be very familiar to you at this point. As you can see we have simply built two vector classes on the stack, specifying some initial values to the class constructor. Once we have created these two vector objects, we simply pass the pointers to both of these into the 'D3DXVec3Dot' function at which point the result is returned. As mentioned previously, our new vector support class implements this same functionality using a member function rather than a global one. As a result, the code we would use in order to perform a dot product on these same two vectors now looks similar to the following:

```
CVector3 Vector1( 1.0f, 0.0f, 0.0f );
CVector3 Vector2( 0.0f, 1.0f, 0.0f );

// Perform the dot product
float fDot = Vector1.Dot( Vector2 );
```

Although the differences are relatively minor, one important thing to notice is how we have called the dot product member of 'Vector1' and simply passed 'Vector2' in as a single parameter. As before however, we are still requesting that the dot product function calculates the resulting value between the same two vectors – 'Vector1' and 'Vector2'. By using member functions in this way, we can often simplify the code that we would need to otherwise write. A good example of such a case is when we might need the ability to perform vector operations on data which is not explicitly a D3DXVECTOR3 object. Such cases have often arisen in the past when we must use *vertex* data as the input to the global vector functions. In the past, it has often been necessary to perform a complex series of casts and de-references in order to achieve this:

```
CVertex     Vertices[3];
D3DXVECTOR3 Edge1, Edge2, Normal ;

// Define Vertices
Vertex[0] = CVertex( 10.0f, 10.0f, 0.0f );
Vertex[1] = CVertex( 10.0f, 20.0f, 0.0f );
Vertex[2] = CVertex( 20.0f, 10.0f, 0.0f );

// Calculate triangle normal
D3DXVec3Normalize(&Edge1,
                  &((D3DXVECTOR3&)Vertices[1] - (D3DXVECTOR3&)Vertices[0]));
D3DXVec3Normalize(&Edge2,
                  &((D3DXVECTOR3&)Vertices[2] - (D3DXVECTOR3&)Vertices[0]));

// Cross the two edges
D3DXVec3Cross( &Normal, &Edge1, &Edge2 );

// Normalize the result
D3DXVec3Normalize( &Normal, &Normal );
```

As the complexity and length of the required operation increases, it can often become difficult to follow the indented outcome of that code. One of the primary advantages in creating a vector class in this way is that we are able to derive other classes from it. This could include our *vertex* class for instance. If we were to derive our vertex class from the new 'CVector3' class, we will gain the ability to perform vector like operations using the derived 'CVertex' object directly:

```
CVertex  Vertices[3];
CVector3 Edge1, Edge2, Normal;

// Define Vertices
Vertex[0] = CVertex( 10.0f, 10.0f, 0.0f );
Vertex[1] = CVertex( 10.0f, 20.0f, 0.0f );
Vertex[2] = CVertex( 20.0f, 10.0f, 0.0f );

// Calculate triangle normal
Edge1  = (Vertices[1] – Vertices[0]).Normalize();
Edge2  = (Vertices[2] – Vertices[0]).Normalize();
Normal = Edge1.Cross( Edge2 ).Normalize();
```

Another item of note is that the members defined within our new vector class no longer require that we pass the input parameters as pointers. Instead we have chosen to use parameter references in most of the class member functions. Recall that references are essentially the same as pointers in that they specify the memory address to an underlying data item. This provides us with most of the benefits and efficiency we would gain by using pointers but without the need to use the address-of (&) operator with every variable we use as an input parameter. This also helps us to create code which is simple and relatively easy to read and follow.

Finally, notice the method by which we have normalized the result of the cross product operation in the above code. By implementing this functionality using members within the vector class, we can often perform many operations in one go as demonstrated. This can reduce the amount of

individual steps necessary to implement such a procedure in code and can often remove the necessity that we keep temporary storage variables at our disposal for transferring the result from one step into the next. At its core, the C++ compiler is of course still creating code which allocates a temporary variable in order to achieve this. However, in this case we will arguably be able to write cleaner code, in a shorter amount of time. In addition, because we have removed the reliance on pointers and can reduce the overall amount of variables we need to keep track of, our code will often contain fewer errors resulting from incorrect casting and pointer operations or the misuse or misplacement of a temporary variable. As you might imagine, the overall complexity of the compilation tasks we will be implementing will increase dramatically as we move forward throughout this lesson and the next. This places a large degree of importance – from a coding perspective – in keeping the commonly used core libraries as clean and simple to use as possible. Hopefully, by doing so, we will eliminate many of the problems we might need to track down and debug as a result.

In the case of a game application, speed of execution is obviously paramount. To a certain degree during the development of a pre-processing tool, we do have the added advantage of being able to balance run-time execution speed against the ease with which we can develop our application. It could be argued that the compilation tasks our application must undertake may execute more slowly by not using the highly tuned D3DX mathematics library. However, this is not as crucial a concern with such one time pre-process computations as we will be developing.

Before we move on to the next new class, let us finish up by examining a selection of the functions exposed in this new implementation.

Member Functions

As we have already discussed, this new class exposes a series of member functions that provide the familiar D3DX functionality such as the dot product. The following table outlines a few of the most common functions. For a complete list of those functions defined by this class you should take a look at the ‘CVector3’ class declaration in the file named ‘CVector.h’.

Member Function	**D3DX Equivalent**
Dot	D3DXVec3Dot
Cross	D3DXVec3Cross
Length	D3DXVec3Length
SquareLength	D3DXVec3LengthSq
Normalize	D3DXVec3Normalize
TransformCoord	D3DXVec3TransformCoord
TransformNormal	D3DXVec3TransformNormal

Although this is not a complete list of the member functions implemented within the CVector3 class, this table does outline a good selection of the most commonly used D3DX equivalents. Each of these functions works in a manner similar to their D3DX counterparts with the exception

that in many cases, the result is passed back via the return value rather than by setting the contents of a variable passed into the function as a parameter.

In addition to the common vector functionality, there are several additional functions which we have developed in previous lab projects that have also been included here. As before, a sample of these functions is shown in the table below.

Member Function	Description
DistanceToPlane	There are many cases in the past where we have needed to calculate the closest distance from a plane at which a point exists. This member wraps this common functionality into a simple function that accepts the required plane as its single parameter.
DistanceToLine	In our previous implementation of the T-Junction repair process, it was necessary to determine the distance between a particular point in space and an edge / line that formed the exterior of a neighbouring polygon. This function wraps this test allowing us simply to pass in the start and end points of such a line and have it return the distance between the vector with which this member is being called and that specified line.
FuzzyCompare	Due to the nature of floating point calculations, it is never a good idea to test whether two vectors describe the same position (or direction) in space by testing for an *exact* equality between their components. We have seen that it is often necessary to use 'Epsilon' or 'Fuzzy' testing to ensure that these inaccuracies do not result in an incorrect comparison. This utility function can be used in cases where we want to test two vectors for equality, given some small tolerance value.

Again, this is not a complete list. However, this small sample should demonstrate the fact that although we have introduced several new concepts into this lab project, it is really just a rearrangement of the concepts and functions we have already developed. In doing so we make the job of developing this pre-processing tool a little more convenient. It also means that we do not have to find creative ways of integrating our rendering and *game specific* classes and utility functions into a framework with a completely different purpose.

Operator Overloads

Just as with the D3DX classes, we have also overridden several of the mathematical and logical operators common to the C++ language. We have often needed to perform mathematical operations directly on our vector structures in the past. An example of such a case is in the calculating of a direction vector by subtracting one positional vector from another. Rather than subtract each of the X, Y and Z components of these vectors individually, it has always been convenient simply to perform this operation on the vectors directly. There are other cases whereby we may want to multiply a vector by a single floating point scalar value for instance. In

this case, overloading the multiplication operator is an ideal candidate because it enables us to multiply our vector *object* by a single floating point value – something which would not otherwise be possible. The table below outlines some of the common operators that have been overloaded in this vector implementation. Again remember that this is not a full list of such operators and you should check out the class declaration for a complete list.

Operator Declaration	**Description**
`CVector3 operator+ ( CVector3& )`	This addition operator accepts a right-hand value of another vector. The implementation for this operator simply adds together each of the respective X, Y and Z components from both the left and right hand values and returns the result as a new vector object. This class also overloads the '+=' operator which functions in a similar manner. However, the right hand vector values are added directly to those of the left hand vector rather than returning a new result.
`CVector3 operator- ( CVector3& )`	Similar to the addition operator overload, this class also overloads the subtraction operator. As before we also overload the '-=' operator to allow a subtraction operation to be directly performed on an existing vector object.
`CVector3 operator* ( float& )`	This multiplication operator accepts a single floating point value as the right-hand argument. This can be used to scale a vector by multiplying each of the left-hand vector's X, Y and Z components by this single scalar value. As before, the '*=' operator for this value type is also overloaded.
`CVector3 operator/ ( float& )`	As with addition and subtraction, we also provide the complement to the multiplication operator in the form of the division operator. This accepts the same floating point argument type and, as with multiplication, simply divides the vector components by this scalar value. As with each of the previous operators, the '/=' operator has been overloaded for this same floating point argument type.

`CVector3 operator* ( CMatrix4& )`	Although we have not yet discussed our new matrix implementation, this vector class provides another multiplication operator overload that accepts a matrix as its right-hand value and returns a three dimensional output vector. As we know, there are two vector-matrix transformation functions that we have at our disposal – TransformCoord and TransformNormal. It is not possible for us to provide two operator overloads that accept the same argument types, so in the case of our vector implementation we have chosen to use the 'TransformCoord' method. This decision was based on the fact that it is often the most commonly used of the two. In the case of 'TransformNormal' however, we can still call the member function directly as we would with D3DX.
`bool operator== ( CVector3& )`	The equality operator is provided in order for us to quickly compare two vector values in a manner similar to that we would use when comparing two integer values. Unlike the aforementioned 'FuzzyCompare' function however, this operator tests for **exact** equality with no tolerance. We did this because it is a more accurate representation of what we expect from the equality operator in general. Whether you choose to use a fuzzy test in this case however, is really a matter of preference and/or convenience.
`bool operator!= ( CVector3& )`	Likewise, the inequality operator is also overloaded to allow us to test for the cases where two vector input values are *not* equal. As with the equality operator, this implementation does not use a fuzzy compare for the inequality test.

Hopefully you can see that our implementation of the 'CVector3' class is very similar to the vector concepts we are already very familiar with. We have tried to keep as close as possible to the D3DX implementation and as a result it should be a relatively simple task to adjust any existing code to use this independent vector class. In addition, by opening up the classes themselves we are able to extend them in a way that would benefit our application as we develop the modules that will rely on this functionality.

Of course, the vector class is not the only component within the D3DX mathematics library that we have come to rely heavily upon. As was mentioned at the beginning of this section, the general design of our new classes will only be discussed in relation to the 'CVector3' class. As a result we will not go into too great a detail about the layout of the remaining classes outlined

over the following pages. So without further ado, let us move on to the next of our five new support classes.

- **CVector4**

The 'CVector4' class is a replacement for 'D3DXVECTOR4' and its associated global functions. This class extends the three dimensional vector previously discussed by including the additional 'w' component as we already know. Although this particular vector class is not used directly by the application we are developing in this lesson, there are several functions available within our math library which accept a four dimensional vector as either an input or output value. An example of such a function is 'D3DXVec3Transform' ('CVector3::Transform' in our new implementation) that takes a three dimensional vector, transforms it by a 4x4 matrix and returns the resulting vector including the w component. As a result, this class has been included to allow these functions to be supported in the event that they may be required for use later in the development cycle.

Similar to its three dimensional counterpart, this class implements much of the four dimensional vector functionality exposed by D3DX within a series of member functions that work directly with the vector data. A sample of the most commonly used functions is again included below, but as before refer to the class declaration in 'CVector.h' for a complete list of those supported.

Member Function	**D3DX Equivalent**
Dot	D3DXVec4Dot
Cross	D3DXVec4Cross
Length	D3DXVec4Length
SquareLength	D3DXVec4LengthSq
Normalize	D3DXVec4Normalize
Transform	D3DXVec4Transform

Again, we are not making use of this class directly within our application at this point. However, we have also provided any appropriate operator overloads in a similar fashion to those discussed in the previous 'CVector3' coverage.

- **CMatrix4**

The 4x4 matrix is probably one of the most commonly used mathematical constructs within game development, second only to that of the three dimensional vector. It is usually quite rare for us to rely heavily upon the use of matrices during the compilation of static scene data. Although this is also true of the compilation techniques we will be implementing in this lesson, there are objects within our scene whose position and orientation are described by matrices. An example of such an object is the game 'entity' which, as we know, is essentially just a generic data storage concept providing drop in scene support for our animating objects, lights, trees etc. Although this external compilation tool will perform no rendering of the scene, this entity

information must still be processed in order for us to transfer the data into what will ultimately be exported as the compiled scene file.

Due to the complex nature of the operations that any matrix implementation is tasked with performing, it is important that the functionality offered by any such matrix class is both efficient and easy to use. Because of the fact that we are already extremely familiar with the 'D3DXMATRIX' class exposed by the D3DX math API, our matrix implementation is based heavily on this class and its associated utility functions. As with the 'CVector3' implementation of the 'D3DXVECTOR3' class, we employ a similar design in which those utility functions are provided as member functions of the matrix class itself.

Member Functions

Some of the D3DX equivalent functions that will most commonly be used are listed in the table below. In the case of our matrix class, it is recommended that you take a look at the class declaration for 'CMatrix4' included in the file named 'CMatrix.h' for a full list of member functions and their parameter layout.

Member Function(s)	**D3DX Equivalent**
Identity	D3DXMatrixIdentity
GetInverse & Invert	D3DXMatrixInverse
Transpose	D3DXMatrixTranspose
RotateAxis	D3DXMatrixRotationAxis
RotateX	D3DXMatrixRotationX
RotateY	D3DXMatrixRotationY
RotateZ	D3DXMatrixRotationZ
Rotate	D3DXMatrixRotationYawPitchRoll
Scale	D3DXMatrixScaling
Translate	D3DXMatrixTranslation
SetPerspectiveFovLH	D3DXMatrixPerspectiveFovLH
SetLookAtLH	D3DXMatrixLookAtLH

One thing that can very often be frustrating about the D3DX matrix API is the fact that almost all of the matrix functions return absolute matrices that will very often be used simply in a further concatenation with an already existing matrix. Take as an example the 'D3DXMatrixRotationAxis' function. As we know, when we examine the matrix that this function generates, we should see a set of values that describes a rotation relative to what is essentially the world axis. In most circumstances we would normally use this result in a further operation, perhaps by concatenating it with an existing matrix in order to rotate an object's world matrix by the values originally passed as parameters to the rotation function. This design can often draw out even a simple operation into a series of matrix creation and multiplication

operations where we essentially just want to rotate an existing matrix. For this reason, many of the new member functions outlined in the previous table include an additional Boolean parameter. This switch allows us to specify whether or not we would like to perform that operation on the matrix itself, rather than simply setting its values such that it *describes* the operation in question. The default in this case is to perform the operation being requested (i.e. to rotate the matrix) but this can be overridden such that the matrix is simply set in a similar fashion to the D3DX functions.

What this slightly altered design allows us to do is to request that a matrix is rotated in a single call – essentially performing the matrix multiplication on our behalf – rather than simply generating a rotation matrix that we will then have to concatenate with our target matrix manually. The code below demonstrates the code we would need to use in order to rotate an existing matrix by 90 degrees about an arbitrary axis using the D3DX library:

```
D3DXMATRIX mtxRotate;

// Generate rotation matrix
D3DXMatrixRotationAxis( &mtxRotate,
                        &D3DXVECTOR3( 0.0f, 1.0f, 0.0f ),
                        1.5707f );

// Concatenate with existing matrix
D3DXMatrixMultiply( &mtxWorld, &mtxWorld, &mtxRotate );
```

In contrast, the following code outlines the same process as applied to our new matrix class.

```
// New method for rotating an existing matrix
mtxWorld.RotateAxis( CVector3( 0.0f, 1.0f, 0.0f ), 1.5707f );
```

This same concept as applied to each of the rotation functions is also carried forward to the 'Scale' and 'Translate' member functions. In a similar way, we can have our existing matrix physically scaled or translated, rather than simply retrieving a scaling or translation matrix for use in an additional multiplication step.

Note: While this technique can be applied to great effect, it is entirely optional. You can override this default behavior by specifying 'true' to the final 'Reset' parameter in each of these functions. This will essentially request that the matrix with which the operation is being performed is reset before calculating the result.

As with our vector implementation, there are some additional utility functions that we have integrated into our matrix class which provide quick and easy solutions to common implementation tasks.

Member Function	Description
IsIdentity	This function examines the contents of the matrix in order to determine whether or not the values describe an identity matrix. If this is found to be the case, this function returns a result of true. This can be especially useful in determining whether or not we need to use this matrix in an operation such as a recursive concatenation step or in a call to 'SetTransform' during rendering. Since the identity test itself is much less expensive than either of these operations, it can often be a good idea to test the state of a matrix using this function before it is considered.
GetIdentity	This is a **static** function that can be used to retrieve a matrix whose values have already been set to the identity state. At many points throughout the development of our applications it has often been necessary to reset – for instance – the current rendering device matrix to identity before rendering certain other objects. Instead of constructing a temporary matrix and setting its values to identity, we can simply call the 'CMatrix::GetIdentity()' function directly, passing the result into the appropriate 'SetTransform' function.
Zero	This function simply clears all internal values, setting each element in the matrix to zero.

Operator Overloads

One thing that was missing from our list of commonly used matrix member functions and their D3DX equivalents was the 'D3DXMatrixMultiply' function. Rather than include this as a class member, we have integrated this functionality by overloading the multiplication operator. Unlike the vector's 'TransformCoord' and 'TransformNormal' functions, the result expected from the matrix multiply operation is unambiguous. As a result, we simply need to provide one multiplication operator overload to add support for matrix multiplication / concatenation. The most obvious benefit of implementing the matrix multiplication operation in this way is that we can concatenate matrices very easily simply by multiplying one instance of the 'CMatrix4' class by another in precisely the same way as we would with any numeric data type as shown below:

```
mtxResult = mtxWorld * mtxTranslation;
```

Whilst there are many other operator overloads provided within the 'CMatrix4' implementation, this is by far the most important. Some of the other operators which have been overloaded include those for matrix addition and subtraction, matrix equality and inequality as well as scalar multiplication and division. For a complete list of all operator overloads provided by this class, refer to the 'CMatrix4' declaration in the project file 'CMatrix.h'.

- **CPlane3**

The plane class is one that we have focused heavily upon in recent lessons. Used throughout each of our spatial partitioning compilation and rendering procedures this is a very important class for us to implement in this processing application. In the past, we have used the D3DXPLANE structure extensively and have become familiar with it. This structure represents a plane using a 'normal' vector and a distance value. The X, Y and Z components of the plane normal in D3DXPLANE are stored in separate member variables named 'a', 'b' and 'c' in keeping with the standard plane equation. The final 'd' value describes the distance to the plane, from the origin, along the reverse of that plane's normal.

In previous lab projects we were often required to cast the plane structure to a 'D3DXVECTOR3' pointer in order to make use of some of the other D3DX global functions designed to work with vector data. In our plane implementation we are representing this information in a similar format, with the exception that the plane normal is stored in a member variable of the type 'CVector3' rather than individual floating point variables. In doing so, we allow our application to perform standard vector operations using the normal of the plane without any type of casting, extraction or manipulation of the plane data in advance. This should help simplify any operations we perform using the plane class during the development of our pre-processing toolset.

Although there are few functions available in D3DX for working with the D3DXPLANE structure, there are several plane related utility functions to which we have already been exposed.

Member Functions

During our coverage of collision detection and spatial partitioning we introduced a series of utility functions designed to classify various different primitive types against a plane. These included classification tests using a polygon, a point and even a ray. In addition, we introduced a plane technique that allowed us to detect any intersection that occurred between a ray and a plane, as well as retrieving the point at which that ray intersected. As we know, each of these tests and classification routines were used in many places throughout our previous spatial partitioning implementations. As we progress to the development of our new solid leaf BSP tree compiler, it will become apparent that this functionality is crucial to the whole compilation process. As a result of this, our plane class exposes several member utility functions that we will need at some point in the very near future:

Member Function	Description
GetPointOnPlane	As you should hopefully be aware at this point, there are two main ways in which a plane can be represented. Obviously we can represent a plane as a normal vector and a distance value, but we can also represent this as a normal and a point that lies somewhere on that plane. In order to provide a level of compatibility between these two methods, this function is provided to allow you to retrieve a point that lies on the plane described by that instance of the class.

ClassifyPoly	During the construction of the oct-tree, kD-tree, quad-tree and BSP tree we have seen how it is necessary to classify our polygons against the separating planes assigned at each node. This is used to determine the child into which certain polygons need to be passed. This function is analogous to the 'CCollision::PolyClassifyPlane' function that we have previously implemented. It returns an enumerator result informing the calling function about the position of the specified polygon in relation to the plane.
ClassifyPoint	Similar to the 'ClassifyPoly' routine, this function is intended to inform the calling function about the position of a point in space in relation to the plane itself. In previous lab projects, this function was found in the CCollision class under the name 'PointClassifyPlane'.
ClassifyRay	As with the other two functions mentioned, this is yet another primitive classification routine that we have already encountered in the 'CCollision::RayClassifyPlane' function. Once again, this function classifies the specified ray against the plane and returns a result depending on whether that ray was in-front, behind, spanning or on-plane.
GetRayIntersect	This function is the equivalent of our 'CCollision::RayIntersectPlane' function and is implemented in the same fashion. This function is called in many places, but the primary use in this lab project is during the splitting of polygon data. We will discuss where and when this splitting occurs later in this chapter.
SameFacing	During our coverage of both the node and solid leaf BSP compilation techniques in this chapter's textbook, we discussed how crucial it was that we pay special attention to the direction of the potential splitting polygons – in relation to the node planes – within the coplanar cases of our compilation techniques. This function simply accepts another plane as input and returns true if both planes point in the same direction, or false if they point in opposing directions. This should simplify several of the coplanar tests we would have to write, to a relatively simple call to this function.

We will be relying on the functionality of this class in many places throughout the development of the pre-processor application covered in this lesson. It is important that you understand how each of the member functions outlined in the above table work. If you are unsure of any of these procedures it would be a good idea to refer back to our previous coverage of these functions in addition to studying the new source code for the 'CPlane3' class found in the project files 'CPlane.h' and 'CPlane.cpp'.

- **CBounds3**

This class is a new concept and one which is not based on any structure or class that currently exists within the D3DX API. This axis aligned bounding box class wraps much of the

functionality we have come to rely on in our spatial partitioning compilation classes. In previous lab projects we have represented a bounding box using two separate 'D3DXVECTOR3' structures which describe the minimum and maximum world space extents of that bounding volume respectively. The 'CBounds3' class – the source for which can be found in the files 'CBounds.h' and 'CBounds.cpp – stores this same information in a single object. Because this bounding box information is now wrapped in a class of its own, there are several bounding box related operations that have been previously discussed which have been included in this class to provide a more integrated approach. The most important of these new member functions are described in the following table:

Member Function	**Description**
GetDimensions	This function calculates and returns the overall dimensions of the axis aligned bounding box volume on each axis. This is achieved simply by subtracting the minimum box extent values from those of the maximum box extents. As a result, this function returns a single 'CVector3' object in which the value of each component of that vector describes the dimension of the bounding box on each of its individual axes.
GetCenter	In order to perform many operations with a bounding box, we need to be able to find its center point. Because of the nature of an axis aligned bounding box, this can be determined using the following simple formula: '(Min + Max) / 2.0'. This function returns the vector that describes the position in space of the box centre point using the same process.
CalculateFromPolygon	In many cases in the past we have manually built our bounding box extent values by looping through the vertices in each individual polygon, growing the extent values if any vertex is positioned outside the box already described. Because this can be a lengthy and laborious coding exercise, this utility function wraps this process and allows us to specify a series of vertices with which it should build the bounding box values. In addition, this function also accepts a 'Reset' parameter that – when set to false – allows us to repeatedly call this function passing in a different polygon to each call and have it accumulate the results at each stage.
IntersectedByBounds	This function is our new math library's implementation of the previously discussed 'CCollision::AABBIntersectAABB' function. Put simply, this function accepts another 'CBounds3' class as an input parameter and returns 'true' if the space described by these two bounding boxes is found to overlap. Conversely, when they are not found to be intersecting, this function will return false.

PointInBounds	Our application has needed to determine whether a point falls within the space described by an axis-aligned bounding box on several occasions. In our previous lab projects this information was made available via a call to the 'CCollision::PointInAABB' procedure. This function accepts a single 'CVector3' input parameter containing the location that we would like to test against this bounding box. If the point is found to be within the bounding box extent vectors then this function will return 'true'. In all other cases, a resulting value of 'false' will be returned.
Reset	This function can be called in order to reset the bounding box member extent vectors to a set of values that can be used as the basis for the construction of a new bounding box. When initializing the axis aligned bounding box extent vectors, we will typically set each of the components of the maximum extent to a large but negative value and each of the components of the minimum extent to a large positive value. This ensures that any positional vertex or vector we consider during the calculation of the actual extent values will be taken into account. This function should be called if you plan on manually constructing the bounding box values.

This concludes the discussion of our new replacement math library. You should already be very familiar with almost all of the functionality exposed by these new classes but it was important that you understand the basic layout of each class in order to more easily follow and understand the compilation techniques we will be developing in this lesson. Before we continue on to our discussion of the code for lab project 16.2, there are one or two remaining differences that must be outlined in the tree building concepts we have been developing to date.

File Based Data Structures

One of the other key differences found when comparing this new compilation tool to the compilation techniques we have implemented to date are the means by which data structures are linked together. Each of the compiler classes we have implemented so far has been integrated directly with the game application itself. In these cases, we have been building the data structures intended for use directly by the game framework classes. In our new tool, we are building structures which are to be written out to file rather than simply maintaining that data in a memory oriented fashion.

In the past, we have often maintained links between data structures by making use of a direct pointer variable. As an example, the node classes provided by the various spatial hierarchy types we have implemented each store a pointer to other physical heap allocated child node and leaf structures. As we know, pointers are essentially variables which store the numeric starting address to the memory location in which another variable, class or structure has been allocated. When writing data to a file, we can not of course simply write the contents of a pointer variable as we would with a primitive data type such as an 'int' or 'char'. Instead we must interpret and write the data that is referenced by that pointer. While this seems simple enough, it can become quite difficult to untangle the referenced items and store them

in a manner which can be easily and efficiently reconstructed in the target application. This is especially the case when we are dealing with tree structures that are many levels deep.

When we are exporting data to file, we very often find data structures that have dependencies on one or more pieces of information – such is the case with most spatial hierarchies. In some cases there are certain pieces of information which are also shared between multiple objects. A classic example of this is with the spatial hierarchy node planes. In this case, we already know that in any individual branch of a BSP tree for instance, there should never be any other nodes that share the same plane. However there are very often many instances in which nodes are coplanar with another node *elsewhere* in the tree (e.g. further down the alternate branch of one of its parents). Due to this fact, it is entirely possible that we could select an individual node and find that it shares a plane with 10s or even 100s of other nodes in that tree.

Imagine a somewhat worse case scenario in which we found that our scene contained 10,000 unique nodes that were coplanar with exactly 9 other nodes in alternate branches of the tree. This is outside of those included in the original figure of 10,000. Even though a single plane structure occupies only 16 bytes for storage, these plane structures alone would consume 1,563kb within the file (10,000 * 10 * 16 bytes). Given that each of these structures defines exactly the same plane it should be clear that it would be much more efficient to simply store only one of these planes, and have each of our nodes simply reference that same plane data structure. If we were to do so, the planes in the above scenario would occupy only a fraction of the space at just 160kb (10,000 * 16 bytes). While this was admittedly an overly dramatic scenario, it should make the point clear that there are certain considerations that we may need to make when writing data such as this to file. Whilst it could certainly be argued that this same logic could be applied to our memory oriented data structures – and in this specific example scenario it would certainly be advisable – when working at runtime we have to balance efficiency and speed against the storage costs. However, speed of execution is rarely a concern when writing data to file and therefore, reducing storage space should certainly be one of our highest priorities.

Given the complexity of most tree structures in addition to the inherently interdependent data structure design and the potential need to reference a single piece of information from multiple items, it is often easiest for us to write data to file in contiguous blocks – whereby similar data structures are written together in one series. In essence this means that we would be exporting separate **arrays** of planes, nodes, leaves and other such data structures to file. In this case, we would simply have each item reference elements from within each of those ‘arrays’ using some form of indexing. As a byproduct of this we are also providing an easy and efficient way for our intended application to load the information back in, enabling it to load the data in a simple loop or even in some cases to read the whole block of data back into an array with a single read operation.

Although in the past we have previously constructed central arrays containing all of our leaf, polygon and detail area data structures, these existed only to provide a convenience to our spatial partitioning applications. We did this to allow our application to access all of the leaf and polygon data stored in the tree – via the base ISpatialTree interface – without having to perform a full scale traversal in order to access each of the individual pieces of information. In addition to this, our data structures referenced the components within the tree by utilizing a pointer based system. Using the node as an example – a data type which was not previously stored in a centralized array – child nodes were only ever referenced by their parent. The only means by which we could gain access to the data stored at any particular node

would be to start at the root, and traverse down the hierarchy using the child pointers stored at each subsequent node. As you might imagine, this would make it quite difficult to write the data to file for two main reasons. The first is that we have no centralized array to begin with and secondly, even if we did have such an array we would somehow have to convert any pointer which references a node within that array, into an index in order to write it to file. This would make our export procedure very complex with many procedures needed in order to search for locations within various different arrays before writing each component.

In our new file oriented tree compilation tool, the centralized arrays mentioned previously will serve as a much more integral concept. In this pre-processor application, the centralized arrays stored within the tree will become the *only* place that our data structures exist.

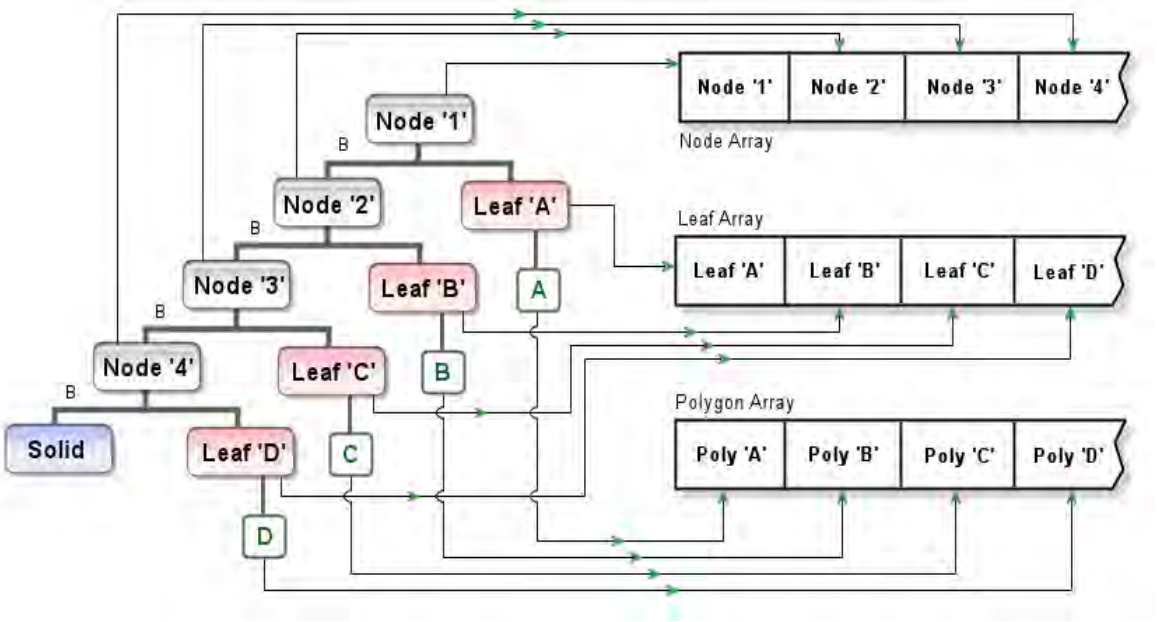


Figure 16.1

Figure 16.1 shows a number of arrays that might be used to store the tree information. We can see that each type of data structure used within the tree has its own centralized array. In addition, each instance of those data structures has a unique position within that array. Recall that we need to move away from the use of pointers in our data structures if we want to easily write the data to file. The upshot of reorganizing our compilation code in this way is that we can begin to use indices that direct us to the correct element in each of these arrays rather than using pointers (physical memory addresses):

```
class CNode
{
public:

    // Public Variables for this Class
    int Front;
    int Back;

    ...
};
```

This pseudo-class demonstrates how we might employ the use of indices within one of the most common tree data structure types. In previous implementations, the child member variables stored within the node were direct memory pointers. In this case, these pointers have been replaced with simple numeric variables of the type 'int'. If we ensure that any new data items are placed into a centralized array at the same time as we allocate that item it is guaranteed that we will have access to the correct array index which can be stored in the data structure itself. The following pseudo-code is an example of how this might be achieved.

```
// Allocate new node
pNewNode = new CNode;

// Setup new node data
...

// Attach to the front using its position as
// it will exist in the array (the next item)
pCurrentNode->Front = m_Nodes.size();

// Add the node to the centralized array
m_Nodes.push_back( pNewNode );
```

In this example we are creating a new front node in preparation to recurse into a new level of the tree construction process. In this code, the first thing we do is to allocate a new node. Imagine at this point that we had already stored 10 nodes in an STL vector called 'm_Nodes'. Recall that array indices are zero-relative which means that the first element in the array can be accessed using index '0', and likewise the 11th element by using index '10'. The very next line of code retrieves the *current* size of the node vector. Because we have not yet added the new node to the array – which as we know contains ten nodes already – the return value from the STL vector 'size' call will be 10. The final line in this example adds the new front node to the end of the vector as the 11th element in the array. Given the zero-relative nature of array indexing it should be clear that the index of '10' stored in the previous line is correct.

There are other types in addition to the node which we will of course have to adapt to this file friendly tree organization approach. These include both the leaves attached to the nodes and the polygons stored within those leaves. With the leaves in particular, we previously created unique child 'leaf-nodes' within our memory based tree structure whose primary purpose was to store a pointer to the leaf that existed there. During the compilation process, these leaf nodes were attached to the relevant child pointer of the current node enabling us to greatly simplify our traversal and construction logic. When written to file, these additional leaf nodes serve no informational purpose and as a result the BSP tree building class we will construct in this lesson does not include these additional nodes. Instead we will be taking advantage of the transition from pointers to indices in order to link the leaves directly to the parent node structures.

The easiest way to achieve this is to use a *signed* data type for the child index member variables stored within the node structure. In the previous example of how we might declare our index based node structure we used the signed type 'int' for the 'Front' and 'Back' member variables. As we know, a node needs to be able to reference two types of children. These are either another child node, or a leaf structure. A 32 bit *unsigned* integer variable is capable of storing values up to and including 4,294,967,295. Since it is not possible for us to ever create anywhere near this number of nodes, it is

safe to assume that we can use a *signed* data type which is capable of storing values between +/- 2,147,483,647. Using standard indexing procedure we know that we can use the positive index stored within a child member variable of a node to reference into our node array. However, since we are using a signed data type we can also use the negative range of values to signal to our traversal procedures – as well as our level import process – that once we convert it back to an absolute value, this member variable is an index into the *leaf* array instead.

One small caveat that you may have already spotted in this procedure is that when indexing into an array the first element is accessed with an index of 0. However, if the node's child index stores a zero value then there would be no way to know whether it is pointing to the first element in the leaf array or that same element in the node array. As a result of this we must make a slight adjustment to the signed / unsigned index ranges used such that nodes are indexed with values of 0 and above, and leaves are indexed using values from -1 and below. Take a look at the code below in which we show an example of how we might generate and store the index for a leaf in its parent node, using this signed / unsigned concept.

```
    // Allocate new leaf
    pNewLeaf = new CLeaf;

    // Setup new leaf data
    ...

    // Attach to the front using its position as
    // it will exist in the array (the next item)
    // but altered such that we use our negative range
    pCurrentNode->Front = -(m_Leaves.size() + 1);

    // Add the leaf to the centralized array
    m_Leaves.push_back( pNewLeaf );
```

As before, we first create our leaf object and set up its values as necessary. Again, on the next line we want to link this leaf to the current node's front by storing an index. In this case, imagine that we have not yet stored any leaves in the 'm_Leaves' vector. Because of the fact that the vector's 'size' function will return a value of 0 at this point, when we add 1 to this value and invert it's sign we would be storing a value of '-1' in the current node's front child member.

So, given that we are now storing indices in our node structure to both its child nodes in addition to directly referencing leaves, how might we go about turning these values back into physical array indices? The following pseudo-code example demonstrates just this.

```
    // Is there a leaf or a node in front of the current node?
    if ( pCurrentNode->Front < 0 )
    {
        // Get the leaf index
        int LeafIndex = abs( pCurrentNode->Front + 1 );

        // Retrieve the leaf
```

```
        CLeaf * pLeaf = m_Leaves[ LeafIndex ];

        ...

    } // End if leaf
    else
    {
        // Get the node index
        int NodeIndex = pCurrentNode->Front;

        // Retrieve the node
        CNode * pNode = m_Nodes[ NodeIndex ];

        ...

    } // End if node
```

As you can see, we can now detect whether a node is referencing a child leaf or another child node by testing the sign of the index stored in the relevant child member variable. If this value is found to be less than zero, then the variable is referencing an element into the leaf array. Conversely if it is found to be greater than or *equal to* zero, then we know that this must be referencing a child node. Due to the ranges that were chosen to describe each type of reference, when this child is found to be a node, we need do nothing with the index stored there. In this case, we can simply use the index to retrive the node from our centralized array directly. If it is a leaf however, we must undo the adjustment to its value that we made when storing the index, as well as flipping its sign such that we have an absolute index value. This is done in the following line of code.

```
int LeafIndex = abs( pCurrentNode->Front + 1 );
```

In this line we take the current value stored in the node's child member variable and add 1 to it before we retrieve the absolute of that resulting value. It may initially seem strange that we are again adding 1 to this value as we did when we were calculating the index for storage. Remember however, that the entire result of the original addition was negated just before we stored it. Before we move on, let us just test this code by using some real values. If you are not sure at this point exactly how this procedure works, then following through the example using real values should be helpful. The first example below demonstrates the initial calculation of the negative value that will be stored in the node when referencing a leaf. For the purposes of this example, assume that the leaf array already contains 10 other leaves.

```
Front = -(m_Leaves.size() + 1)

=
Front = -( 10 + 1 )

=
Front = -( 11 )
```

As you can hopefully see, even though our node will need to index into the leaf array using an index value of 10, we actually store a value of -11 in the node. Obviously this means that if we needed to index into the first element in the leaf array (index 0) that this same logic would generate a value of -1 as

we discussed previously. Let us finish off this example by retrieving the correct index based on the value that we have just calculated.

```
LeafIndex = abs( Front + 1 )

=
LeafIndex = abs( -11 + 1 )

=
LeafIndex = abs( -10 )

=
LeafIndex = 10
```

Following this example through demonstrates that the returned index value references into the leaf array using an index value of 10 as we had expected.

Although this does add a level of complexity to both our compilation and import processes, we are able to eliminate a number of nodes equal to that of the number of leaves from the resulting file. Given that the storage of an average node data structure might be in the area of 36 bytes per element or more, this would save us over 100kb in our final export file for a level containing 3000 leaves. Since these nodes do not give us any particular benefits within the file itself, this is an important storage optimization.

With these alterations made to the memory based structure we have previously used in our run-time projects, we should be able to quickly and efficiently export the tree data to file. Although the exact implementation details will ultimately be discussed as we move through the code and structures of our new application, this section should have made you aware of the implications of and reasons why we have moved to an array and index solution in our new pre-processing tool. As we move forward with this lesson, we will discover that our compiler tools make heavy use of this concept throughout and – as mentioned – will be heavily biased toward the way in which it will finally be exported. Before we finish up this discussion thefore, let us take a look at the final layout of the data as it will be written to file when saving the leaf tree information.

Table 1: Plane Data Layout

Name	Description	Type	Size (in bytes)
PlaneCount	The number of planes that have been written to file.	unsigned long	4
Repeated for each plane as described by the previously written 'PlaneCount'			
PlaneNormal	The normal of the plane being described.	CVector3	12
PlaneDistance	The plane distance / 'd' component of the plane.	float	4
End of 'PlaneCount' repeat.			

Table 2: Node Data Layout

Name	Description	Type	Size (in bytes)
NodeCount	The number of nodes that have been written to file.	unsigned long	4
Repeated for each node as described by the previously written 'NodeCount'			
PlaneIndex	Index into the previously written plane data / array that describes the plane used to construct this node. Note: Multiple nodes may reference the same plane.	long	4
BoundsMin	The minimum bounding box extents of this node. This describes the extent of all of the polygons contained below it in the hierarchy.	CVector3	12
BoundsMax	The maximum bounding box extents of this node. This describes the extent of all of the polygons contained below it in the hierarchy.	CVector3	12
Front	The front child index for this node. This can be either a positive or negative number as described previously.	long	4
Back	The back child index for this node. This can be either a positive or negative number as described previously.	long	4
End of 'NodeCount' repeat.			

Table 3: Leaf Data Layout

Name	Description	Type	Size (in bytes)
LeafCount	The number of leaves that have been written to file.	unsigned long	4
Repeated for each leaf as described by the previously written 'LeafCount'			
BoundsMin	The minimum bounding box extents of this leaf. This describes the extent of all of the polygons stored within this leaf alone.	CVector3	12
BoundsMax	The maximum bounding box extents of this leaf. This describes the extent of all of the polygons stored within this leaf alone.	CVector3	12
PVSIndex	This is used in the next lesson, for now it should be considered as a 'reserved' data area and should be written with a value of '0'.	unsigned long	4
PolygonCount	The number of polygons that are stored within / referenced by this leaf.	unsigned long	4
PortalCount	This is used in the next lesson, for now it should be considered as a 'reserved' data area and should be written with a value of '0'.	unsigned long	4
Reserved	This value is literally reserved for later use / expansion. This should be written with a value of '0'.	unsigned long	4
Repeated for each polygon as described by the previously written 'PolygonCount'			
PolygonIndex	Index into the main polygon array that was written into the **first** mesh in the IWF file.	unsigned long	4
End of 'PolygonCount' repeat.			
End of 'LeafCount' repeat.			

Navigating the Compiler Project Source Code

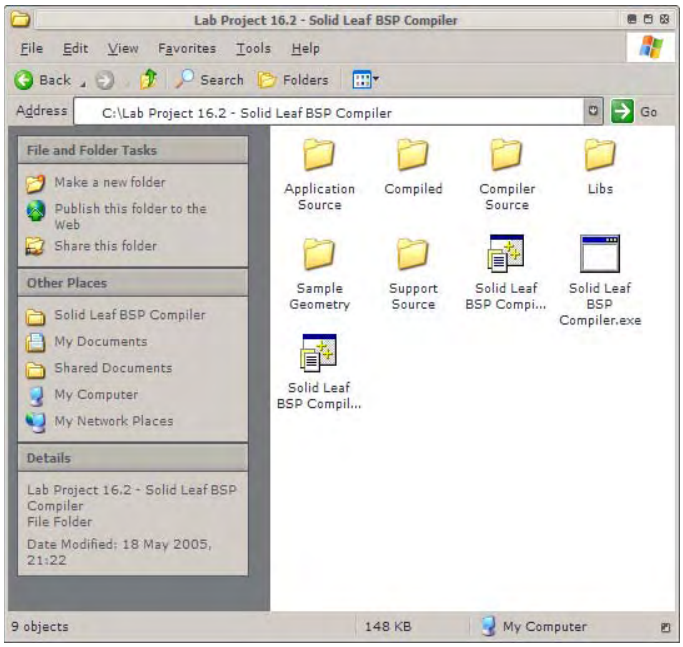

Figure 16.2

Because we are building a brand new application in lab project 16.2 and one that is not based on the previous demo framework we have used in the past, there are some changes to the layout of the project directory structure. As was mentioned previously, the pre-processing application that we are building in this lesson is designed to be as modular as possible. This will allow us to add additional features and compilation procedures to the application in the future without having to rewrite large portions of code. In addition to this, we have tried to design a portable system whereby the core compilation portions of the application is completely separated from whatever front end interface might be desired. In certain cases there are situations in which some form of feedback is required by the application. One example of this is how the application displays the current progress and outcome of each compilation task. As we have discussed, some compiler computations can take a long period of time to complete. If our application simply displayed a blank screen until the scene was completely processed, the user might reasonably believe that the application had stopped responding. Due to the fact that we want to keep the compiler completely separated from the application front end, and that only the compiler is really in a position to inform the user about how each task is progressing, this presents us with a problem. We can overcome this situation however, by defining a base interface – which we have named 'ILogger' – that both the front end and the compiler are aware of. The application is then responsible for deriving a class from this interface and its defined functions, which displays the logging information in any way it requires. Because the compiler uses the abstract 'ILogger' interface to output any progress information, we preserve the independence of the compiler and our ability to insert it into any application.

At this point, rather than become distracted by a comprehensive and potentially complex full blown GUI front end, we have opted for a relatively simple console based framework in which we will insert the compiler code. We have also developed a derived logging class which simply outputs the progress information directly to the console window itself.

It is clear that we have two separate components at this stage. We have the application framework and its associated front end, in addition to the compiler logic and compilation process source code. We have also introduced several new support classes however – such as our new vector, matrix, AABB and plane classes – that bring several new header and source files with them. In an effort to ensure that our pre-processing tool source code can be more easily managed, each of the source components that make up our application has been separated into various directories.

Although it should be relatively easy to find your way around the source code folder, the following list outlines the contents of each of the directories in the new project structure in addition to the intention behind them should you need to add additional source files of your own.

Application Source

This directory contains the main source files and headers related only to the application framework and interface front end that will create and call the compiler classes and functionality. The intention behind this directory is that it should contain the source files and header files that define the application entry point, any sort of display procedures, graphical user interface classes and anything which is not part of the core compiler itself. In this lab project, there are two main source file and header combinations located in this directory:

Main.cpp & Main.h
These source files define the application entry point (the *WinMain* function) which is ultimately responsible for setting up and calling the compiler class functionality. These files are relatively simplistic but are responsible for handling how the compiler is set up as well as the main logic of the application execution.

LogOutput.cpp & LogOutput.h
These source files define the derived 'ILogger' class named 'CLogOutput'. This class's purpose is to output the progress information to the application's console window, as reported by each compilation process. This class implements the pure virtual functions declared by the 'ILogger' interface.

Compiler Source

This directory is the home of our compiler application's core processing source code. Any source code files relating to the individual compilation tasks such as the BSP compilation, hidden surface removal and T-Junction repair procedures included in this lab project can be found here. This is also the directory into which we will place any additional modules that will be developed in later lessons. In addition, all source files relating to the import and export of the scene and compiled data can be found here.

Compiler.cpp & Compiler.h
These files define the class 'CCompiler'. This class exposes the primary compiler API that our application front end will use in order to perform the core tasks of our pre-processing tool. For instance, this class includes functions which allows the application choose which compiler tasks to perform, to set any applicable compiler options and to instruct the compiler component to load and save a particular file. The application will never typically work directly with the individual compiler process classes (outlined shortly), but will instead work through the interface defined by this class.

CompilerTypes.cpp & CompilerTypes.h
There are many classes defined by these files which include items such as 'CMesh', 'CPolygon' and 'CVertex'. In each case, the classes and structures defined here are dependencies of the compiler code. In most cases, these classes are used to house any data that has been loaded from the scene file specified

by the application. Also defined here are the various options structures and miscellaneous definitions that are used by the application to setup the various compiler processes.

CFileIWF.cpp & CFileIWF.h
The 'CFileIWF' class is defined in these files. This class is responsible for loading and saving our scene data both before and after compilation. Although we have previously been using the 'CFileIWF' class as provided by the static 'libIWF' import library, in this project we also need to include the file export logic that is executed once the compilation procedures have completed and the application requests that the compiled file is saved. In addition we are using several custom classes – such as the custom mesh, polygon and vertex classes discussed later. Rather than complicate matters by using intermediate data structures for importing and exporting the tree data, we will implement the 'CFileIWF' class directly here in order to extend it and allow us to use our custom classes directly.

CBSPTree.cpp & CBSPTree.h
The classes defined in these files are the very foundation of everything we will be developing in both this lesson and the next. These classes include our main solid BSP leaf tree compilation class (CBSPTree) in addition to the leaf (CBSPLeaf), node (CBSPNode) and other associated classes. The 'CBSPTree' class also serves as the central hub for storing most of the information which we will be building throughout the various compilation tasks.

ProcessHSR.cpp & ProcessHSR.h
Because our compiler tool is designed to be modular, each of the individual compilation processes is separated out into individual source files and classes. These files define the 'CProcessHSR' class which is home to the hidden surface removal processing logic. This module is created and called by the aforementioned 'CCompiler' class during the overall build process.

ProcessTJR.cpp & ProcessTJR.h
As with the HSR process, the T-Junction repair step is segregated into its own modular class. This class as defined within these files is named 'CProcessTJR'. Again, this class is instantiated and executed by the 'CCompiler' class during scene compilation. Although we will implement additional processing modules in the future, this process is generally the one that will be executed as the very final step before saving.

Support Source

The support source directory contains all of the miscellaneous supporting classes used by the compiler in addition to any header files which may be common to both the application front end and the compiler classes. Recall that we previously discussed the inclusion of a new supporting math library which included the classes 'CVector3', 'CVector4', 'CMatrix4', 'CPlane3' and 'CBounds3'. Although not listed below, this directory also contains the source code implementations for each of these new classes.

Common.h
This is the common header file which links the front end application with our compiler core. This file includes several macros and other useful definitions that are used by both components of our application. It also includes certain other headers which will need to be in place for the compiler to

integrate into the application without issue. This header is also one in which the 'ILogger' interface is declared, from which the application should derive its progress display class.

AppError.h
Last but not least is the header that contains all of the potential error definitions used by the compiler and available for use by the application. Modeled after D3D's HRESULT error codes, these types of error descriptions should be familiar to you. Although we are using a 'result code' system similar to that of D3D in this application, for the most part these errors are not used as return codes. Instead the compiler makes extensive use of exception handling. As a result, whenever we need to handle errors which occur within the compile process, we include a catch block using an argument type of 'HRESULT' which is also defined here.

Now that we are familiar with the new project layout and design, it should be a little easier to navigate to the various portions of the source code with greater ease as we progress onto the implementation of our new tool. As such, let us finally move on to the next section in which we will begin to focus on the actual implementation of some of the classes we have discussed.

Scene Data Classes – CompilerTypes.cpp

Before we can realistically move on to the implementation of our new compiler application, there are several scene related classes that need to be discussed first. Throughout the development of the many lab projects we have built in the previous lessons of this series, we have created many classes whose purpose is to create, store and render the scene data. These included classes such as CMesh, CPolygon and CVertex. In each of these cases, a lot of thought had to go into developing a system which could be easily integrated into our application and was able to construct data in a hardware friendly fashion. We also developed several other structures and classes that stored and processed any secondary data such as texturing and material information. Obviously, these previous applications were heavily biased toward the rendering of a scene. As a result, a lot of work had to be done in order to prepare the information contained within the 'IWF' scene file that would ultimately allow our application to display the game world correctly.

In this application the primary focus is on importing and storing the data for use by the various compilation procedures. As a result we are able to simplify most of the scene data concepts we have previously employed, into one that simply provides a logical place for storage and that grants our tool easy access to that information. There is an additional step in this new project that will make use of the scene data however. In this tool we must also *save* the scene to file. This is something that we have not had to consider in those previous rendering applications. Because of this additional process, there are several pieces of information that must be imported and maintained that have no other purpose than to be exported back out to the resulting file. Some examples of this type of data are: surface textures and materials, any shader references that may be contained within the file and also scene entity information which we have come to rely so heavily upon in the various rendering projects.

The tools that we have traditionally used to load all of our scene information have always been those exposed by our static IWF import library. Recall that the main functionality needed for the importation of the scene data from the IWF file was made available to us through the 'CFileIWF' class and its support structures. We have previously touched upon the fact that we will be implementing our own

custom version of that class in this project. We need to do this because there are several custom scene data storage classes which are being utilized within the tool. In addition, our application is of course now required to add export functionality to this file handling class. Shortly we will be discussing the classes and structures we will implement for the data types used directly by our new compiler application. However, rather than re-implement each of the data classes that our application will **not** make direct use of – e.g. materials, entities, textures and shader information – we will rely once again on the data classes exposed by the import library. Since we have previously covered most of the support classes provided by the libIWF library, let us just quickly recap on each of the data classes that our pre-processor tool will employ.

- **iwfMaterial**

```
class iwfMaterial
{
public:
    // Constructors & Destructors for This Class.
     iwfMaterial( );
    ~iwfMaterial( );

    // Public Variables for This Class
    char           *Name;           // Material Name (if applicable)
    COLOUR_VALUE    Diffuse;        // Diffuse reflection component
    COLOUR_VALUE    Ambient;        // Ambient reflection component
    COLOUR_VALUE    Emissive;       // Emissive reflection component
    COLOUR_VALUE    Specular;       // Specular reflection component
    float           Power;          // Specular reflection power ratio
};
```

This is a class that we have already encountered in previous demo lab projects. The data members declared within this class closely represent those defined by the Direct3D 'D3DXMATERIAL9' structure and is used almost exclusively in the calculation of scene lighting information. The member variables declared by this class include the ambient, diffuse, specular and emissive surface reflection properties with which you should be familiar. Each of these material properties are common throughout many of the available vertex and pixel lighting techniques and should therefore also be portable to other immediate mode rendering APIs. As with each of these data storage classes, the declaration for this class can be found in the 'iwfObjects.h' header file in the project's 'Libs' subdirectory.

- **iwfEntity**

```
class iwfEntity : public IIWFObject
{
public:
    // Constructors & Destructors for This Class.
             iwfEntity( ULONG Size );
             iwfEntity( );
    virtual ~iwfEntity( );

    // Public Variables for This Class
    UCHAR           AuthorIDLength; // Length of the author ID code
    UCHAR           AuthorID[255];  // Actual author ID data.
```

```
    USHORT          EntityTypeID;   // The Type Identifier for the entity.
    char           *Name;           // Entity Name
    MATRIX4         ObjectMatrix;   // The matrix assigned to the entity.
    ULONG           DataSize;       // The size of the entities data area
    UCHAR          *DataArea;       // The entities data area.

    // Public Member Functions Omitted
};
```

As with the aforementioned 'iwfMaterial', we have seen and used the 'iwfEntity' class many times in previous lab projects. As we know, the entity type is a generic object concept that can be used to store many different types of information. We have used this class for objects such as lights, fog, trees, references, external meshes / characters, terrains and even a skybox. In this application we will not interact directly with the imported entity objects. This class will simply be used to store the imported entity data until such time as the scene has been processed, and the application chooses to export the scene to another file.

- **iwfTexture**

```
class iwfTexture
{
public:
    // Constructors & Destructors for This Class.
             iwfTexture( ULONG Size );
             iwfTexture( );
    virtual ~iwfTexture( );

    // Public Variables for This Class
    UCHAR   TextureSource;  // Information about where the texture is
    char   *Name;           // The texture name.
    UCHAR   TextureFormat;  // The format of the internal texture if used
    USHORT  TextureSize;    // Size of the TextureData array
    UCHAR  *TextureData;    // The data being referenced

    // Public Member Functions Omitted
};
```

Although we have not used the 'iwfTexture' class itself in the past, this class is just a more object oriented version of the 'TEXTURE_REF' structure that we have used in almost every lab project we have developed from chapter five onwards. This class is designed to store various pieces of texturing information, but the most common use is one in which each instance stores the filename of a scene texture to be applied to the appropriate pieces of level geometry that reference it. As with the material and entity information, this application will not interact directly with objects of this type. This data will simply be imported along with the scene data, and exported again when the processed scene is saved.

- **iwfShader**

```
class iwfShader
{
public:
```

```
    // Constructors & Destructors for This Class.
             iwfShader( ) {};
    virtual ~iwfShader( ) {};

    // Public Variables for This Class
    ULONG           Components;     // Which components are included
    iwfScriptRef    VertexShader;   // The vertex shader if included
    iwfScriptRef    PixelShader;    // The pixel shader if included
};
```

We have not previously used the shader classes or structures exposed by the libIWF import library, but they are maintained within this application in order to allow for future enhancement. The 'iwfShader' class itself does not store any specific pieces of shader information. Instead it declares two members named 'VertexShader' and 'PixelShader'. Each of these members is of the type 'iwfScriptRef' outlined below. Once again this information is only imported for the purposes of being transferred to the export file once the scene has been compiled.

```
class iwfScriptRef
{
public:
    // Constructors & Destructors for This Class.
             iwfScriptRef( ULONG Size );
             iwfScriptRef( );
    virtual ~iwfScriptRef( );

    // Public Variables for This Class
    UCHAR   ScriptSource;   // Information about where the script is
    char   *Name;           // The script name
    USHORT  ScriptSize;     // Size of the ScriptData array
    UCHAR  *ScriptData;     // The data being referenced

    // Public Member Functions Omitted
};
```

This class is intended to reference script files or script data in much the same way as the 'iwfTexture' class references texture files. While this structure is used independently in other locations within the IWF specification, the script reference concept is used only for storing shader file references in this lab project.

If you would like further information about the various structures, flags and concepts surrounding each of these IWF data classes it would be a good idea to refer to the IWF SDK documentation available from the classroom download area.

The CVertex Class

We should already be extremely comfortable with the concept of a vertex class because we have used them extensively since the very first chapter. In each of the lab projects to date however, our vertex class has been used primarily for storing data in a format best suited for the purposes of rendering, or building vertex buffer data. In this application we are focused more on the storage and ease of use aspects due to the fact that our pre-processing tool will have no rendering component. As a result, there are a few

changes which have been made to the vertex class concept that should make the task of developing this new application a little easier.

```
class CVertex : public CVector3
{
public:
    // Public Variables For This Class
    // (X/Y/Z components inherited)
    CVector3    Normal;    // Vertex Normal
    float       tu;        // Vertex U texture coordinate
    float       tv;        // Vertex V texture coordinate
```

The first thing to notice about the declaration of our new 'CVertex' class is that it is derived from one of the new math support classes discussed earlier in this chapter. As you can see, we derived this class from 'CVector3' which if you recall contains most of the vector functionality previously offered by the D3DX math component. By deriving the vertex class from 'CVector3' in this way, our compiler component is able to interact with either a vertex or vector object in exactly the same way. In addition, we are able to pass any *vertex* object into a function that is expecting a vector typed parameter. As an example, using this class hierarchy we might perform a dot or cross product on the vertex data directly. We could also classify a vertex against a plane without any of the confusing casting operations that we would previously have included with our standalone vertex structure. In essence, our vertex class is simply extending the functionality of the vector, allowing us to integrate the two concepts more easily.

In this portion of the class declaration it is important to notice that the X, Y and Z components of the vertex have not been included as data members. This is due to these positional components having already been declared by the new three dimensional vector class from which it is derived. By doing so, the vertex class inherits these three public member variables from the vector and as a result they should not be declared again. This is the very thing that allows our vector class functionality to work directly with the positional component of our vertices.

Although there is no direct implementation of the 'CVertex' within any source module (.cpp file) – outside of those member functions inherited from the vector class – there are several constructors defined directly within the 'CompilerTypes.h' header file:

```
    // Constructors & Destructors
    CVertex( ) { x = y = z = tu = tv = 0.0f; }
```

The first of these is the default constructor for this class. This function accepts no input parameters and simply resets each of the vertex component values to zero. Notice how in this function we are setting the inherited vector component values to zero in addition to those declared by the vertex class itself (the texture coordinate values tu & tv). One thing that may appear to be lacking in this constructor function is the setting of any default values for the 'Normal' member. The vertex normal is declared using the 'CVector3' class however, which defaults the X, Y and Z components to zero automatically within its own default constructor. The normal component's constructor will be called implicitly when an instance of the 'CVertex' class is created at any point within the application and as a result we need node duplicate this functionality here.

Of course, the condition under which the default constructor is called is only one of the many situations in which we may want to construct a vertex object. In many of our previous lab projects we have included several vertex class constructors which allow us to initialize its values quickly and efficiently. Similar alternate constructors have also been included in this application for the same reason.

```
    CVertex( float _x, float _y, float _z )
    {
        x = _x; y = _y; z = _z; tu = tv = 0.0;

    } // End Constructor
```

This constructor should be relatively self explanatory. It accepts three parameters which are simply used to initialize the positional portion of the vertex component. We can use this constructor in several situations including either object initialization or assignment as shown below:

```
// Stack Allocation / Initialization
CVertex Vertex1( 10.0f, 5.0f, 0.0f );

// Heap Allocation / Initialization
CVertex * pVertex = new CVertex( 10.0f, 5.0f, 0.0f ) ;

// Assignment
CVertex Vertex2 = CVertex( 10.0f, 5.0f, 0.0f ) ;
```

The other vertex components, such as the vertex normal and texture coordinate values, are set to an initial value of zero in this case.

The next constructor provided by this class is one that accepts a parameter of the type ‘CVector3’ which is again used to construct only the positional component of the vertex.

```
    CVertex( const CVector3& vec )
    {
        x = vec.x; y = vec.y; z = vec.z; tu = tv = 0.0f;

    } // End Constructor
```

This constructor is one of the most important for providing a level of interoperability between the new vector and vertex classes. As with the previous constructor we can use this for both initialization and assignment of the vertex data as shown below:

```
// Vector
CVector3 SomeVector( 10.0f, 5.0f, 0.0f );

// Stack Allocation / Initialization
CVertex Vertex1( SomeVector );

// Heap Allocation / Initialization
CVertex * pVertex = new CVertex( SomeVector );

// Assignment
CVertex Vertex2 = CVector3( 10.0f, 5.0f, 0.0f );
```

```
CVertex Vertex3 = SomeVector;
CVertex Result  = SomeVector.Cross( CVector3( 0.0f, 1.0f, 0.0f ) );
```

The latter of these examples – in which we assign the value of a vector directly to the vertex – is probably the most common situation in which this constructor will be utilized. The bottom-most assignment example shows how we might return the result from a vector cross product operation and store it directly within a vertex object. In this case, the vector assignment constructor will be called and the positional components updated. The remaining vertex components are initialized to a default of zero as before.

There are obviously several other components within our vertex class that may need to be initialized along with the vertex position. In response to this our vertex class also includes constructors which accept additional parameters for this purpose.

```
    CVertex( float _x, float _y, float _z, float _tu, float _tv )
    {
        x = _x; y = _y; z = _z; tu = _tu; tv = _tv;

    } // End Constructor

    CVertex( float _x, float _y, float _z, const CVector3& _Normal,
             float _tu, float _tv )
    {
        x = _x; y = _y; z = _z; Normal = _Normal; tu = _tu; tv = _tv;

    } // End Constructor
};
```

The final two constructors in our vertex class provide the ability to initialize the remaining vertex data not covered by those previously discussed. In each case there are additional parameters which match up to the data members exposed by the vertex. In the former of these final constructors, two new parameters labelled '_tu' and '_tv' are included. These will be used in circumstances in which the application would like to initialize the vertex using both positional and texture coordinate information. The latter of these two extends the first by including a parameter labelled '_Normal' which is used for the initialization of the vertex normal component.

There are of course many additional combinations of vertex class constructor which we may want to include at some point in the future. However, the constructors included here should be more than enough to provide our application with a flexible and comprehensive system by which vertices can be created, initialized and manipulated in many situations.

The CPolygon Class

With our vertex class fully defined, we now need a container in which they can be stored. As has been the case in many of the lab projects developed in previous lessons, the storage and logical grouping of the scene vertex information is the responsibility of the 'CPolygon' class. Although in some cases we have stored vertices directly within a mesh object – such as a 'CTriMesh' – this was almost exclusively built as a final step prior to its use within the rendering portion of the application.

As has been discussed in previous chapters, the spatial hierarchy compilation process that has been developed to date requires that the polygons used during the spatial partitioning phase are each convex winding ‘n-gons’. This is due to the fact that we often needed to split the polygon data, a process which is most easily achieved when the polygon data fits these criteria. In the case of the *polygon aligned* BSP tree however, the polygon concept plays a much more crucial role. Because the scene data itself will be used as the basis of the separating planes and nodes within the spatial hierarchy, it is vital that we ensure that each of the individual polygons within the scene remain separate. If we were to store all of the vertices directly within a mesh type container, indexing them using a triangle list for instance, this would obviously make the construction of our polygon aligned BSP tree much more complex.

Unlike these previous applications, we are now attempting to construct a much more comprehensive tool. In the past, the polygon class was often merely a means to an end in which vertex data was stored until it was used in the construction of hardware friendly vertex and index buffers for the purposes of being rendered. Our pre-processing tool on the other hand will need to work much more closely with various types of polygon data. As we add more features to the tool, there will be an increasing number of situations in which a particular compilation process will need to have access to additional polygon member variables, or even require an entirely custom polygon data structure. To see why this is the case we need only think back to the discussion of collecting polygons at the leaves in a polygon aligned BSP leaf tree.

At each stage in this compilation process, a polygon is chosen to become the separating plane for the current node in the hierarchy structure. Whenever a polygon is selected, it is removed from further consideration but it should still be passed down the relevant side in order to be collected in a leaf structure at a later stage in the process. This can be achieved very simply by exposing a custom ‘UsedAsSplitter’ flag from within the polygon itself for instance which is set whenever a polygon is chosen to become a node plane. As the already selected polygon is passed through the many levels of the recursive procedure, this flag can then be tested very quickly in order to determine if it should be used as a separating plane or not.

This is a prime example of a situation in which an individual compilation process might need an additional data member within the polygon structure. As you might imagine, there could be many circumstances under which this situation might arise as we add additional compiler modules to this tool. In the next chapter we will be introducing an additional compiler step that creates polygon-like constructs called portals. These portals are generated such that they describe the gaps in the geometry that exist between the leaf areas in the compiled tree. If you imagine that we had two rooms connected by a short length of corridor, the portal can be thought of as describing the holes that exist in each ‘doorway’ that connects each of the rooms to either side of that corridor. Essentially this will provide us with a form of leaf connectivity information that describes how each area of the scene connects to its one or more neighboring areas. In the case of the portal, we are only really interested in the shape of these portal polygons as defined by the vertices stored within them. In addition, this portal will need to store information about which leaf exists on either side of that portal polygon.

In the former of these example situations, we are required to add an additional member to the polygon class in order to store the ‘UsedAsSplitter’ information. With the later implementation of our portal compiler, there are yet more data members that are required and even some common concepts that

should not be included – such as texturing and material information – to keep memory requirements as low as possible. So, with the many types of polygon data requirements imposed upon us by this modular compiler concept, what is the best way to define our polygon class?

There are several ways in which this can be achieved. The first, and by far the simplest, is to add everything that we might need to our 'CPolygon' class, for every process that we implement, and simply not worry about any of the memory implications at all. While this certainly works in the majority of situations, it does mean that we will probably have to modify the polygon class every time we plug a new module into the compilation process. If our application makes copies of polygon members for any reason (such as during the splitting of that polygon into two new fragments), we will also have to ensure that the new members get duplicated across the board. As you might imagine, this could become a significant task and is somewhat in opposition to our wish for a modular pre-processing tool. Another way by which this can be achieved is for us to create a new polygon class for each process in which we need a custom data structure. This however, would require that much of the functionality which makes use of the polygon data and that which can be exposed by the polygon class itself – such as splitting, classification etc – may have to be duplicated for each type of polygon class that is implemented.

In this application we will be using a combination of both of these solutions in addition to borrowing one of the ideas we recently introduced in the new vertex class – that of utilizing class inheritance to make the process of development and future upgrades a little easier.

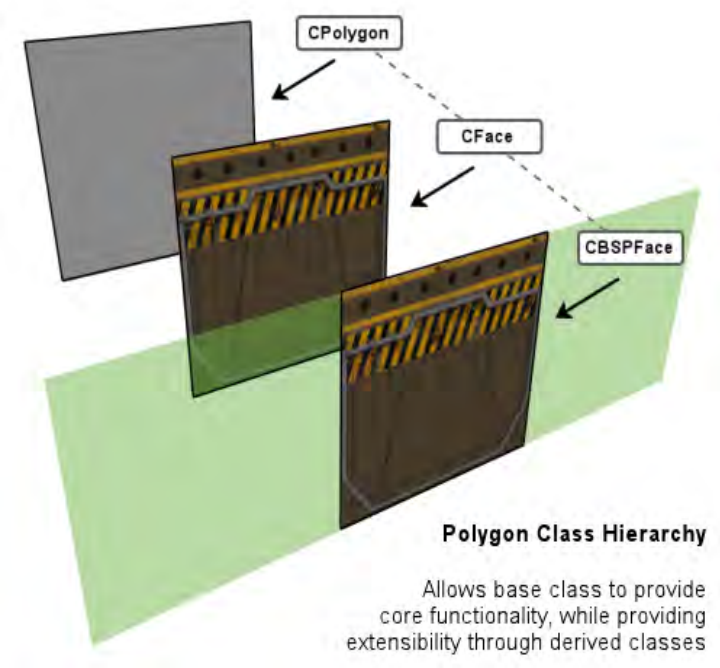

Figure 16.3

Figure 16.3 demonstrates how this type of hierarchical class design might work. In the top left of the image we can see our 'CPolygon' class which represents a plain polygon structure. In this class we would store only the vertex data required to define the polygon. This class would also implement several pieces of key polygon functionality such as the vertex storage and access functions, as well as the 'Split' function required by many of the spatial partitioning compilation techniques that we have already encountered. This base 'CPolygon' class would not declare any additional member variables or functionality that deal with additional surface properties such as texture or material information. By doing this we will later allow new structures to be derived from 'CPolygon' – such as the portal construct described earlier – that does not require any of these additional members, but does require the base functionality. With each of the vertex data members and management functionality provided by this base class, we can then derive a new class from 'CPolygon' in order to extend it for use in situations where additional rendering properties are required. This extended class is depicted in figure 16.3 by the polygon labelled 'CFace'. This class will include several additional

properties that we will need to store. Such properties might include texture, material and shader properties, surface normal, blending modes and any other additional data that we may want to use for rendering purposes in our runtime application. The final class in this diagram is depicted by the polygon labelled 'CBSPFace'. As you may have already guessed, this class is designed for use by our new BSP compiler during the spatial partitioning process. Because the BSP compiler will need to work directly with the *renderable* data, it makes sense that the new 'CBSPFace' class derives directly from the middle class 'CFace'. In this way, the custom BSP compiler polygon class will inherit any and all data members provided by its parent. It also allows us to extend this polygon class with any additional properties – such as our 'UsedAsSplitter' flag – that may be required **only** during BSP compilation.

We will discuss each of these classes in detail a little later on in this lesson. It is important however to understand the general design of our polygon data classes before we move on. Hopefully it is clear that by using a class hierarchy in this way, we are able to extend the functionality of the polygon class without the base class having to be aware of any of the additional properties required by any of the future processor modules. Each of these modules can simply derive a new class from the relevant base implementation which will automatically inherit the functions and data members defined by its parent thus sparing us from having to duplicate large amounts of functionality in each process specific polygon class.

With these general design concepts understood, let us move on to discussing the base 'CPolygon' class that is used within our new pre-processor tool.

```
class CPolygon
{
public:
    // Constructors & Destructors
             CPolygon( );
    virtual ~CPolygon( );

    // Public Variables for This Class
    CVertex        *Vertices;          // Polygon vertices
    unsigned long   VertexCount;       // Vertices in this poly

    // Public Virtual Functions for This Class
    virtual HRESULT Split( const CPlane3& Plane, CPolygon * FrontSplit,
                           CPolygon * BackSplit, bool bReturnNoSplit = false );

    // ** Non-Virtual Public Member Functions Omitted **

};
```

> **Note:** As with most class declarations shown throughout this workbook, member functions have been omitted where appropriate. Each of these omitted member functions is discussed in detail independently within that section.

As you can see, the class declaration for our base 'CPolygon' is relatively simple compared to those we have encountered in the past. We previously discussed how our base 'CPolygon' class would only contain the basic member variables and functionality required to define the polygon layout itself. This is in order to allow any individual compiler module to derive from the most appropriate base class. As a result, this declaration includes only two member variables.

CVertex *Vertices

The first and most important member variable declared within this class is a pointer that will store the address to our heap allocated linear vertex array. Each element in this array will contain a 'CVertex' object in the same way as we have seen implemented many times before throughout this course. Each of the vertices in this array defines the shape and boundaries of the convex winding 'n-gon' that is a pre-requisite for the compiler procedures that we will go on to implement shortly. Remember that our 'CVertex' class is derived from 'CVector3' and as a result we will be able to perform 3D vector operations directly on any element within this array.

unsigned long VertexCount

This member variable contains the value which describes the total number of vertices stored within the above vertex array. Although we have become accustomed to using STL vectors for the storage of data within recent lab projects – which would remove the need for a separate count variable – the vertex array stored here is most often static in size. As a result it is sometimes more efficient for us to handle the array allocation / resizing manually in this way.

The final important point to notice about the base 'CPolygon' class is how the 'Split' function has been declared. Although this function and its parameters should be very familiar to you at this stage, unlike the previous implementations this function has been declared as *virtual*. This allows us to safely include a new split function in any future polygon class in order to extend it with additional functionality. In addition, the class destructor is also declared as virtual to ensure that when the application deletes an instance of a polygon using a pointer of a *base* class type, the data members declared by the whole class hierarchy are correctly released. We will see how these concepts can benefit us when we move on to discuss the derived 'CFace' class in the next section.

CPolygon::CPolygon()

In this application, the default 'CPolygon' constructor does not have a great deal of work to do. As demonstrated in the following code, this constructor simply initializes the two base class member variables to ensure that they can be tested and used safely in later functions.

```
CPolygon::CPolygon()
{
    // Initialise anything we need
    Vertices    = NULL;
    VertexCount = 0;
}
```

CPolygon::AddVertices

This function allows the application to reserve space within the polygon for the required number of vertices. It can be called multiple times in order to grow the vertex array in each subsequent call. In each case, this function will return the index to the first vertex added to the array in that specific call. Although we have encountered this type of function several times in past lessons, we are using a different vertex concept in addition to a slight variation of the error handling concepts we are familiar with.

```
long CPolygon::AddVertices( unsigned long nVertexCount )
{
    CVertex *VertexBuffer = NULL;

    // Validate Requirements
    if ( nVertexCount == 0 ) return -1;
```

The only parameter accepted by this function allows the application to specify how many additional vertices we would like to add to the vertex array stored here. If the vertex array has already been created by a previous call, this will be the number of elements by which that array will be grown. As in the many functions we have implemented before, this parameter is validated to ensure that the allocation will not fail due to the application specifying a count of zero.

The first real task that this function must undertake is to allocate a temporary array of the correct size that will be used as the new vertex array.

```
    // Allocate brand new buffer
    try
    {
        VertexBuffer = new CVertex[ VertexCount + nVertexCount ];
        if (!VertexBuffer) throw std::bad_alloc(); // VC++ Compat
```

Here we allocate the memory that will be used to build a new vertex array of the requested size. We specify a number of vertices to be allocated which is made up of the number of additional vertices requested by the application (nVertexCount) added to the number of vertices that were previously stored within the polygon. This array of vertices will eventually replace the one currently stored within the polygon. Remember that because the 'CVertex' class contains a default constructor, there is no need for us to initialize the elements within the vertex array as we may have done in the past.

In previous implementations of the memory allocation functions, we have often simply tested the resulting value stored within the temporary buffer variable to see if it contains a 'NULL' pointer. In some version of Microsoft Visual C++ this was the means by which the 'new' operator signalled that an allocation failure had occurred. In later versions of Visual C++ however this behaviour was changed such that an exception will be thrown in this case. In order for us to support both methods of error detection we have wrapped the allocation of the new vertex array in a 'try' block. This ensures that if the 'new' operator throws an exception, we are able to handle this failure gracefully. To enable us to provide backwards compatibility however, we have included the aforementioned 'NULL' pointer test here also. In this case, we generate the same exception as we would expect the 'new' operator to throw. In doing so, we are able to support both types of error handling simply by including a single catch block.

```
        // If any old data
        if (Vertices)
        {
            // Copy over old data
            memcpy( VertexBuffer, Vertices, VertexCount * sizeof(CVertex));

            // Release the memory allocated for the original vertex array
            delete []Vertices;
```

```
        } // End if old vertices created

    } // End try block
```

This next portion of the code tests to determine whether or not vertex data already exists within this polygon. If this is found to be the case, then that vertex data is copied into the new vertex array to ensure that any vertices already inserted by the application persist. Notice how we copy only the amount of data that is contained within the *original* vertex array. This is important because we need to ensure that we do not attempt to read any memory past the end of the previously allocated block. This means that if our polygon previously contained 5 vertices, and our application was requesting space for an additional 5 then only those original vertices would be copied into the first 5 elements of the new array, leaving the last 5 elements in their default state.

The final task in this block of code is to release the memory (if any) that was allocated in a previous call to this function. If a vertex array already exists, we must release it to ensure that our application does not leak any memory when the 'Vertices' member pointer is overwritten with that of our new array.

With all of our memory allocation and initialization completed, there are no further exceptions which are likely to be generated within the context of this function.

```
    // Was an exception thrown?
    catch (...)
    {
        if (VertexBuffer) delete []VertexBuffer;
        return -1;

    } // End catch block
```

The catch block we are using in this function specifies an ellipsis in place of a specific exception handling type. What this basically means is that this catch block will capture any and all exceptions generated in the try block regardless of the type of exception thrown. Because the application is not interested in the specifics of any exception that may have occurred in this function, we simply release the memory allocated for the new vertex array – if the exception was thrown after the allocation line – and return a value of -1. Because the application is expecting a valid index in the range of 0 and above, this *invalid* index return code can be used to inform the calling function that the allocation was **not** successful.

At this point we have allocated a new vertex array that has enough elements to contain all of the original data that was stored in the array prior to this call, as well as those additional elements requested by the calling function. With the original data back into this new array, and the original one released, we can now simply overwrite the old vertex array pointer, with that of the new array. We also increment the polygon's internal 'VertexCount' member variable to ensure that both the application and subsequent calls to this function have access to up to date information about the size of the vertex array.

```
    // Store the new buffer
    Vertices     = VertexBuffer;
```

```
    // Increment vertex count
    VertexCount += nVertexCount;
```

The final task that must be undertaken here is to return the index to the first of the vertex elements added to the array during that call. This index will be equal to the number of vertices that were originally stored in the polygon before this function was called. Returning the correct index can be achieved in one of two ways, either by making a temporary copy of the 'VertexCount' variable before we increment it, or by subtracting the requested additional vertex count parameter from the newly incremented 'VertexCount' value. Our implementation chooses the latter of these two methods as shown in the following snippet:

```
    // Return the base vertex
    return VertexCount - nVertexCount;
}
```

Although there is a relatively small amount of code in this function, it was important to discuss this given the changes in the way we are handling errors within our pre-processing tool. This exception handling scheme is used throughout this new application, and as a result we will not be going into quite as much detail about future memory allocation routines.

CPolygon::InsertVertex

There are relatively few cases in which we will ever need to insert a vertex into a polygon after it has been built. In most cases we will be generating new polygons with which we would build new vertex arrays from scratch each time. With that said, there are situations in which certain tasks are made easier by inserting a single vertex into a particular position around the polygons exterior. An example of such a case is with the recently covered T-Junction repair process. Because we have covered this function recently, we will only provide a brief recap to demonstrate this function as it applies to our new tool.

As before, this function's main purpose is to reshuffle the polygon's internal vertex array in order to create space for a new vertex. This vertex will be inserted *before* the vertex specified by the single parameter passed to this function. By doing so, we ensure that the new vertex will have an index that is equal to the value requested by the calling function.

```
long CPolygon::InsertVertex( unsigned long nVertexPos )
{
    CVertex *VertexBuffer = NULL;

    // Add a vertex to the end
    if ( AddVertices( 1 ) < 0 ) return -1;
```

The first thing we need to do here is to resize our vertex array to make sure that here is enough room for a single new vertex to be inserted. As outlined in our earlier coverage, the 'AddVertices' function will return a value of -1 if the allocation was unsuccessful. If this is found to be the case, then this function will return immediately using a similar error code.

At this stage, the polygon remains unaltered with the exception that there is a new empty vertex at the end of the internal vertex array. Due to the fact that our application requires a free slot to be created at an arbitrary position within the array – not necessarily at the end – we must shuffle the array elements such that this spare vertex now exists at the correct location. This is achieved by moving each of the vertices along by one, starting with the final element from the original vertex array, continuing backwards until we have moved each vertex up to and including the element specified by the input parameter. This could be achieved using the following code:

```
long i; // Signed type, we're counting backwards
for ( i = VertexCount - 2; i >= nVertexPos; ++i )
{
    // Move the current vertex forward by one.
    Vertices[i + 1] = Vertices[i];

} // Next Vertex
```

In this code you can see that we are simply assigning each vertex to the value of the one that falls directly prior to it in the vertex array. This is repeated until we reach the requested position, leaving a gap in the array at the element on which the loop exits.

Although this is a relatively simple loop, there is a quick and easy way to achieve this same effect using the 'memmove' function exported by the standard C runtime library.

```
    // Reshuffle the array unlesss we have inserted at the end
    if ( nVertexPos != VertexCount - 1 )
    {
        // Move all the verts after the insert location, up a ways.
        memmove( &Vertices[nVertexPos + 1], &Vertices[nVertexPos],
                 ((VertexCount-1) - nVertexPos) *  sizeof(CVertex) );

    } // End if not at end.
```

Internally, this function works in a similar fashion to the looping method described previously. The 'memmove' function is not however concerned with the layout and structure of the data or any form of class assignment or protection. It basically performs a byte for byte transfer of the specified area of memory, into the required destination address. This is not a problem for our vertices because they are essentially just data structures that do not use any form of virtual function mapping that may cause problems when moving the array contents in this way. One test that we must perform before we call this function however is to determine whether the requested vertex position is already at the end of the array. If this was found to be the case, then the data area that we would pass to this function would be empty and could potentially cause the operation to fail. Since the previous call to the 'AddVertices' function results in the new vertex being added to the end of the array, we need take no further action if this was the position requested by the calling function.

Once the contents of the array have been moved such that a gap remains at the correct location, we must finally overwrite the values of that spare vertex with those of a default state and return a success code to the calling function.

```
    // Initialize data to default values
```

```
    Vertices[ nVertexPos ] = CVertex( 0.0f, 0.0f, 0.0f );

    // Return the position
    return nVertexPos;
}
```

CPolygon::Split

The polygon split function remains largely unchanged from the implementations we have seen in earlier lab projects. However, there are a few alterations that have been made to allow us to take full advantage of our new hierarchical polygon class design.

```
HRESULT CPolygon::Split( const CPlane3& Plane, CPolygon * FrontSplit,
                         CPolygon * BackSplit, bool bReturnNoSplit )
{
    ...

    // Local variable definitions remain unchanged

    ...

    // New local variable
    CVertex NewVert;

    ...

    // Temporary array allocation and early-out logic is
    // largely unchanged. As a result it is not included here.

    ...
```

Although this function is largely identical to the previous implementation, there are some changes that affect how the ‘FrontSplit’ and ‘BackSplit’ parameters are declared and how they should be used by the application. Up until this point, the split function has been responsible for allocating any new polygon instances in cases where the source polygon is found to be spanning the input plane. These new polygon instances were returned to the calling function via the ‘FrontSplit’ and ‘BackSplit’ parameters which were previously declared as double ‘CPolygon’ pointers:

```
Split( const D3DXPLANE& Plane,
       CPolygon ** FrontSplit, CPolygon ** BackSplit, bool bReturnNoSplit )
```

Recall that our application would pass in a pointer to another ‘CPolygon’ pointer *variable* that would then be dereferenced by the split function in order to store the new polygon pointers in the variables referenced by these two parameters.

In this implementation we do not wan to force the application to use any particular polygon class at any point in the process. If the split function was to allocate any new polygon objects using the ‘CPolygon’ type, then we would be unable to make use of any form of class hierarchy in this way. As a result, the calling function must now be responsible for creating the polygon instances in advance – using the

applicable class type – and pass in these already instantiated objects via these same two parameters. Because we are no longer passing in pointers to variables as before, these two parameters are now simply single 'CPolygon' pointers. Although it may seem as though we are still placing a restriction on the application by accepting pointers of this base class type, remember that in C++ we are able to use a pointer to any type found within the class hierarchy when we need to access the superclass information. In the case of this base split function, we will only be modifying the properties defined by the base 'CPolygon' class itself.

We mentioned in the comments included in the previous code snippet that all of the logic we have previously implemented for the temporary array allocation and any 'early out' testing remains the same. Let us therefore move on to discussing those changes made to the core splitting functionality.

```
    // Compute the split if there are verts both in front and behind
    if (InFront && Behind)
    {
        for ( i = 0; i < VertexCount; i++)
        {
            // Store Current vertex remembering to MOD with number of vertices.
            CurrentVertex = (i+1) % VertexCount;

            if (PointLocation[i] == CLASSIFY_ONPLANE )
            {
                if (FrontList) FrontList[FrontCounter++] = Vertices[i];
                if (BackList)  BackList [BackCounter ++] = Vertices[i];
                continue; // Skip to next vertex
            } // End if On Plane

            if (PointLocation[i] == CLASSIFY_INFRONT )
            {
                if (FrontList) FrontList[FrontCounter++] = Vertices[i];
            }
            else
            {
                if (BackList) BackList[BackCounter++] = Vertices[i];

            } // End if In front or otherwise

            // If the next vertex is not causing us to span the plane then continue
            if ( PointLocation[CurrentVertex] == CLASSIFY_ONPLANE ||
                 PointLocation[CurrentVertex] == PointLocation[i]) continue;

            // Calculate the intersection point
            Plane.GetRayIntersect( Vertices[i], Vertices[CurrentVertex],
                                   NewVert, &fDelta );
```

The above code also remains largely unchanged. The only real difference here is that we are no longer using our collision library to retrieve information about the relative locations of each vertex in respect to the specified plane. Notice the last line in this snippet in which we are using one of our new 'CPlane3' class functions named 'GetRayIntersect'. This is in place of the previous call to the 'CCollision' class's 'RayIntersectPlane' function that has not been included in this application. Unlike the previous ray

intersection function – which required a ray start point and a ray velocity – this function accepts both a ray start and end point as its input parameters. Notice however that we are passing the vertices directly into this function without any sort of casting, even though the function we are calling is declared using 'CVector3' parameter types. This is just one of the benefits of deriving our vertex from the vector class as discussed earlier.

The 'GetRayIntersect' function outputs both the point in space at which the ray intersects the plane, as well as the optional 't' value we are familiar with. In the initial code listing for this function you may have noticed that we included a new local variable named 'NewVert'. This variable was also of the type 'CVertex'. Once again, because of our vertex class hierarchy design, the intersection function is able to set up the vertex values directly even though it is expecting a parameter of the type 'CVector3'. We also pass to this function the floating point variable 'fDelta', into which the intersection 't' value will be stored. We will need both of these values in order to correctly interpolate the remaining vertex components.

In this next block of code we perform these remaining vertex component interpolation steps. This ensures that after the polygon has been split, any new vertices inserted by the splitting procedure contain the correct values based on their position along the edge of the original polygon. Once the new vertex has been completely initialized, we then store it in both of the front and back fragment lists as before.

```
            // Interpolate Texture Coordinates
            CVector3 Delta;
            Delta.x    = Vertices[CurrentVertex].tu - Vertices[i].tu;
            Delta.y    = Vertices[CurrentVertex].tv - Vertices[i].tv;
            NewVert.tu = Vertices[i].tu + ( Delta.x * fDelta );
            NewVert.tv = Vertices[i].tv + ( Delta.y * fDelta );

            // Interpolate normal
            Delta          = Vertices[CurrentVertex].Normal - Vertices[i].Normal;
            NewVert.Normal = Vertices[i].Normal + (Delta * fDelta);
            NewVert.Normal.Normalize();

            // Store in both lists.
            if (BackList)  BackList[BackCounter++]   = NewVert;
            if (FrontList) FrontList[FrontCounter++] = NewVert;

        } // Next Vertex

    } // End if spanning
```

Once the front and back vertex lists have been created, we then store this data into the applicable polygon fragments allocated and passed in by the application. Unlike previous polygon class implementations however, this class does not store any additional information which needs to be duplicated into those fragments. This will in fact be handled by those classes which are derived from this base class. We will see how this achieved in the next section where we will discuss one of these derived classes.

```
    // Allocate front face
    if (FrontCounter && FrontSplit)
    {
```

```
        // Copy over the vertices into the new poly
        FrontSplit->AddVertices( FrontCounter );
        memcpy(FrontSplit->Vertices, FrontList, FrontCounter * sizeof(CVertex));

    } // End If

    // Allocate back face
    if (BackCounter && BackSplit)
    {
        // Copy over the vertices into the new poly
        BackSplit->AddVertices( BackCounter );
        memcpy(BackSplit->Vertices, BackList, BackCounter * sizeof(CVertex));

    } // End If
```

With our polygon fragments fully constructed, the only thing that remains for us to do is to clean up any of the temporary arrays that may have been allocated at the beginning of the function, and return our success code.

```
    // Clean up
    if (FrontList)      delete []FrontList;
    if (BackList)       delete []BackList;
    if (PointLocation)  delete []PointLocation;

    // Success!!
    return BC_OK;
}
```

CPolygon:: ReleaseVertices / ~CPolygon()

The final two base polygon member functions are those that are responsible for cleaning up and releasing any memory allocated and stored within this class. The first of these is the 'ReleaseVertices' function. This is a public member function that can be called by the application if it needs to release the memory allocated by this polygon, perhaps in order for this object instance to be reused. The second of these functions is the class destructor. Rather than duplicate the clean up code provided by the 'ReleaseVertices' function, the class destructor simply calls it at the point where the polygon object is released or goes out of scope.

```
void CPolygon::ReleaseVertices()
{
    // Clean up after ourselves
    if ( Vertices ) { delete []Vertices; Vertices = NULL; }
    VertexCount = 0;
}
```

```
CPolygon::~CPolygon()
{
    // Clean up after ourselves
    ReleaseVertices();
}
```

With our polygon base class defined, let us now take a look at how we might derive a new polygon class that will provide the data members needed to store any renderable polygon information loaded from file.

The CFace Class

This is the first of our derived polygon classes. It is used by a large portion of our application for the storage of renderable polygon information. That is the polygon data which is loaded from file, compiled and exported, and is finally intended to be rendered by our game application. As a result, this class stores the common pieces of information we have come to rely on such as the polygon normal, texture and material information in addition to any flags and alpha blending properties that may be required.

Recall during our discussion of the new polygon class hierarchy design, we ideally want to create a class structure in which each module is responsible for defining its own variables within an independent polygon class. However, at this point in time we need an intermediate concept that we can use to load the data contained within the source IWF file. This will enable us to initialize each processing module easily, using a common polygon structure, from which they can each base their own storage classes. At a later point in this lesson, we will derive a further class from this one which will be responsible for storing additional information required during the BSP compilation process for instance.

Due to the fact that this class is derived from the 'CPolygon' base class, much of the functionality is inherited. As a result, we are only really responsible for extending this class for the purposes of storing and retrieving any additional render based information. Let us therefore take a look at the declaration for this intermediate storage class.

```
class CFace : public CPolygon
{
public:
    // Constructors & Destructors
    CFace( );

    // Public Variables for This Class
    CVector3        Normal;                 // Face Normal
    short           TextureIndex;           // Index into texture look up
    short           MaterialIndex;          // Index into material look up
    short           ShaderIndex;            // Index into the shader look up
    ULONG           Flags;                  // Face Flags
    UCHAR           SrcBlendMode;           // Face Source Blend Mode
    UCHAR           DestBlendMode;          // Face Dest Blend Mode

    // Public Virtual Functions for This Class
    virtual HRESULT Split( const CPlane3& Plane, CFace * FrontSplit,
                           CFace * BackSplit, bool bReturnNoSplit = false );

};
```

Earlier we mentioned that any applicable member functions have been omitted from many of the class declarations being discussed throughout this chapter. In the case of this derived class however, with the exception of the virtual 'Split' function shown, this class defines no additional member functions. Much of the functionality available to the application through an instance of this type is provided by the base

'CPolygon' class from which it inherits. There are however several new member variables declared here that are discussed below.

CVector3 Normal
This member variable is responsible for storing the normal vector for this polygon / surface. As you should already be aware, this piece of information is extremely important to us when we are constructing a *polygon aligned* BSP tree compiler. This is due to the fact that both the polygon normal, and at least one of its vertices, is used as the basis for creating the separating planes assigned to each node in the tree.

short TextureIndex
Previously we mentioned that this class is responsible for storing each of the pieces of information that may be required to render this polygon in our final application. As a result, we store the index into a texture information array in this member variable. Although this application does not perform any sort of rendering itself, the texturing information must be exported back out to file when the compilation process has been completed. Notice that we declare this member variable using a signed type. This is because we use a value '-1' to signify that no texture has been assigned to this particular polygon.

short MaterialIndex
As with the aforementioned 'TextureIndex', we also store an index into the global material array much as we have done before in previous lab projects. Again this is a signed type in which '-1' signifies that no material has been applied to this polygon and a default material should be assumed. Although we have not yet discussed the application texture and material arrays at this point, we will see later how this information is loaded from file within our main compiler class.

short ShaderIndex
At this point in the course we have not yet encountered the use of pixel or vertex shaders within our application. However, we are currently constructing a tool which will hopefully be applicable to future lessons. As a result we also retain additional pieces of information that are available in the source IWF file such as the per-polygon shader index. As with each of the texture and material indices, a value of '-1' signifies that no shader has been applied to this polygon.

ULONG Flags
As we have discussed in previous lessons, each of the surfaces stored within the IWF file also carries with it a number of possible flags. These include as an example whether the polygon should be considered invisible or not. Although we do not pay an attention to this information within the various compilation processes in this application, the flags assigned to each polygon should be retained in order for them to be exported back out to the compiled file.

UCHAR SrcBlendMode
The source alpha blending mode is again another piece of information that is only really applicable to our rendering application. This information is loaded from file and retained here only for the purposes of exporting it back out to file for the run-time application's import procedure to process.

UCHAR DestBlendMode

This member variable is the complement of the source blending mode variable and is provided only for the purposes of export for the rendering application.

Although many of these member variables serve no other purpose than to be exported to the resulting file, it is important that this information is retained and is processed as each compiler task is performed. During the BSP compilation process for instance, we already know that many polygons will be discarded and likewise new polygons created in their place. As a result it is imperative this information be considered in several places in the application and – as we will discover shortly – one such place is during the splitting of our polygon data against the separating planes.

This class is of course merely an extension of the base 'CPolygon' class we covered in great detail in the previous section. As a result, there are only two member functions exposed by this class, each of which we will be discussing next.

CFace::CFace()

As with most of our classes, we start with the class constructor. We have defined several new member variables in this derived class that we need to initialize. Remember that in C++, the constructor of the base classes are called automatically when an object of this type is created. As a result we need only initialize the variables that are declared explicitly by this class declaration.

```
CFace::CFace()
{
    // Initialise anything we need
    MaterialIndex = -1;
    TextureIndex  = -1;
    ShaderIndex   = -1;
    Flags         =  0;
    SrcBlendMode  =  0;
    DestBlendMode =  0;
}
```

CFace::Split

Here is where our new hierarchical polygon class design comes into its own. Even though we have declared many new member variables that need to be duplicated into each of the split fragments, we need not re-implement the split functionality provided by the base 'CPolygon' class.

```
HRESULT CFace::Split( const CPlane3& Plane, CFace * FrontSplit,
                      CFace * BackSplit, bool bReturnNoSplit )
{
```

As before, the first parameter to this derived 'Split' function is a reference to the separating plane that will be used to classify and potentially split the polygon into two component fragments. The second and third parameters are pointers to each of the *pre-allocated* polygon instances into which the split function will place the output data. Notice however that the types of these two polygon pointers are declared as 'CFace', rather than 'CPolygon' as before. This allows us to both inform the application about the type of polygon this function is expecting, as well as granting us easy access to the newly defined member

variables within this class. This is why it was vital that we made the alterations discussed earlier, such that the application would pass in pointers to two pre-allocated polygon objects of the correct type. Because we are being passed two new 'CFace' objects via the 'FrontSplit' and 'BackSplit' parameters, we will be guaranteed to have access to the new member variables that we have declared.

The fourth and final parameter is the early out flag that informs the split procedure whether or not to return immediately if no split has occurred. Recall that if the application passes true to this parameter and the polygon's vertices are found not to span this plane, then the function will exit immediately without copying any information into either of the child fragments. If the application should specify false, then this function would proceed to copy the vertex data into the appropriate fragment even if no split has occurred.

Due to the fact that a large portion of the tasks undertaken during the splitting of a polygon are related to the building and separating of vertex data, there is obviously a lot of common functionality that we have already implemented in the base 'CPolygon'. As a direct result of deriving the 'CFace' class from 'CPolygon' in this way, we are able to make use of this functionality by simply calling the base class' 'Split' function, passing in each of the parameters specified by the application directly:

```
    // Call base class implementation
    HRESULT ErrCode = CPolygon::Split( Plane, FrontSplit, BackSplit,
                                       bReturnNoSplit );
    if (FAILED(ErrCode)) return ErrCode;
```

At this point, the base class implementation of the split function will have separated any applicable vertices into the appropriate polygon fragments specified by the application. Of course the base implementation is not aware of any of the member variables that have been included in this extended polygon class. To this end, the only remaining task that our derived class's split function must undertake is to copy the data stored within each of these variables, into those of the new split fragments as shown in the following snippet.

```
    // Copy remaining values
    if (FrontSplit)
    {
        FrontSplit->Normal        = Normal;
        FrontSplit->MaterialIndex = MaterialIndex;
        FrontSplit->TextureIndex  = TextureIndex;
        FrontSplit->ShaderIndex   = ShaderIndex;
        FrontSplit->Flags         = Flags;
        FrontSplit->SrcBlendMode  = SrcBlendMode;
        FrontSplit->DestBlendMode = DestBlendMode;
    } // End If

    if (BackSplit)
    {
        BackSplit->Normal         = Normal;
        BackSplit->MaterialIndex  = MaterialIndex;
        BackSplit->TextureIndex   = TextureIndex;
        BackSplit->ShaderIndex    = ShaderIndex;
        BackSplit->Flags          = Flags;
```

```
        BackSplit->SrcBlendMode   = SrcBlendMode;
        BackSplit->DestBlendMode  = DestBlendMode;
    } // End If

    // Success
    return BC_OK;
}
```

You can hopefully gather from this simple function that: in creating a relatively simple class hierarchy design, we are able to easily extend the functionality of the base class and provide new custom member variables at will. This will be of enormous benefit to each of the future compilation process modules that we will construct because it allows them to create their own polygon structures and store custom information without having to re-implement any of the common polygon functionality.

One other item of note is that we have not included a destructor in this class. Remember that because this class is derived from 'CPolygon', this base class destructor will always be called. Due to the fact that none of the member variables in the extended 'CFace' class contain pointers to any form of allocated memory we do not need to include any release or cleanup code. The vertices that were allocated will however be released by the base class constructor automatically, even if we were to include a destructor here.

With the 'CFace' class fully defined, we are now able to load and save the renderable polygon information to and from the source and destination IWF files. However, we still need to implement a class that serves as the container for this polygon data.

The CMesh Class

The mesh class is a concept that will already be very familiar to us. We have developed several different mesh classes in previous lab projects, but these too were heavily biased toward the construction of hardware friendly buffers used for rendering. As with the polygon classes we have covered so far, the mesh class we are developing in this tool is intended to store information only for the purposes of easy access to the scene data and final export to file.

```
class CMesh
{
public:
    // Constructors & Destructors
             CMesh( );
    virtual ~CMesh( );

    // Public Variables for This Class
    char           *Name;                // Stored name loaded from IWF
    CFace         **Faces;               // Mesh faces
    ULONG           FaceCount;           // Faces in this mesh
    CMatrix4        Matrix;              // Meshes object matrix
    CBounds3        Bounds;              // Meshes local space bounding box
    ULONG           Flags;               // Mesh flags (i.e. detail object)

    // Public Member Functions Omitted
```

```
};
```

This mesh class is relatively simple and declares only a handful of member variables. These variables match the information stored within the IWF file. Let us examine each of these in detail.

char * Name
Each of the meshes contained in the scene geometry file can have a name associated with them. This name string is usually specified by the artist or level designer within a scene editor such as GILES™ which can be used by the application to identify a particular mesh. As an example of why this might be useful, imagine that we created a mesh that served as a door within the level. Our application might want to open this door whenever the player triggered a script by entering the correct code on a door panel. Rather than opening every door in the level, this script would obviously need to identify a particular door to open. By naming each of the door meshes individually, the script writer would then be able to identify just the specific door that should open when the correct code has been entered into that panel.

Again this information is not used directly within our compilation tool, but we are required to retain this string in order to export it once again, after the compilation procedures have been executed.

CFace ** Faces
Because the mesh data stored in the file will ultimately be used for rendering by the final game application, this mesh class is designed to store and manage polygons using the 'CFace' class type. As a result, this member variable stores a pointer to an array of 'CFace' object instances rather than its base class 'CPolygon' found in previous implementations. Notice how we are using a double pointer declaration here. This is because we want to store an array of 'CFace' *pointers* which allows us to perform a simple shallow copy on the array each time it is resized. Just as our polygon class exposed a series of functions to manage the internal vertex array, the mesh class does the same in order to allow our application to manage this polygon array in an easy to use fashion.

ULONG FaceCount
This variable simply stores a value describing the number of polygons currently stored in the aforementioned 'Faces' array. We need to maintain this information in order to resize this array in each call to the 'AddFaces' member function, in addition to correctly reporting the length of the array to the application.

CMatrix4 Matrix
In previous applications, mesh object matrices were maintained by a wrapping 'CObject' class. This was provided in order to allow our application to create references to individual meshes and still maintain the ability to position each mesh independently. In the IWF file however, this reference information is maintained by individual 'entity' structures within the file and will be handled separately. In effect, each individual mesh may have its own matrix that describes the position and orientation of the *first* instance of that mesh. This first mesh may then be subsequently referenced by an entity that will override this position and orientation information. Again, because we are not rendering this mesh data, we have no need for the wrapping object class concept and therefore this matrix is simply maintained directly within the mesh itself. In GILES™, the vertices stored within each polygon are expressed in world space directly. This means that for the most part this member variable will contain an identity matrix. With that said, other scene creation tools may export an IWF file that does not define its mesh vertices in

world space. This imported variable should therefore still be taken into consideration. We will discuss how this matrix is used within the pre-processing tool a little later on in this lesson.

CBounds3 Bounds
This variable describes the axis aligned bounding box extents of the mesh vertex data in world space. The bounding box information provides us with a quick initial broad-phase mechanism by which we can test for intersection between two meshes. Among other things, this variable will be used later on in this chapter during the hidden surface removal process to determine whether two meshes might need to be merged together using the CSG union operation.

ULONG Flags
Just as with the polygon / surface information stored within the IWF file, each mesh also carries with it a number of possible flags. These include as an example whether the mesh itself is a detail object that should not be considered during the BSP compilation step. We will discuss the implications of these flags when they are encountered during the coverage of each of the main compilation tasks.

Let us now discuss the functions to the CMesh class that were omitted from the class declaration. We will start by looking at the initialization procedure (the constructor) and will then discuss the array management. Finally we will look at the various utility functions that allow us to more easily integrate the mesh into the compilation tool.

CMesh::CMesh()

The only constructor defined by the new mesh class is the default one, which simply initializes the member variables of the mesh whenever an instance of this class is created.

```
CMesh::CMesh()
{
    // Initialise anything we need
    Faces       = NULL;
    FaceCount   = 0;
    Flags       = 0;
    Name        = NULL;
}
```

As you can see, we simply set each of the member variables to a default state of either NULL or 0. In the case of the two pointer variables – ‘Faces’ and ‘Name’ – we set them to an initial state of NULL in order for us to identify whether or not any memory has already been allocated and should potentially be released. If either of these values is found to be equal to NULL at a later point, then we should obviously not attempt to release the memory to which this variable points because it had not yet been allocated.

CMesh::AddFaces

This is a public method that is used by the application in order to grow the ‘CFace’ array maintained by an instance of this mesh class by the specified amount. Lab project 16.2 uses this function when loading internal meshes within the IWF file in addition to cases where it is required to manually construct a new mesh as we will see shortly.

The ‘AddFaces’ function is similar in many respects to the memory allocation functions we have been using throughout the development of each lab project in this series. However, as with the polygon’s ‘AddVertices’ function, there are a number of key differences that we must draw your attention to.

```
long CMesh::AddFaces( unsigned long nFaceCount )
{
    CFace **FaceBuffer = NULL;

    // Validate Requirements
    if ( nFaceCount == 0 ) return -1;
```

The only parameter accepted by this function allows the application to specify how many additional polygons we would like to add to the ‘CFace’ array stored here. If the array has already been created by a previous call, this will be the number of elements by which that array will be grown. As in the many functions we have implemented before, this parameter is validated to ensure that the allocation will not fail due to the application specifying a count of zero.
This function has a return type of a simple signed long. This will be used to return the index to the first of the polygon elements added to the array during that call. This index – as always – will be equal to the number of polygons that were originally stored in this mesh before the ‘AddFaces’ function was called. If an error occurred during the execution of this function, a value of ‘-1’ will be returned.

As before, our first job is to attempt to allocate a new array of the same type as the internal ‘Faces’ member variable that has been correctly sized to take into account those new requested polygons. Subsequently, any data already stored within the mesh must then be copied into this new polygon array. Because we are simply storing *pointers* to heap allocated ‘CFace’ objects, this can be achieved by a single call to the standard C runtime ‘memcpy’ call. This new array will eventually be used to overwrite the one currently stored by the mesh.

```
    try
    {
        // Allocate brand new buffer
        FaceBuffer = new CFace*[ FaceCount + nFaceCount ];
        if (!FaceBuffer) throw std::bad_alloc(); // VC++ Compat
        ZeroMemory( FaceBuffer, (FaceCount + nFaceCount) * sizeof(CFace*) );

        // Copy over any old data
        if (Faces) memcpy( FaceBuffer, Faces, FaceCount * sizeof(CFace*));

        // Allocate new faces
        for ( long i = 0; i < (signed)nFaceCount; i++ )
        {
            FaceBuffer[FaceCount + i] = new CFace;
            if (!FaceBuffer[FaceCount + i]) throw std::bad_alloc(); // VC++ Compat

        } // Next face

    } // End Try Block
```

There is one very important addition that has been made to the above code that we have not yet encountered in any of our memory allocation routines. The latter part of the function actually allocates the new 'CFace' objects on behalf of the application and stores them in the array in advance. There are several reasons why we have chosen to do this with our new mesh class. The first of these is due to our new class hierarchy design. Because the application has much more freedom to create an object using one of the several potential types of polygon classes, we have introduced a situation in which the application could create a polygon object of a type which does not store much of the information required. This could also lead to a situation in which one of the virtual functions defined by the polygon class could be called erroneously. By allocating the polygon objects explicitly within this function, we are able to enforce the type of polygon stored within each element of the mesh's member array. An additional benefit of including this allocation step here is that we are able to make use of the error handling logic in this function without having to include that same logic each time we need to allocate a mesh polygon.

At this point in the function, we have allocated the newly sized array and copied over any of the polygon pointers previously stored in the 'Faces' member variable. A series of new 'CFace' class instances have also been created and initialized by their own constructors, and finally stored within this new array. As always, there are potentially many situations under which an error may have occurred with all of the memory allocation that has been performed.

All of the allocation steps within this function have been wrapped in a try block that will allow us to capture any exceptions that may have been thrown during the execution of the lines of code within that block. Backwards compatibility has also been preserved by testing the pointer value returned from each allocation operation and explicitly throwing a similar exception if the value was found to be 'NULL. Of course, an exception may be thrown at any point in this block of code that might result in only some of the intended allocations having been attempted. Therefore, in the event of an exception, we must clean up and release those memory areas that were successfully allocated. In the following catch block, a great deal of care is taken to test each of the potentially allocated memory pointers and release them only if they are *not* equal to NULL. This should ensure that we do not attempt to deallocate memory that was not allocated prior to the exception being thrown.

```
    // Did an exception get thrown ?
    catch (...)
    {
        if (FaceBuffer)
        {
            // Release any already allocated faces
            for ( long i = 0; i < (signed)nFaceCount; i++ )
            {
                if (FaceBuffer[FaceCount + i]) delete FaceBuffer[FaceCount + i];

            } // Next face

            // Release buffer
            delete []FaceBuffer;

        } // End if FaceBuffer

        return -1;
```

```
    } // End Catch Block
```

With our correctly sized array now allocated and initialized with new 'CFace' object pointers, the next job is of course to release the old 'Faces' array, and overwrite the member variable with the new heap allocated array pointer. Once this is done, we can increment the internal 'FaceCount' variable to ensure that we keep an accurate record of the number of polygons stored in the polygon array.

```
    // Free up old buffer and store new
    if (Faces) delete []Faces;
    Faces = FaceBuffer;

    // Increment face count
    FaceCount += nFaceCount;
```

Finally, with the task of adding new faces complete, this function returns the array element index to the first polygon that has been added. This allows the application to retrieve and iterate through the polygon array beginning with the correct element.

```
    // Return the base face
    return FaceCount - nFaceCount;
}
```

CMesh::BuildFromBSPTree

Although we have not yet discussed our new BSP leaf tree class, we should be familiar enough with the general concepts involved in the construction of leaf trees to know that, once the compilation has completed, the tree will store a list of each of the polygons contained within its leaves. Once the BSP tree has been built, we need to write the polygon information to file in a format that is easy for the application to retrieve. Due to the fact that our application is already capable of loading mesh and polygon data from the IWF file, it makes sense that we export the resulting BSP tree polygon data out to file as a standard mesh. This will prevent us from having to implement another series of polygon import functionality and will allow the BSP tree's polygon data to be loaded seamlessly by *any* IWF import procedure.

This 'BuildFromBSPTree' function has been provided in order to help us convert the BSP tree polygon data into a format compatible with the pre-defined IWF mesh / polygon structures. It can also be used by any additional compilation process in situations where the polygon information must be extracted. We will discuss the process by which the remainder of the BSP tree information is accessed and exported at a later stage, but for now this is a good example of how a mesh might be constructed using existing polygon information.

```
bool CMesh::BuildFromBSPTree( const CBSPTree * pTree, bool Reset /* = false */ )
{
    ULONG Counter = 0, i;

    // Validate Data
    if (!pTree) return false;
```

There are two parameters declared by this function. The first is the BSP tree class instance from which we would like to extract the polygon information. We need not concern ourselves with how this class is defined at this point because our primary focus is on how the mesh is being constructed.

The second 'Reset' parameter allows the application to specify whether or not the polygons contained within the specified BSP tree should be released before the specified BSP tree is processed. This parameter is optional, and has a default value of 'false'. If the application specifies 'true' to this parameter, then the mesh will be reset to a default state before extracting the polygons from the BSP tree and storing them in a newly built polygon array. Specifying 'false' will *prevent* the mesh from being reset. This will result in each of the BSP tree polygons being appended to the already existing mesh polygon array.

The very first task is to test the value of the 'Reset' parameter and reset our mesh to a default state if it found to contain a value of 'true'. This is achieved simply by making a call to the mesh's 'ReleaseFaces' function that is responsible for releasing all of the memory associated with the polygon array and resetting each of the associated member variables to their initial state. This function will be covered shortly. We must also reset the matrix stored within the mesh to an identity state.

```
    // Reset if requested
    if (Reset) { ReleaseFaces(); Matrix.Identity(); }
```

With the mesh having been reset or otherwise left intact, we next begin the task of building the mesh data. Before we do so however we need to determine how many polygons must be allocated in the mesh for the storage of those BSP tree polygons that we are interested in. Although we could simply allocate enough storage space for every polygon within the BSP tree and copy the data regardless of its status, there may be cases in which a polygon in the tree has been marked as deleted but has not physically been removed from the array. In addition, there may be polygons stored in the BSP tree that are invalid, however unlikely this may be. For this reason, it is advisable for this function to validate each of the polygons contained with the BSP tree and count the number of polygons that we will ultimately store.

This is demonstrated in the following code snippet in which we make use of two of the access functions exposed by the 'CBSPTree' class. These functions are named 'GetFaceCount' and 'GetFace' respectively. The 'GetFaceCount' function is responsible for retrieving the number of polygons / faces currently stored within the BSP tree class instance. Likewise, the 'GetFace' function is used to retrieve a pointer to a polygon situated at the specified index in the BSP tree's internal polygon array. This polygon is of a type derived from the 'CFace' class named 'CBSPFace' that is intended to extend our renderable polygon with additional BSP specific information. We will cover this additional polygon class in further detail a little later, but for now it should be fairly obvious as to the purpose of each of these additional variables.

The following code implements this validation technique. Put simply, this code loops through each of the polygons contained within the BSP tree and validates two of its exposed parameters. The first is the 'Deleted' member. In certain situations, such as during the hidden and exterior surface removal processes, polygons may need to be removed. Rather than physically remove the polygons from the tree, they are flagged as deleted. This allows us to undo a split operation if necessary, as we shall see in our coverage of HSR split repair later in this chapter. The second test we perform is simply to validate that this particular polygon contains at least the 3 vertices required to constitute a single triangle. If both of

these tests are passed, then a local counter variable is incremented. Once this loop has completed, the counter variable will contain the total number of polygons that we need to allocate in order to store every polygon that passed the validation tests.

With this tallying process completed, we then attempt to perform the actual allocation of the mesh's internal polygon array via a call to 'AddFaces'. Recall that the 'AddFaces' function returns either '-1' if a failure occurred, or the index to the first polygon added to the internal array should the allocation be successful. We will need this information a little later, so the return value from this function is retrieved and stored. Since the value currently stored in the counter variable we had previously used is no longer required, we can reuse this variable and overwrite its value with that returned by 'AddFaces'.

```
    // Count valid BSP tree faces
    for ( i = 0; i < pTree->GetFaceCount(); i++ )
    {
        if ( !pTree->GetFace(i)->Deleted &&
              pTree->GetFace(i)->VertexCount >= 3 ) Counter++;

    } // Next BSP Face

    // Allocate our faces
    Counter = AddFaces( Counter );
    if ( Counter < 0 ) return false;
```

At this point we have allocated the memory required to store the information for each of the BSP tree polygons that passed the initial validation tests. As a result we are now able to begin copying this polygon data into the mesh's internal array. We begin by looping through each of the BSP tree polygons once again, skipping over any of those which are considered to be invalid using the same two tests as were used in the previous loop.

```
    // Now we loop through and copy over the data
    for ( i = 0; i < pTree->GetFaceCount(); i++ )
    {
        CBSPFace * pTreeFace = pTree->GetFace(i);

        // Validate tree face
        if ( pTreeFace->Deleted ) continue;
        if ( pTreeFace->VertexCount < 3 ) continue;
```

With the validation tests carried out, we are guaranteed to have access to a valid BSP tree polygon at this point. Because of the fact that the BSP tree's 'CBSPFace' class is derived from the 'CFace' class, it might seem that we could simply copy over the pointer to this object without any adverse affects. However, we should not make any assumptions about the ownership of the BSP tree polygon data because there is no way for us to know if the application has further use for this information. If we were to simply copy the BSP tree polygon pointers into the mesh, and were to subsequently release that mesh, the BSP tree's internal array would now contain pointers to an invalid memory location. It is much safer and cleaner for us to perform a 'deep' copy at this point.

The following code does just this. Each of the 'CFace' members are populated using their counterparts in the 'CBSPFace' class retrieved from the BSP tree. Likewise, we also allocated a new vertex array for this new mesh polygon and duplicate the vertex data.

```
        // Retrieve faces for processing
        CFace    * pFace     = Faces[Counter];

        // Copy over data
        pFace->MaterialIndex = pTreeFace->MaterialIndex;
        pFace->TextureIndex  = pTreeFace->TextureIndex;
        pFace->ShaderIndex   = pTreeFace->ShaderIndex;
        pFace->Flags         = pTreeFace->Flags;
        pFace->SrcBlendMode  = pTreeFace->SrcBlendMode;
        pFace->DestBlendMode = pTreeFace->DestBlendMode;
        pFace->Normal        = pTreeFace->Normal;

        // Copy over vertices
        if ( pFace->AddVertices( pTreeFace->VertexCount ) < 0 ) return false;
        memcpy( pFace->Vertices, pTreeFace->Vertices,
                pFace->VertexCount * sizeof(CVertex) );

        // We used a new face
        Counter++;

    } // Next BSP Face
```

Note in the previous code that we used the 'Counter' variable to index into the mesh's newly allocated internal polygon array. This polygon would be the destination object into which this particular BSP polygon data would be copied. Recall that this variable was used to store the value returned from the 'AddFaces' function which specified the first polygon in the newly allocated set. Each time we find a valid polygon within the BSP tree and subsequently store it within the mesh, this counter variable must be incremented in order to move on to the next destination polygon.

The final task in this function, before returning a success code, is to update the mesh's bounding box information to take into account any new polygons that have been added to the mesh. This is achieved with a call to the 'CalculateBoundingBox' member function.

```
    // Calculate our bounding box
    CalculateBoundingBox();

    // Success
    return true;
}
```

Although it may not be clear at this point where and when we might make use of this function, it remains a useful discussion because it allowed us to examine a common usage of the mesh class. As mentioned earlier, we will be utilizing this function later on in the development of our compilation tool at which point any remaining questions you may have about this functions use should be resolved.

CMesh::CalculateBoundingBox

By now you should be very familiar with the techniques involved in calculating a bounding box using mesh polygon and vertex information. This is something we have had to implement many times, in several different parts of our previous run-time applications. Thankfully, the new 'CBounds3' utility class that we have implemented in this lab project performs the majority of the laborious work on our behalf.

The 'CalculateBoundingBox' function accepts no parameters. It simply iterates through each of the polygons contained within the mesh and passes the vertex data into the 'CalculateFromPolygon' bounding box member function. This function accepts a pointer to a set of vertex data, the number of vertices in that set, the size of the vertex structure used – which enables it to step to the positional information of each vertex in the array – and a final 'Reset' parameter that dictates whether to calculate new bounding box extent vectors from only that polygon, or to grow those extent values already contained within the object. In the implementation of this function we need to grow the bounding box for each polygon that is contained within the mesh. To this end, we reset the bounding box in advance and then specify 'false' to the reset parameter of the bounding box's member function.

Finally, once the mesh's 'Bounds' member has been calculated, this function returns to the calling function with a reference to this variable. This allows the application to use the result of the operation performed by this function as the input to another, without having to access the bounds member separately. Because this is achieved via the function return value, this is of course optional and the calling function need not consider this result.

```
const CBounds3& CMesh::CalculateBoundingBox()
{
    // Reset bounding box
    Bounds.Reset();

    // Loop through each face
    for ( long i = 0; i < (signed)FaceCount; i++ )
    {
        Bounds.CalculateFromPolygon( Faces[i]->Vertices, Faces[i]->VertexCount,
                                     sizeof(CVertex), false );

    } // Next face

    // Return our bounds reference
    return Bounds;
}
```

CMesh::ReleaseFaces / ~CMesh()

The final two functions in this class are those responsible for cleaning up and releasing any resources allocated by the mesh object. The first is a public method named 'ReleaseFaces'. This function is responsible for releasing only that memory allocated for the internal polygon array in addition to each of the heap allocated polygon objects stored within that array. As always, each value is tested to see whether it contains a value other than NULL. If this found to be the case then that object or array can be safely released. While this function can be called by the application at any point if it wishes to reuse a particular mesh object, this function is also called by the second of these two functions – the class

destructor – as the object is released or goes out of scope. In addition to calling the 'ReleaseFaces' function, the class destructor also releases any memory allocated for the storage of the 'Name' member string.

```
void CMesh::ReleaseFaces()
{
    // Clean up after ourselves
    if ( Faces )
    {
        // Release all face pointers
        for ( long i = 0; i < (signed)FaceCount; i++ )
        {
            if ( Faces[i] ) delete Faces[i];

        } // Next face

        // Release the array itself
        delete []Faces;
        Faces = NULL;

    } // End if Faces

    FaceCount = 0;
}
```

```
CMesh::~CMesh()
{
    // Clean up after ourselves
    ReleaseFaces();
    if ( Name ) delete[] Name;
}
```

Prerequisite Class Conclusion

At this stage we have now covered each of the prerequisite classes and functionality that we will need to have at our disposal as we move forward with the development of our new compilation tool. Although it may seem as though we have been covering a lot of topics that we have already discussed in previous chapters, there are many nuances to this new set of utility classes that we had to be aware of both in their implementation and their usage. Even though we have not yet begun to discuss the core implementation of the new pre-processing application, we have built a solid framework on which we can build that will make the job of creating both the tool itself, and each of the compiler modules a much more simple task.

With this new arsenal of utility classes at our disposal, let us now move on to the discussion of the application core.

Application Front End – Main.cpp & LogOutput.cpp

We discussed previously that we wanted to build a modular and portable tool that would enable us to integrate the core compiler functionality with any front end application that we might design. This could be a standalone GUI tool that serves only as the container for the compiler itself, or it could be another more comprehensive tool such as a level editor or modelling package. In lab project 16.2, we will be constructing a simple console like application that will serve as the front end for the compiler functionality. This will ensure that the code required to provide the interface does not obfuscate the more important compiler logic.

If we open and examine the source modules contained in the 'Application Source' folder of our source project, it is clear that the actual wrapper application that we will construct really is nothing more than the logic required to open a console window and output progress and log information to the end user. Given that the logging procedures constitute such a large portion of this lab project's responsibilities, let us quickly summarize how this process works.

Earlier in this chapter we touched briefly upon the mechanism by which the compiler integrates itself into the application for the purposes of writing progress and status information. Recall that this is achieved by using a base interface from which the application must derive. This base interface is named 'ILogger' and is declared in the header file 'Common.h' which can be found in the 'Support Source' project directory. This pure abstract interface class declares several virtual functions which must be implemented by the application derived class.

The following list outlines the purpose of each of these interface functions.

```
void LogWrite( unsigned long Channel, unsigned long Flags, bool NewMessage,
               LPCTSTR Format, ... );
```

This function is intended to be called by any part of the application to output messages to the user.

As a high level concept, the logging class is required to keep track of the information being output by several sources. These are referred to as channels within this implementation. Put simply, the application may be required to output the information for various different compiler process tasks that may be executed. These would be in addition to the general process status information that our application may need to display. Each compilation process is assigned a unique channel index that only that specific process will ever pass to the logging class member functions. The first parameter to the 'LogWrite' interface function is this channel index used to signify the destination to which this message is intended.

The second parameter can be passed one or more of the following flags:

```
#define LOGF_WARNING     1      // Log Flags : Display with warning format
#define LOGF_ERROR       2      // Log Flags : Display with error format
#define LOGF_UNDERLINE   4      // Log Flags : Display with underline property
#define LOGF_BOLD        8      // Log Flags : Display with bold property
#define LOGF_ITALIC      16     // Log Flags : Display with italic property
```

The derived class is not required to obey these flags due to the fact that in certain circumstances, such as in a console application, not all of these flags are even able to be supported. As a result, when calling the 'LogWrite' function, the values we specify should be considered to be only hints.

The third parameter, 'NewMessage' is used to inform the logging class whether or not this is the start of a new message. If a value of false is passed to this parameter then the logging class should consider this message to be a continuation of the previous.

The fourth and final defined parameter is the 'Format' value. You may have noticed that this method is declared using an ellipsis modifier. This format parameter is intended to be used in the same way as we would use the format parameter in the 'printf' function. If you are developing a derived logging class of your own, it is recommended that you look up the 'va_start', 'va_arg', 'va_end' and 'vsprintf' C++ runtime functions that can be used to interpret the format value in conjunction with variable argument lists.

```
void SetRewindMarker( unsigned long Channel );
void Rewind         ( unsigned long Channel );
```

This function is intended to cause the logging class to store a value indicating the current position within the specified channel when this function is called. This is used in conjunction with the 'Rewind' function to have the logging class roll back the channel text to the marker location recorded earlier. This is incredibly useful in tool environments like this where we might want to constantly update a piece of text within the log text with a percentage progress counter for instance.

```
void Clear( unsigned long Channel );
```

The derived class should clear the specified log channel of all text and marker information whenever this function is called.

```
ULONG GetCurrentChannel( );
```

Whenever a call is made to the 'LogWrite' function, the derived log class should record the most recently specified channel index. This value can then be retrieved by the application to continue writing to the same log channel as it wrote some initial text for instance.

```
void SetProgressRange( long Maximum );
void SetProgressValue( long Value );
```

The 'SetProgressRange' function is the means by which the application informs the derived logging class of the maximum value it might pass to the 'SetProgressValue' function. As an example, we might specify a value to the 'SetProgressRange' function of 900. With this value as a maximum, when we then pass a value of 450 to the 'SetProgressValue' function, the logging class would interpret this value to mean '50%' (i.e. 450/900 = 0.5 * 100 = 50).

```
void UpdateProgress( long Amount = 1 );
```

The 'UpdateProgress' function is the means by which the application has the logging class print the current progress percentage value to the current logging channel. Optionally, this function can be passed

a value used to increment the progress value as if it was passed in to the 'SetProgressValue' function. As an example, we might have set our maximum progress range to be equal to the number of polygons that we want to process. We might then call the UpdateProgress function, passing an amount value of '1', each time we processed another polygon. In this case the logging class would automatically output a value of '100%' at the moment we processed the final polygon and called 'UpdateProgess' for the final time.

```
void ProgressSuccess( unsigned long Channel );
void ProgressFailure( unsigned long Channel );
```

These two functions are utility functions that can be called to have a success or failure message output to the specified channel in a format decided by the derived logging class developer. This might also allow the logging class to take further action when a success or failure occurred such as sending an e-mail to a technician should any process fail.

We will not go into any further detail about how we have implemented the derived console output class in this workbook. If you would like to take a look at the source for this class you can do so in the 'LogOutput.cpp' file in the 'Application Source' project directory.

With these general application concepts out of the way, lets move straight on to the application entry point function.

WinMain

Although we are constructing a console *like* application in this lab project, we have used a standard Win32 project to enable us to gain access to all of the benefits provided by such an application. This includes the ability to create and use the Windows™ common dialogs such as the standard 'Open' and 'Save' dialogs. In addition to supporting common Win32 API functionality, building an application of this type allows for future Win32-centric enhancements an example of which might be the inclusion of an additional window in order to preview the compiled scene perhaps.

Because we are developing our front end as a Win32 application, our entry point is defined using the standard 'WinMain' function, as opposed to the 'main' function we would use if we were creating a native console application. You should already be familiar with the WinMain entry point function at this stage, so we will not go into any further detail about the parameters or their intended use.

```
int WINAPI WinMain( HINSTANCE hInstance, HINSTANCE hPrevInstance, LPTSTR lpCmdLine,
                    int iCmdShow )
{
    OPENFILENAME  File;
    TCHAR         FileName[MAX_PATH];
    CLogOutput    LogOutput;
    CCompiler     Compiler;
    bool          bSuccess;
    ULONG         i;
```

Notice in the above code that we have defined several local variables for use within this function. By far the most important of these is the 'Compiler' variable of the type 'CCompiler'. This class is the one that

provides our application with its entire scene processing ability. We will be discussing this class in the next section of this chapter, but for now let us examine how the application might make use of the functionality exposed by this compiler class.

Due to the fact that this is not a native console application, the very first thing that our application must do is to open a console window that will serve as the channel through which the user is informed about the progress and status of each of the compiler tasks to be executed. This is achieved via a call to the Win32 'AllocConsole' function. This function will create the console window for use by our application but will *not* redirect the standard output to this window automatically. Functions and template classes such as 'printf' and 'cout' are designed to output string data through the 'stdout' data stream also know as the standard output stream or channel. In a native console application this data stream is automatically attached to the console that is implicitly created when the application begins. This would result in any string data passed to a call to 'printf' being output to the console window as we would expect. In a Win32 application however, this is obviously not the case because no console window exists without our explicit instruction. Therefore, we must also perform this operation ourselves by attaching the 'stdout' stream to the newly created console window once it has been created.

In C++, the standard output stream is defined by a global variable most easily accessed using the name 'stdout'. This is actually a variable of the type 'FILE' which is a structure provided by the standard C runtime library in the 'stdio.h' header file. You should already be familiar with this structure because a pointer of this type is returned and passed to functions we have used extensively in the past such as 'fopen' and 'fread'. Despite the name of this structure, the 'FILE' type can apply to any sort of data stream be that a literal file, or other data buffers such as that maintained by a simple console window. So, given the fact that 'printf' writes the string data out to the 'stdout' *file* we can take advantage of this fact by making a call to the 'freopen' function that allows us to redirect the output of an already existing data stream – such as 'stdout' – to a new destination. This function works in a similar fashion to the 'fopen' function in that it accepts a filename and a mode used to describe how the stream should be accessed. However, it also accepts a pointer to an existing 'FILE' object that we would like to redirect.

Obviously we do not want to save the data written to the standard output stream to a file and yet the first parameter of this function is expecting a filename. So how exactly does this function help us place the output of calls such as 'printf' to a console window? We can in fact utilize a feature of the underlying operating system to enable us to output string data to the console by specifying a string of "CONOUT$" to the path parameter of this function. This is essentially a special path name that is reserved for just this type of situation. In fact, we can use this path name with many of the file handling functions in order to access and output data to and from the console window. In order to integrate the standard output functions with the console window we must also pass "a" (or append) to the mode parameter, and finally the 'stdout' stream pointer variable to the final parameter.

With the 'stdout' *file* stream now redirected to the new console window, we should find that any function or library designed to write information to the standard output stream will now seamlessly output to our application's console window.

```
    // Create a console window so that we can use it as our logging output
    AllocConsole();

    // Redirect all standard output to console (i.e. printf, cout etc).
```

```
    freopen("CONOUT$", "a", stdout);
```

Now that the main window into our application has been created and attached, we can now begin to output logging and progress information to the user. The following code first initializes the instance to our custom 'CLogOutput' class by calling the 'Create' function. We pass the total number of channels that we would like it to maintain to this function. We use an arbitrary figure of 20 in this code to ensure that there are enough to be going on with.

Once we have initialized the logging class, we then output the leading messages for this application such as its name, version and copyright information. Refer back to our discussion of the base interface 'LogWrite' function in order to understand the meanings of the specified parameters.

Finally, we pass a pointer to the instance of our console logging CLogOutput class into the compiler. This will then be distributed throughout the system to allow the various components to output progress and status information to the user.

```
    // Create the log output handler and attach it to the compiler
    LogOutput.Create( 20 );
    LogOutput.LogWrite( LOG_GENERAL, 0, false,
                        _T("\nSolid Leaf BSP Tree Compiler v1.0.0\n"));
    LogOutput.LogWrite( LOG_GENERAL, 0, false,
                        _T("Copyright © 2005 GameInstitute.com.")
                        _T("All Rights Reserved.\n"));
    LogOutput.LogWrite( LOG_GENERAL, 0, true,
                        _T("Compiler startup successful, awaiting user input."));
    Compiler.SetLogger( &LogOutput );
```

The only piece of information that we need from the user in this application is the filename of the IWF file that they wish to be imported and passed through the various compilation procedures. In this application, rather than using a potentially cumbersome command line parameter scheme, this is achieved by using the Win32 'GetOpenFileName' function and associated structures that have been used and discussed in previous lessons. If the user selected a valid file then the 'GetOpenFileName' function will return a value of true, after storing the selected path and filename information in the variable specified through the 'lpstrFile' member of the 'OPENFILENAME' structure passed to this function. In our implementation this would be the local string variable named 'FileName'. If the user chose to cancel the open dialog, or some other failure occurred, then this function will return false and our application will exit.

```
    // Fill out our default file dialog structure
    ZeroMemory( &File, sizeof(OPENFILENAME) );
    ZeroMemory( FileName, MAX_PATH * sizeof(TCHAR));
    File.lStructSize  = sizeof(OPENFILENAME);
    File.hwndOwner    = NULL;
    File.nFilterIndex = 1;
    File.lpstrTitle   = _T("Select Input IWF File for Compilation.");
    File.Flags        = OFN_EXPLORER | OFN_HIDEREADONLY | OFN_FILEMUSTEXIST |
                        OFN_NOCHANGEDIR | OFN_PATHMUSTEXIST;
    File.lpstrFile    = FileName;
    File.nMaxFile     = MAX_PATH - 1;
```

```
    File.lpstrFilter  = _T("All Supported Formats\0")
                        _T("*.IWF;*.BWF\0")
                        _T("Interchangable World Format (*.iwf)\0")
                        _T("*.IWF\0");

    // Retrieve a filename.
    if ( !GetOpenFileName( &File ) ) return 0;
```

Once the user has selected the file that they would like to be processed, the application can then inform the compiler class of the user's selection via a call to the 'SetFile' function and begin the compilation process with a call to 'CompileScene'. It is important that we store the return value from the latter of these two functions because it will be used later to determine if the compilation process was successful or not.

```
    // Inform the compiler about the file to compile
    Compiler.SetFile( FileName );

    // Compile the scene
    bSuccess = Compiler.CompileScene();
```

In this application, these two lines of code constitute the majority of the application's interaction with the core of our compiler. Although it is possible to play a much more active role in deciding which processes the user would like to perform on the scene geometry, in addition to setting several available options for each processor module, we will use the default settings in this application. These default settings specify that every available compiler task should be enabled and executed using sensible process parameters. We will see the means by which we can construct and specify these options in the next section when we cover the actual compiler classes shortly.

With the compilation process completed, our application then proceeds to clear the console window using one of the handy member functions exposed by our console logging class – 'ClearConsole' -- and then requests that all of the logged process information for each channel is output to the console as a last step. This is achieved via a call to the 'CLogOutput::SwitchChannel' channel function. This allows the user to see the final results of each task undertaken by the compiler. If a failure was encountered, the user will be able to identify the step at which this failure occurred and potentially remedy that situation.

```
    // Clear the console window and output all of the status text one last time
    LogOutput.ClearConsole();
    for ( i = 0; i < 20; ++i )
    {
        // Was there any text in this channel?
        if (LogOutput.GetChannelText( i ) != NULL)
        {
            // Print the channel information out
            LogOutput.SwitchChannel( i, false );
            printf( _T("\n\n-------------------------------------------\n" );

        } // End if anything in channel

    } // Next Channel
```

If the compilation process was a complete success then the return code we previously stored in the local Boolean variable ‘bSuccess’ will contain a value of true at this stage. If this is found to be the case then we can instruct the compiler to save the resulting data to a new file as specified by the user. The next task therefore is to request that the user input a location and filename into which the compiled scene information will be exported.

Because we had previously initialized the ‘OPENFILENAME’ structure that was passed into the earlier call to the Win32 open dialog function, we need only alter those structure variables that must change in order to display the common *save* dialog with a call to the Win32 ‘GetSaveFileName’ function. If the user selected a valid output path and file name within this dialog, then the ‘GetSaveFileName’ function will return true, after having copied the selected file and path name into the local variable ‘FileName’ as before. This file name string can then be passed into the compiler object’s ‘SaveScene’ method in order to have the newly compiled scene data exported to that location.

If the compiler failed for any reason, or the user chose to cancel the save dialog, then the scene export request will be bypassed altogether as we move onto the closing stages of this function and our application front end.

```
    // Save the scene if it compiled succesfully
    if ( bSuccess )
    {
        // Alter structure for any changed options
        File.nFilterIndex = 1;
        File.lpstrTitle   = _T("Select Output BWF File.");
        File.lpstrFilter  = _T("BSP Compiled IWF (*.bwf)\0*.BWF\0");
        ZeroMemory( FileName, MAX_PATH * sizeof(TCHAR));

        // Retrieve a filename.
        if ( GetSaveFileName( &File ) )
        {
            // Save the scene
            Compiler.SaveScene( FileName );

        } // End if Selected File
        else
        {
            // Output information
            printf( "User chose to cancel save operation." );

        } // End if no file

    } // End if success
```

One of the downsides of running a console application in a windows environment is that as soon as the application exits, the console window is automatically closed and destroyed. It is often the case however, that the application may have output several pieces of important information to the console that the user may not see if the window were to close as soon as the process was complete. For this reason we include a call to the runtime ‘_getch’ console function which is designed to retrieve character input from the keyboard in a synchronous fashion. This means that the ‘_getch’ function will cause our application to wait until a key has been pressed before program control is returned and the remainder of

the code is executed. When combined with a standard 'Press any key' message, this will allow the user to examine any messages output to the console window at their leisure.

```
    // Hold application until user presses key
    printf( "\n\nPress any key to exit..." );
    _getch();
```

The final piece of code within this function simply releases the console window that we allocated earlier, and returns from the WinMain function with an exit code of 0. This will signal the end of the application's lifetime and will then exit.

```
    // Clean up console
    FreeConsole();

    // Return
    return 0;
}
```

With our application front end fully implemented, let us now focus on the inner workings of our pre-processing application by examining the core compiler classes.

The Compiler Core – CCompiler.cpp

The core of the compiler tool we are developing in this lesson is centered on the 'CCollision' class found in the 'CCompiler.cpp' source file. This class is the primary wrapper around the various tasks that our pre-processing compiler tool must undertake. Rather than require that the application be heavily involved in the compilation process, this class provides a simple interface through which much of the common functionality required by the pre-processing tool can be executed without any further involvement by the application. This common functionality includes:

1) Loading all of the required scene information from file. This information will include the scene data that is to be passed into the various compiler processes, as well as the scene data that must be exported back out to the resulting file.

2) Setting the options for each compiler task that has been selected for execution by the application.

3) Performing any high level logic for setting up the data required as input into each compilation process, and also to interpret any pieces of resulting information that may need to be merged back into the scene data set managed by the compiler class.

4) Managing and executing any compiler process modules that have been enabled by the application.

5) Writing the compiled information back out to a new file.

We have made several references in the past to individual compiler modules. Recall that one of the development goals of this tool was to create a modular core that could be easily extended to include

additional pre-processing tasks in the future. With this design concept in mind, each of the individual compilation / processing tasks that we will be implementing in this tool are separated into individual classes that are each responsible for performing only a smaller portion of the overall scene compile process. The following list outlines some of the modular processing classes that we will encounter. The first three in this list are covered in this lesson, and the final two will be covered in the next.

CProcessHSR
This procedure in effect pre-processes our scene geometry and removes any 'Illegal Geometry' ready for processing by the BSP compiler. These fragments of illegal geometry are described as ‘hidden surfaces’ due to the fact that any surfaces – or fragments of surfaces – that intersect the solid area of another part of the scene cannot usually be seen due to depth-based pixel culling. These fragments are potentially destructive and often cause complete failure when attempting to generate solid and empty leaf information within the BSP compiler. For this reason, these illegal polygon fragments must be removed.

This process works at the mesh level, meaning the scene data must be in its primitive form on import. Once processing is complete, all illegal geometry should have been removed, and the mesh data merged into a single set of polygons ready for BSP compilation.

CBSPTree
The leaf-based BSP compile process is used, among other things, for partitioning the scene (along each polygons plane) and collecting a series of convex polygon clumps, or leaves, that make up the scene. These 'nodes' and 'leaves' are then utilised by many procedures we may wish to perform on our scene database, such as portal and PVS compilation, constructive solid geometry (including HSR) and much more. The tree itself can then also be used at runtime for many operations such as collision detection and line of sight.

CProcessTJR
T-Junctions are often (not exclusively) the result of a surface being split, while its neighbour remains intact. This has the effect of splitting the edge of one surface, adding at least one vertex, while the edge of the adjacent polygon remains in tact. The problem with this situation is that it often results in artifacts during rasterization due to the differing amounts of floating point errors that occur while traversing each of these edges. These artifacts are often called 'Sparklies' or 'Sub-Pixel Gaps' where certain pixels along those edges are not rendered. This allows whatever color pixels may have been rendered behind to show through. This is not the only problem caused by T-Junctions however. Because the vertices of these two surfaces no longer link exactly, moving the centre vertex along one edge will not adjust the adjacent edge in the same manner. This process locates such problematic edges, and attempts to repair the problem by inserting a vertex on the adjacent edge.

CProcessPRT
In order to calculate the visibility between our scene's leaves, we need to determine the shape and location of the gaps that exist between them. Once we have this information, we can then proceed to use it in order to determine what is visible through the gaps these portal polygons now occupy.

Essentially this procedure feeds extremely large initial surfaces through the tree at each node, clipping it to every other subsequent node, as it traverses the tree. This process continues until the fragments of such surfaces reach an empty leaf. These remaining fragments, assuming they pass final validation,

accurately describe these gaps and become portals between our scene's leaves ready for visibility processing among other things. **Note: This process is not discussed until the next lesson.**

CProcessPVS
The PVS compilation procedure ultimately determines the 'potential' visibility between the leaves within our scene. For every leaf contained within the BSP tree, this process will determine which other leaves in the scene are visible from any position within that particular leaf. This is an extremely intensive process and can take several orders of magnitude longer to complete than every other compile process combined. **Note: This process is not discussed until the next lesson.**

The CCompiler Class

In this lab project we will only need one instance of a 'CCompiler' object that will be created and managed by the application front end discussed in the previous section. Although this application will only ever use one instance of this type, the compiler class has been designed to provide an independent, standalone interface that allows the application to easily manage multiple compiler class instances. This would allow the application to use multi-threading in order to maintain more than one compiler process that can be run concurrently – compiling multiple levels at any one time – or to simply allow the compiler to run in the background whilst the user carries on working with the tool / application into which the compiler core has been integrated.

Before we move on to the implementation of the compiler class functionality, let us begin by examining the declaration for the main compiler class. We have removed the list of member functions to improve readability, so check the source code for a full list of methods. All we are interested in at the moment are the member variables and structures declared within the class scope.

```
class CCompiler
{
public:

    // Constructors & Destructors for This Class.
             CCompiler();
    virtual ~CCompiler();

    // Public Variables for This Class.
    vectorMesh      m_vpMeshList;       // A list of all meshes loaded.
    vectorTexture   m_vpTextureList;    // A list of all textures loaded.
    vectorMaterial  m_vpMaterialList;   // A list of all materials loaded.
    vectorEntity    m_vpEntityList;     // A list of all entities loaded.
    vectorShader    m_vpShaderList;     // A list of all shaders loaded.

    // Public Member Functions Omitted

private:

    // Private Variables for This Class.
    HSROPTIONS      m_OptionsHSR;       // Hidden Surface Removal Options
    BSPOPTIONS      m_OptionsBSP;       // BSP Compilation Options
    TJROPTIONS      m_OptionsTJR;       // T-Junction Repair Options
```

```
    ILogger         *m_pLogger;          // Interface used to log progress etc.
    LPTSTR           m_strFileName;      // The file used for compilation
    COMPILESTATUS    m_Status;           // The current status of the compile run
    ULONG            m_CurrentLog;       // Current logging channel for messages.

    CBSPTree        *m_pBSPTree;         // Our compiled BSP Tree.

    // Private Member Functions Omitted

};
```

There are several important member variables declared within this class that we must first examine, so let us briefly discuss each of them.

vectorMesh m_vpMeshList
This member variable will be used to store a list of all of the meshes loaded from the source IWF scene file. It is of type 'vectorMesh', which is a typedef for an STL vector of 'CMesh' pointers.

```
typedef std::vector<CMesh*>       vectorMesh;
```

This STL vector is populated by the IWF loading code covered later in this lesson. Each mesh object stored within this array will potentially be processed by the compiler as each compilation module is executed.

vectorTexture m_vpTextureList
vectorMaterial m_vpMaterialList
vectorEntity m_vpEntityList
vectorShader m_vpShaderList
These four member variables serve as the means by which our compiler stores the static scene information that will not be processed by the compiler portion of the application. Instead this information is only maintained in order for it to be exported back out to the destination file once the scene has been processed. The type of each of these member variables is a typedef of one of the STL vector items outlined in the following list.

```
typedef std::vector<iwfTexture*>  vectorTexture;
typedef std::vector<iwfMaterial*> vectorMaterial;
typedef std::vector<iwfEntity*>   vectorEntity;
typedef std::vector<iwfShader*>   vectorShader;
```

Due to the fact that we are simply maintaining this information so that the final scene can be exported correctly, each of these STL vector items is simply designed to store pointers to each type of storage class provided directly by the IWF import library. As with the mesh information, these STL vectors are populated by the IWF loading code covered later in this lesson.

HSROPTIONS m_OptionsHSR
Each compiler module in this application has its own unique options structure that can be used by the application to alter the way in which each module performs its task – if it is to be executed at all. These structures can be found in the 'CompilerTypes.h' header file in the 'Compiler Source' project directory.

Although we do not alter these option values from their default state in this lab project, an application can access and modify the information stored in these options structure members by calling the appropriate 'GetOptions' or 'SetOptions' functions defined by the 'CCompiler' class.

This member variable contains those options available to the application for the hidden surface removal process implemented within this lab project.

```
typedef struct _HSROPTIONS
{
    bool Enabled;

} HSROPTIONS;
```

We can see that the 'HSROPTIONS' structure contains only a single Boolean variable named 'Enabled'. This variable can be used by the application to specify whether or not the scene data should be passed through the hidden surface removal process. By placing a value of 'true' into this variable we are instructing the compiler that we would like to enable the HSR process in order to ensure that all of the meshes are unioned together into a single valid mesh ready for BSP compilation.

BSPOPTIONS m_OptionsBSP

In a similar fashion to the hidden surface removal module, there are also a set of options available that allow us to alter how the binary space partitioning module will compile the final BSP leaf tree. This member variable stores these BSP module options and is declared with the type 'BSPOPTIONS'. This structure is outlined below.

```
typedef struct _BSPOPTIONS
{
    bool            Enabled;
    unsigned long   TreeType;
    float           SplitHeuristic;
    unsigned long   SplitterSample;
    bool            RemoveBackLeaves;
} BSPOPTIONS;
```

In addition to the 'Enabled' flag – used to instruct the compiler as to whether or not this process should be performed – the 'BSPOPTIONS' structure defines several options that dictate how the final scene BSP tree will be compiled. The purpose of each of these option values are detailed in the following list.

- *TreeType*
  In the previous spatial hierarchy compilation classes that we have implemented, we exposed the ability to compile a tree that did not split the polygon data against the separating planes as the tree was being constructed. While compiling the tree without splitting polygon data was not suitable for the hardware rendering techniques we constructed to handle the tree data, there were many non-rendering situations in which storing unsplit polygon data in the leaves of the tree may have been beneficial to us.

  If you have read the textbook for this chapter, you should know that splitting the polygon data during the compilation of a polygon aligned BSP leaf tree is critical and cannot be avoided. This

is due to the fact that the splitting of the source polygon data is a key aspect of how the BSP tree forms its convex leaf areas in addition to providing valid solid and empty leaf information. Although the splitting of polygons cannot be avoided during the compilation of the BSP tree itself, it is possible to adapt the way that polygon data is stored in the leaves in order to achieve a similar effect. We will not go into detail about how this process works at this point and we will defer this discussion until the coverage of our new BSP tree compilation class. Just know for now that the BSP tree compiler will have the ability to generate a tree which can store unsplit polygon information.

This option variable is intended therefore to instruct the BSP compiler as to whether or not it should generate the final scene tree using this non-split concept. This tree type variable should be set to one of the two defined constants shown below.

```
#define BSP_TYPE_NONSPLIT   0
#define BSP_TYPE_SPLIT      1
```

The first of these two constants instructs the compiler to generate a tree that stores unsplit polygon data, and the second will cause the BSP tree to be generated using the more traditional split polygon approach.

Note: If the BSP tree is intended for use by a rendering engine, then it is recommended that you select the 'BSP_TYPE_SPLIT' option. Because the non-split solution will result in certain polygons ending up in multiple leaves, selecting the traditional splitting option will prevent duplicate polygons from being rendered when using a static vertex / index buffer solution.

- *SplitHeuristic*
  This variable defines the splitting heuristic value that will be passed into the BSP compiler's 'SelectBestSplitter' function. We have already discussed the purpose of this value in detail earlier in this lesson, but to summarise this value allows us to specify the importance of building a balanced BSP tree versus reducing the number of polygons which get split during the compilation process. A good default value to specify for this heuristic variable is one of around 3.0 although you should experiment with this in order to get the best results for the specific requirements of your application.

- *SplitterSample*
  In addition to the SplitHeuristic parameter, the 'SelectBestSplitter' function also accepts a SplitterSample value which can be specified by the application through this option structure member. Recall that this concept allows us to specify the maximum number of potential polygons that will be considered for use as a separating plane by this function. This is simply an early out mechanism that allows us to select a polygon from the first 'n' polygons in the list passed to the selection function rather than testing the entire set. By reducing the number of potential splitters tested during this select step we can greatly reduce the time it takes to compile the polygon aligned BSP tree. This can be useful during the development of our application in which we might only want to build the tree quickly for testing purposes. This member can be set to 0 however when we are compiling a *release* version of the level, in order to have the 'SelectBestSplitter' function test every polygon in the specified polygon list.

- *RemoveBackLeaves*
  When compiling a polygon aligned BSP leaf tree, we have the added advantage of being able to determine the solid and empty areas within the compiled scene. As you should know if you have already been through the textbook for this chapter, the integrity of this solid information is entirely dependant on the validity of the geometry being used. If the scene geometry has been created in a manner compatible with the solid BSP leaf tree, then we should find than no polygons end up behind any terminal node within the tree structure. There are situations in which this is not the case however, even when the input geometry is valid. Due to the inherent inaccuracy of single precision floating point values on today's processors, the possibility still exists that there will be slight errors within either the source polygon data, or those polygons generated during the BSP compilation process. These small, potentially accumulating errors could lead to a situation in which a small fragment of a polygon ends up behind a terminal node that would traditionally be considered solid space.

  This flag allows the application to specify whether or not it would like the BSP compiler to enforce the removal of any polygon fragments which end up behind a node where solid space should exist. Whilst this technique does resolve many situations in which erroneous polygon fragments might fall into solid space, it should not be considered to be a replacement for hidden surface removal.

  Of course, if your application is not interested in maintaining this solid and empty space information, then it is possible to set this variable to a value of 'false'. In this case, a leaf will be generated behind those terminal nodes in which any polygons are found to exist. This is done in a manner similar to that when creating a leaf that will be attached to the front of a node.

  Again, we will look at how this process is implemented later in this chapter during the coverage of our new BSP tree compiler class.

As with each of these compiler option member variables, the 'm_OptionsBSP' member can be retrieved and altered by the application via the 'GetOptions' and 'SetOptions' compiler functions.

TJROPTIONS m_OptionsTJR

The final member variable used to store the options for an individual compiler process is the 'm_OptionsTJR' variable. This variable is of the type 'TJROPTIONS' which describes any settings available to the application for the T-junction repair compiler module. Similar to the 'HSROPTIONS' structure, this contains only a single Boolean variable that instructs the compiler as to whether or not the T-junction repair process should be enabled. In the interest of completeness, this structure is shown below.

```
typedef struct _TJROPTIONS
{
    bool Enabled;

} TJROPTIONS;
```

ILogger * m_pLogger

Earlier we discussed how the compiler portion of the application integrates itself with the front end interface using a base class named 'ILogger'. This interface is used throughout the various compiler modules in order to report any progress, success or failure information to the user. Recall that the 'ILogger' interface is a pure abstract base class that cannot be instantiated in its own right. This forces the application to derive a class from this base interface in which the code required to display the compiler's status information to the user is implemented. In order to maintain the independence of the compiler core from the application front end, this member variable stores a pointer to an instance of the applications log output object using the type 'ILogger' rather than a pointer to any application specific class. This variable should be set by the application with a call to the 'CCompiler::SetLogger' method, passing a pointer to its own logging class instance.

LPTSTR m_strFileName

This member variable stores a string that specifies the path and file name of the IWF file to be imported and processed. This variable is populated by the application using a call to the 'SetFile' method of the compiler class. This variable should be set *before* the compilation process is triggered as this string is read by the compiler when importing the scene geometry that will be subsequently passed through each processing module.

COMPILESTATUS m_Status

Earlier in this section we discussed how the compiler class was designed to function in a multi-threaded environment as either a single background process, or to run concurrently with other compilation tasks. In order to afford the application some control over the execution of each compilation process, this class exposes the ability to both query and modify the running state of the object in order to pause, resume or cancel the currently executing operation. We will discuss how the application can manipulate the state of the compiler shortly.

The 'm_Status' variable stores the current state of this compiler object and can be retrieved by the application with a call to the 'GetCompilerStatus' method of this class. This may contain any one of the four values declared in the following enumerator listing.

```
enum COMPILESTATUS
{
    CS_IDLE         = 0,
    CS_INPROGRESS   = 1,
    CS_PAUSED       = 2,
    CS_CANCELLED    = 3
};
```

Although the meaning of each status item should be relatively obvious given its name, let us just briefly examine these values and the situations in which they may be returned.

- *CS_IDLE*
  This enumerator item specifies that the compiler is currently in an idle state. This means that no compilation process is currently executing. A value of CS_IDLE will only be returned in those cases both before and after the 'CompileScene' function has been executed in order to run the compilation process.

- *CS_INPROGRESS*
  This item specifies that the compiler object is currently in the process of compiling the scene data. As soon as the application calls the 'CompileScene' function, the 'm_Status' variable will be assigned this value to signify that it has begin the operation. If this value is returned, it also means that the compiler is not currently in a paused state and has also not been cancelled by the user.

- *CS_PAUSED*
  As mentioned, the application is able to put the compiler object into a paused state that will temporarily halt any currently executing compilation task. This process can be resumed once again at a later stage should the application choose to do so. We will discuss the method by which this is achieved shortly.

- *CS_CANCELLED*
  In addition to pausing the compilation process, the application also has the ability to cancel the operation all together. Once this cancel request has been received, the 'm_Status' variable will be updated to contain this value. This informs both the various compilation modules, in addition to the application, that the task is currently in the process of being cancelled. As soon as the executing compiler module has been able to gracefully clean up and exit, the status variable will once again be assigned a value of 'CS_IDLE'. During the time in which the status variable contains the 'CS_CANCELLED' value, the application should wait for the compiler to finish before taking any further action with this compiler object.

ULONG m_CurrentLog
This member variable is maintained in order to store the log channel index for the compilation module that is currently executing. When the application's running state is altered, such as having been paused or cancelled, this variable is used to allow the compiler object to output a notification to the log channel for the current task.

CBSPTree * m_pBSPTree
The primary goal of our pre-processing tool is to build a polygon aligned BSP leaf tree based on the information imported from the IWF file specified by the application. Should the application have enabled the BSP compilation process, this member variable will store a pointer to the 'CBSPTree' object that has been compiled from this scene data.

Let us now discuss the functions to the CCompiler class that we have not yet seen. We will start by looking at the initialization functions – such as the constructor, and the member variable accessor functions. We will then examine the methods charged with importing and processing the level data.

CCompiler::CCompiler()

We begin our coverage of the 'CCompiler' methods with the class constructor. This is the function in which each of the compiler class member variables and structures are initialized with a sensible set of default values. In lab project 16.2, the front end interface does not require that the user specify any of the compilation options we discussed earlier. As a result, the compiler and each compilation process will use those default settings specified by this function.

```
CCompiler::CCompiler()
{
    // Set up default HSR options
    m_OptionsHSR.Enabled            = true;

    // Set up default BSP options
    m_OptionsBSP.Enabled            = true;
    m_OptionsBSP.TreeType           = BSP_TYPE_SPLIT;
    m_OptionsBSP.SplitHeuristic     = 3.0f;
    m_OptionsBSP.SplitterSample     = 60;
    m_OptionsBSP.RemoveBackLeaves   = true;

    // Set up default TJR Options
    m_OptionsTJR.Enabled            = true;

    // Reset Vars
    m_strFileName = NULL;
    m_pBSPTree    = NULL;
    m_pLogger     = NULL;
    m_Status      = CS_IDLE;

}
```

We begin by enabling both the hidden surface removal processor and BSP compilation modules. In addition to enabling the latter of these two processes, we also specify the default values for the remainder of the BSP compiler settings.

In this tool, we are intending for the exported data to be loaded by a rendering application. Bearing in mind our previous discussion of the non-split BSP tree option, we first specify that we would like to compile a standard tree in which the traditional *split* polygon fragments are stored within its leaves. Next we specify a reasonable split heuristic value of 3.0 and a maximum splitter sample count of 60 to ensure that the BSP compilation is relatively quick and efficient. Finally we enable the removal of any polygon fragments that end up in what should be solid space during the BSP compilation process, by setting the 'm_OptionsBSP.RemoveBackLeaves' variable to true.

We finish initializing the compiler process options variables by finally enabling the T-junction repair process. This module has no further options.

The final part of the constructor is responsible for setting the remaining member variables to their initial states. This includes setting any pointer variables to NULL to ensure that we do not attempt to access an invalid memory location at some future point, as well as setting our compiler's current status variable to that of an idle state.

CCompiler::SetFile

This function is called in order to inform the compiler of the path and filename to the IWF formatted scene file that will be compiled. As we observed in our coverage of the application front end, the 'SetFile' function should be called by the application prior to beginning the actual process of compiling the scene data.

In this function we begin by releasing any string data found to already exist within the 'm_strFileName' variable. This prevents any previously allocated memory from being leaked when we overwrite the pointer value stored in this member in the next step – which is to duplicate the file name string passed as the single parameter to this function. This duplication is achieved by calling the '_tcsdup' function which returns a pointer to a newly allocated copy of the specified string.

```
void CCompiler::SetFile( LPCTSTR FileName )
{
    // Release any old filename
    if ( m_strFileName ) free( m_strFileName );
    m_strFileName = NULL;

    // Duplicate the filename
    m_strFileName = _tcsdup( FileName );

}
```

> **Note:** Remember that when releasing any memory allocated through a call to this string duplication routine, we must use the 'free' function rather than using the more common 'delete' method.

Once we have a copy of this file name string, the compiler will be able to read the contents of the 'm_strFileName' member variable at a later stage in order to determine which file to import. We duplicate this character string, rather than simply storing the specified pointer, because we are unable to guarantee that the string passed to the 'FileName' parameter will not go out of scope and be released before the compiler has had a chance to import the file.

CCompiler::SetOptions / GetOptions

As we know, each compilation processing module in this application has its own unique options structure that can be specified by the application in order to alter the way in which each module performs its task. The two public 'SetOptions' and 'GetOptions' methods are the means by which the application can access and set the options structures for each process module available within the compiler. The first of these two functions – 'SetOptions' – accepts two parameters. The first of these parameters accepts a constant value that specifies the compiler process for which the calling function would like to set the options. The available constant values that can be passed into this parameter are found in the 'Common.h' header file and are shown below:

```
#define PROCESS_HSR         0   // Hidden Surface Removal
#define PROCESS_BSP         2   // Binary Space Partition
#define PROCESS_PRT         3   // Portals
#define PROCESS_PVS         4   // Potential Visibility Set
#define PROCESS_TJR         5   // T-Junction Repair
```

As you can see, there are six constant values defined in this list that match up with each of the processor modules described earlier in this section. Only three of these modules are applicable to this lab project however – 'PROCESS_HSR' for hidden surface removal, 'PROCESS_BSP' for BSP compilation and 'PROCESS_TJR' for the T-junction repair process. The remaining two process modules will be discussed and implemented in the next lesson. This demonstrates however, that each process has a

unique index value that can be used to identify a particular compiler module when interacting with the compiler interface through functions such as those outlined here.

The second parameter declared by this method is a void pointer named ‘Options’, into which the calling function should pass a pointer to the options structure it would like to set. This structure should be of a type applicable to the process specified by the ‘Process’ parameter because this information will be used to cast the void pointer to the correct structure type before assigning that cast structure to the appropriate compiler member variable.

```
void CCompiler::SetOptions( UINT Process, const LPVOID Options )
{
    switch (Process)
    {
        case PROCESS_HSR:
            m_OptionsHSR = *((HSROPTIONS*)Options);
            break;

        case PROCESS_BSP:
            m_OptionsBSP = *((BSPOPTIONS*)Options);
            break;

        case PROCESS_TJR:
            m_OptionsTJR = *((TJROPTIONS*)Options);
            break;

    } // End Switch
}
```

The ‘GetOptions’ method functions in a similar manner to that of the ‘SetOptions’ method. This function accepts the same two parameters. The only difference between these two functions is that the ‘Options’ parameter is now used to pass information back *out* to the calling function, rather than to receive it. Similar restrictions apply to the type of the structure passed to the ‘Options’ parameter. This should match the appropriate options structure type for the specific module passed to the ‘Process’ parameter as before. In the following code block you can see how the void pointer specified by the ‘Options’ parameter is cast to the appropriate type – based on the value contained in the ‘Process’ function parameter – and the data contained within the relevant class member variable is copied into that structure owned by the calling function.

```
void CCompiler::GetOptions( UINT Process, LPVOID Options ) const
{
    switch (Process)
    {
        case PROCESS_HSR:
            *((HSROPTIONS*)Options) = m_OptionsHSR;
            break;

        case PROCESS_BSP:
            *((BSPOPTIONS*)Options) = m_OptionsBSP;
            break;

        case PROCESS_TJR:
            *((TJROPTIONS*)Options) = m_OptionsTJR;
```

```
            break;

    } // End Switch
}
```

CCompiler::PauseCompiler / ResumeCompiler / StopCompiler

One of the features of the compiler core we are developing in lab project 16.2 is its additional support for use in a multi-threaded environment. During the earlier coverage of the 'm_Status' member variable declared by this class, we discussed the fact that the compiler class exposed the ability for the application to alter the state of the compiler object by pausing, resuming or cancelling the current operation. The three methods outlined here are the means by which the application can control this behavior.

The first of these is the 'PauseCompiler' method. In this function we begin by testing the current status of the compiler object. Due to the fact that the act of pausing the process implies that it is already running, we return immediately of the current status variable contains any value other than 'CS_INPROGRESS'. If this test passes, we then update the value of the 'm_Status' variable such that it now represents the paused state. The final task undertaken by this function is to notify the user of the update to the current compilation module's status. This is done by printing a 'Pausing…' message to the user with a call to the logging interface' 'LogWrite' method.

```
void CCompiler::PauseCompiler( )
{
    if ( m_Status != CS_INPROGRESS ) return;
    m_Status = CS_PAUSED;

    // Write Log Info
    if ( m_pLogger )
    {
        // Rewind and write 'pausing' message
        m_pLogger->Rewind( m_CurrentLog );
        m_pLogger->LogWrite( m_CurrentLog, LOGF_WARNING | LOGF_ITALIC, false,
                             _T("Pausing..."));

    } // End if Logger Available
}
```

One thing that should be clear about this function is that it does nothing more than essentially update the compiler's 'm_Status' member, followed by the output of a notification message to the user. At no stage however, does it actually pause any currently executing compilation process. This is due to the fact that each individual module is responsible for testing the current state of the compiler and taking any appropriate action based on that information. The majority of this is achieved through a call to one of the additional compiler functions named 'TestCompilerState' method that we shall be covering shortly.

The next status function available to the application is the 'ResumeCompiler' method. Applicable only if the compiler is currently in a paused state, this function updates the current status of the compiler object only if this is found to be the case. As with the 'PauseCompiler' function previously outlined, this function finally also prints an updated status message to the log channel of the currently executing

process. This function is not responsible for physically resuming the execution of the active compiler process. As before, this is the responsibility of each individual processing module and the 'TestCompilerState' method covered shortly.

```
void CCompiler::ResumeCompiler( )
{
    if ( m_Status != CS_PAUSED ) return;
    m_Status = CS_INPROGRESS;

    // Write Log Info
    if ( m_pLogger )
    {
        // Rewind and write 'resuming' message
        m_pLogger->Rewind( m_CurrentLog );
        m_pLogger->LogWrite( m_CurrentLog, LOGF_WARNING | LOGF_ITALIC, false,
                             _T("Please Wait..."));

    } // End if Logger Available
}
```

The final of the three status update functions is the 'StopCompiler' method. This can be called by the application in order to have the currently executing compiler process cancelled. As with each of the previous two methods, this function is only responsible for updating the 'm_Status' member variable and notifying the user of this updated status. In this case, a value of 'CS_CANCELLED' is used to update the status member only if the compiler process is not idle – e.g. is currently equal to CS_PAUSED or CS_INPROGRESS.

```
void CCompiler::StopCompiler( )
{
    if ( m_Status == CS_IDLE ) return;
    m_Status = CS_CANCELLED;

    // Write Log Info
    if ( m_pLogger )
    {
        // Rewind and write 'pausing' message
        m_pLogger->Rewind( m_CurrentLog );
        m_pLogger->LogWrite( m_CurrentLog, LOGF_WARNING | LOGF_ITALIC, false,
                             _T("Cancelling..."));

    } // End if Logger Available
}
```

With each of these three methods it is important to bear in mind that, while the compiler object's status variable is updated immediately, the currently executing compilation module may not be in a position to respond to this update until a much later point in time. In the interests of efficiency, each module implemented by this lab project will only test the state of the compiler at periodic intervals. This periodic testing can unfortunately lead to a slight delay in which the application must sometimes wait.

CCompiler::TestCompilerState

There are several calls to the 'TestCompilerState' method scattered throughout each of the compiler modules developed in both this lesson and the next. This function is called by the various compiler modules in order to respond to any compiler status change that may have occurred.

When this function is called by the compiler module, the first part of this function deals with the situation in which the compiler has been put into a paused state. As we can see in the following block of code; after informing the user that the compiler has been successfully placed into a paused state this function enters a while loop that will only exit following a call to 'ResumeCompiler' method that will return the 'm_Status' variable to a state of 'CS_INPROGRESS'. Inside this continuing loop, a call is made to the runtime 'sleep' function in order to have the compiler thread wait 500 milliseconds before testing the 'm_Status' member again. By calling the sleep function in this way, we prevent this compiler thread from consuming a great deal of the CPU resources available to our application.

```
bool CCompiler::TestCompilerState( )
{
    if ( m_Status == CS_PAUSED )
    {
        // Write Log Info
        if ( m_pLogger )
        {
            // Rewind and write 'pausing' message
            m_pLogger->Rewind( m_CurrentLog );
            m_pLogger->LogWrite( m_CurrentLog, LOGF_WARNING | LOGF_ITALIC, false,
                                 _T("Paused..."));

        } // End if Logger Available

        // Sleep the thread until compiler is resumed
        while (m_Status == CS_PAUSED) Sleep(500);

    } // End if Paused
```

Assuming the application had not been placed into a paused state, it is possible that the compile process had been cancelled. If this is found to be the case, a value of 'false' is returned to the compiler module making the call to this function in order to inform it of the fact that it should clean up and exit gracefully. In all other cases this function simply returns a value of true to denote that the compile process should continue to execute.

```
    // Should we cancel ?
    if ( m_Status == CS_CANCELLED ) return false;

    // Continue running.
    return true;
}
```

CCompiler::CompileScene

The 'CompileScene' function is the means by which the application can instruct the compiler to execute each of the various compilation modules that may have been enabled. This function should be called by the application only after having selected and informed the compiler of the file that is to be imported and

processed. If any customization of the various module options is required, these should also have been set prior to this function being called. This function accepts no parameters, and returns a single Boolean result that signifies whether the compilation process as a whole was successful or not.

Although not strictly necessary for this method to function correctly, the first task undertaken here is to retrieve the filename portion of the path string stored in the 'm_strFileName' member variable. With the path stripped from the import file string; this will be used only as part of the information output to the compile process log. This is achieved by searching for the *last* forward or backslash contained in the string and – if one exists – retrieving a pointer to the portion of the string which immediately follows that character.

> **Note:** In order to prevent any obfuscation of the logic contained within this and other class methods, much of the logging code has been omitted and replaced with a single line comment outlining the information that would be output to the log at that point. Refer to the source code in the lab project archive provided with this lesson if you wish to view the source files with all log output code included.

```
bool CCompiler::CompileScene( )
{
    CFileIWF IWFFile;

    // Validate Data
    if (!m_strFileName) return false;

    // Retrieve the filename portion only of the string
    LPTSTR FileName = NULL;
    FileName = _tcsrchr( m_strFileName, _T('\\') );
    if (!FileName) FileName = _tcsrchr( m_strFileName, _T('/') );
    if (!FileName) FileName = m_strFileName;
    if (FileName[0] == _T('\\') || FileName[0] == _T('/')) FileName++;
```

The first real job that the 'CompileScene' function must perform is to import the scene information from the IWF file specified by the application. In previous lab projects we have used the 'CFileIWF' class provided by the IWF import library to perform the file handling and data loading steps. Our pre-processing tool is no different in this regard. At the start of this function we have defined an object named 'IWFFile' which is of the type 'CFileIWF'. Although we are using a custom IWF loading class in this application rather than that provided by the libIWF library, the concepts are the same in both cases. As we have done many times in the past, we instruct the IWF loading object to import the data from the IWF file by calling the 'CFileIWF::Load' method, passing in the name and path of the scene data file to be imported as the single parameter input to this function.

```
    try
    {
        // We Are starting the process
        m_Status = CS_INPROGRESS;

        // Load the specified file
        IWFFile.Load( m_strFileName );
```

As has been the case with the 'CFileIWF' class used in each of our previous lab project applications, this class maintains a list of the individual pieces of information loaded from the file within internal STL

vector members. In our rendering applications, it has traditionally been the responsibility of the 'CScene' class to then iterate through these arrays and process each piece of information in an effort to build renderable data where applicable. However, our pre-processing tool is not required to perform any kind of rendering; we simply need to store this information such that we can gain easy access to the file information at any point in the future.

Because of the fact that the STL vector variables within the 'CFileIWF' class are defined with an identical type to those corresponding members contained within our compiler class, making a copy of this data is made extremely simple. As a result of this typed similarity, we can simply take ownership of the information stored in the 'CFileIWF' class instance by assigning the matching member variables in our compiler class to those STL vectors stored in the file object as demonstrated in the following code.

```
        // Obtain ownership of the objects loaded
        m_vpMeshList     = IWFFile.m_vpMeshList;
        m_vpMaterialList = IWFFile.m_vpMaterialList;
        m_vpTextureList  = IWFFile.m_vpTextureList;
        m_vpShaderList   = IWFFile.m_vpShaderList;
        m_vpEntityList   = IWFFile.m_vpEntityList;
```

At this stage we have made a copy of the data stored within the IWF file object into our compiler class's internal member arrays. However, recall that these STL vectors simply store pointers to heap allocated storage classes. This means that by making a simple shallow copy of the array from one class instance to the other, both sets of arrays will now contain elements that reference the same instance of each data object. If the IWFFile object was to go out of scope and be released at some point in the future, this would have the unfortunate side effect of releasing all of the objects now referenced by the compiler class too. To prevent this, we must clear the IWF object's STL vector members to ensure that the compiler object remains the only place in which these data items are referenced.

```
        // Clear out the IWF's object vectors (don't destroy)
        IWFFile.m_vpMeshList.clear();
        IWFFile.m_vpMaterialList.clear();
        IWFFile.m_vpTextureList.clear();
        IWFFile.m_vpShaderList.clear();
        IWFFile.m_vpEntityList.clear();

        // Log - General: 'FileName' was imported succesfully

    } // End try Block
```

Notice in the previous code how the file loading logic was wrapped in a try block that will attempt to catch any exceptions which may have been thrown by the 'CFileIWF::Load' function, or any of the subsequent STL vector operations. The following catch blocks are provided to ensure that all memory allocated to date by both the IWF object during the loading procedure, in addition to any memory allocated by the compiler class are fully released before we return a failure code from this function.

```
    catch (HRESULT & e)
    {
        // Log - General: Import of 'FileName' failed with error 'e'
```

```
        IWFFile.ClearObjects();
        Release();
        return false;

    } // End Catch Block
    catch (...)
    {
        // Log - General: Import of 'FileName' failed

        IWFFile.ClearObjects();
        Release();
        return false;

    } // End Catch Block
```

At this point in the execution of the 'CompileScene' function, we have imported all of the applicable scene data from the source IWF file and have stored that information within the internal STL vector members ready for processing.

We briefly touched upon the fact that the compiler class is responsible for preparing the input data for each process earlier in this section. Rather than have the 'CompileScene' function perform each of these process specific tasks, the code for the actual preparation and execution of each processing module has been placed in a series of functions named 'PerformHSR', 'PerformBSP' and 'PerformTJR'. We will examine these functions in detail shortly, but for now we need only be aware that when any one of these three functions is called, that particular compiler process will be executed from start to finish before returning control back to this 'CompileScene' function.

In the following code we can see that this is the point at which we begin to actually process the scene data, calling each of these three processing functions in order if they have been enabled by the application. In later lessons we will be adding additional compiler modules to the pre-processing tool. For each module that we add, a new separate 'Perform*' method will need to be developed and called from within this function in a similar fashion to those shown below. Once each of the enabled processing functions has been called, we simply exit from this function and return control back to the application having completed the entire compilation process.

```
    // Log - General: Beginning compile run

    // Start compiling by removing all hidden surfaces
    m_CurrentLog = LOG_HSR;
    if ( m_OptionsHSR.Enabled && m_Status != CS_CANCELLED) PerformHSR();

    // Build the BSP Tree if requested
    m_CurrentLog = LOG_BSP;
    if ( m_OptionsBSP.Enabled && m_Status != CS_CANCELLED) PerformBSP();

    // Repair any T-Juncs if requested
    m_CurrentLog = LOG_TJR;
    if ( m_OptionsTJR.Enabled && m_Status != CS_CANCELLED) PerformTJR();

    // Clean up if required
    if ( m_Status == CS_CANCELLED ) Release();
```

```
    // Processing Run Completed
    m_Status = CS_IDLE;

    // Log – General: Compilation Success

    // Success!
    return true;
}
```

As you can see, this relatively simple function is essentially just a wrapper that first loads the scene information, and then simply triggers each of the requested processing modules. Let us therefore begin to take a look at how each of these processing modules is implemented within lab project 16.2.

CCompiler::PerformHSR

The first of the three main module functions implemented within this initial pre-processing application is the 'PerformHSR' function. This function is intended to prepare the data destined to be merged together by the hidden surface removal processor. Recall that the hidden surface removal process accepts a series of meshes that will be combined using the constructive solid geometry *union* operation. This is done in order to remove any surfaces that would introduce illegal geometry into the tree during BSP compilation. If we do not remove these illegal polygon fragments before the tree is compiled, then we end up in a situation in which the solid and empty leaf information is compromised and cannot be resolved. For this reason, the hidden surface removal process must be executed prior to compiling the final scene BSP tree. We will cover the actual hidden surface removal processing module a little later, but first we must understand the type of data that is to be passed into this process and how it is accessed.

In summary, the general process that the 'PerformHSR' function must follow is listed below:

1) Set up the hidden surface removal processor module ready for its execution.

2) Collect a list of all of the meshes in the scene that are not flagged as detail objects and pass each of them into the HSR module class ready for processing.

3) Trigger the HSR module and allow it to run its course.

4) If the HSR process was successful, each of the original non-detail meshes will now have been merged into one single resulting mesh with all hidden surfaces removed. This function must therefore release each of these original meshes from the compiler's scene database in order to ensure that the scene polygon data is not duplicated.

5) Finally, we must retrieve the single resulting mesh from the processing object that constitutes the union of each of those meshes used in the merging operation. This mesh will then be stored in the compiler's internal mesh array ready for compilation by the following BSP compilation process should it have been enabled.

It should be clear from this general outline that this function is not physically responsible for performing any part of the hidden surface removal process. Under the conditions set forth by our modular design,

each processing module is a stand alone class that has its own API. This interface is used by the compiler class in order to initialize, execute and retrieve any data that may have resulted from that module class's execution. While each processing class may differ in the way data is passed in and retrieved, this separation of functionality into individual processing classes should allow us to more easily integrate additional processing tasks into the tool we are building.

We made mention in the previous summary outline that a mesh could be flagged as a 'detail object'. Although we have not been introduced to this type of object in the past you can think of them as being somewhat like those objects that have been linked to the previous spatial tree types using the detail area concept. These are objects that are not compiled directly into the tree itself, but are instead linked at runtime by passing them through the tree and attaching them to any leaves into which they may fall. In this pre-processing tool we treat these objects in a similar fashion. Although the objects will eventually be linked to the leaves only in our rendering application, we must ensure that any scene meshes that have been flagged as detail objects are not altered or compiled into the resulting BSP leaf tree.

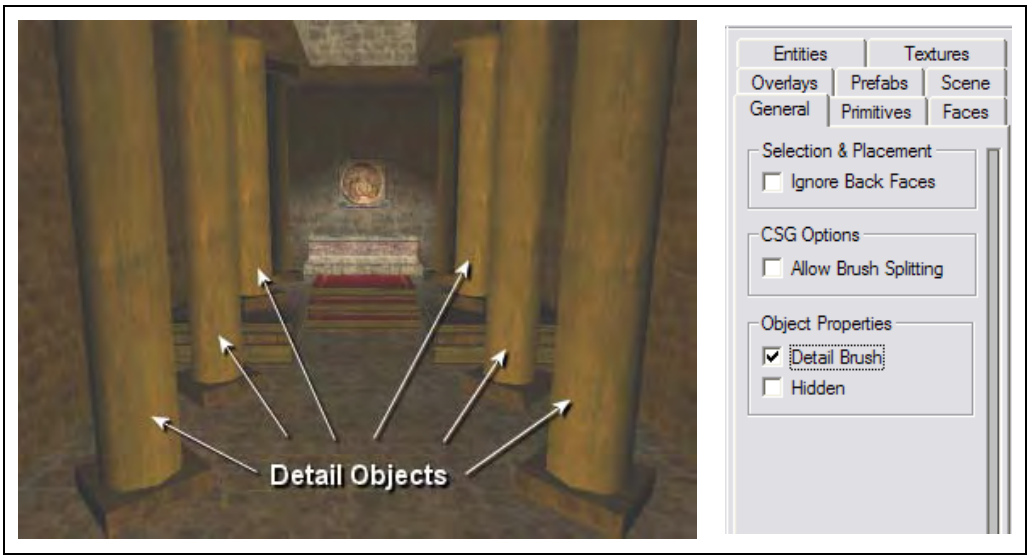

Figure 16.4

Figure 16.4 demonstrates the type of situation in which we might decide to make use of the detail object concept when compiling a level using the polygon aligned BSP leaf tree compiler. This scene contains a series of high resolution cylinders used to depict several roof support columns. Objects – such as these cylinder meshes – which contain a high level of detail, or a large amount of variation in the orientation of their polygons, can be ideal candidates for selection as detail objects. This is due to the fact that objects of this type can potentially introduce many hundreds of nodes and leaves when included in the BSP tree compilation process, without providing any significant benefit to the tree structure. In this figure we can also clearly see that these column meshes would not provide a significant amount of occlusion information for the visibility module (developed in the next lesson) that might have made their inclusion in the tree worthwhile.

On the right hand side of this figure we have included an image of the general properties tab from the GILES™ level editing tool. We can use this editor to select any mesh in our IWF scene, and flag it to become a detail object by checking the 'Detail Brush' box highlighted. After saving scene back out to

file, when we subsequently load it back into our rendering application or compiler tool we can check for the existence of this flag using the following bit test:

```
if ( pMesh->Flags & MESH_DETAIL ) { // This is a detail object }
```

Another good example of common types of detail objects are those meshes that are used as set decoration within the scene. This might include items such as tables, chairs, beds or basically anything that is not part of the scene architecture.

So, armed with this additional knowledge of what types of meshes should and should not be included in the hidden surface removal and BSP compilation processes, let us now take a look at how the 'ProcessHSR' function has been implemented in this lab project.

```
bool CCompiler::PerformHSR()
{
    // One time compile process
    CProcessHSR ProcessHSR;
    ULONG       i, MeshCount = 0;

    // Set our processor options
    ProcessHSR.SetOptions( m_OptionsHSR );
    ProcessHSR.SetLogger( m_pLogger );
    ProcessHSR.SetParent( this );

    // Log – HSR: Beginning Process
```

As we should have gathered from our examination of 'CompileScene', this function accepts no parameters. All of the data required by this function should have been imported into the compiler class' internal member arrays at this point, and can be access directly within this function. At the top of this function we can observe that an instance of our first processing class 'CProcessHSR' is created on the stack, as a local variable named 'ProcessHSR'. This object exposes all of the functionality required for initializing, executing and retrieving the mesh data resulting from the hidden surface removal process.

Once this processing object has been instantiated, we can then begin to initialize the various settings and values required by this module. The first of these is the 'HSROPTIONS' structure that we encountered earlier. Like the compiler class itself, each of the processing module classes – such as 'CProcessHSR' – implements a 'SetOptions' function used to set that object's option values. Recall that the 'HSROPTIONS' structure contains only a single variable that denotes whether or not this process is enabled. Regardless of this fact, we pass the options structure in at this point in order to ensure that the hidden surface removal class will have access to any additional process settings that may be added to the options structure in the future.

During each of the processing tasks, specific progress and status information must be reported to the user as we know. The next item that we pass to the HSR processing object therefore, is a reference to the logging class specified by the application. This gives the module a chance to report any process specific failures that may have occurred, in addition to providing any general information such as an operation progress percentage.

The final item that we pass into the 'ProcessHSR' object in the previous block of code is a reference to the compiler object itself. Having access to the compiler object will allow the process module to call the aforementioned 'TestCompilerState' method of the compiler as required.

With the processing module having been initialized with all of the various options and house-keeping items we can now begin to pass in the mesh data that will be used. Before we do this however, we must perform a final validation step. Of course, in order to perform a union CSG operation such as that required by the hidden surface removal process, we need at least *two* meshes in order for this operation to function correctly. If there is only one mesh in the scene to begin with, then there would be nothing else available for us to merge that mesh with. With this in mind, we first total the number of non detail meshes that have been loaded. If we find ourselves in a situation whereby there is only one available scene mesh to be processed and compiled, we simply output this information to the user and take no additional action.

```
    // Count the number of scene meshes
    for ( i = 0; i < m_vpMeshList.size(); i++ )
    {
        CMesh * pMesh = m_vpMeshList[i];
        if ( !pMesh ) continue;

        // Tally Mesh ?
        if ( !(pMesh->Flags & MESH_DETAIL) ) MeshCount++;

    } // Next Mesh

    // How many meshes ?
    if ( MeshCount <= 1 )
    {
        // Log – HSR: Nothing to do.

    } // End if single mesh
    else
    {
```

At this stage we know that we have at least two non detail meshes that must be unioned in preparation for the BSP compilation step. In the next section of code from this function we then begin to loop through each of the meshes stored in the compilers internal mesh array. If there is no mesh stored in any particular element (e.g. the mesh pointer stored there is equal to NULL) then we automatically continue to the next element in the array. It is imperative that we perform this simple test due to the fact that whenever a mesh is to be removed from consideration it is simply released before having its associated element in the mesh array set to NULL. This is done in the interests of efficiency and prevents us from having to reshuffle the mesh array at each step. We will see this behaviour shortly. In addition to testing the mesh pointer, the content of the mesh's 'Flag' member must also be tested within this loop. If this mesh is considered to be a detail object, then it should not be merged by the HSR process and so we simply move on to the next element in the array without action. With both of these tests completed, we reach a point in which we have a valid pointer to a non-detail mesh. This mesh is then passed into the HSR processing object with a call to the 'AddMesh' method of that class.

Once this loop has completed, the HSR processing module will now have a list of every mesh that we would like to merge together into one single resulting mesh, with all illegal geometry having been

removed. This is all the information this processing module needs to be aware of and so we call the object's 'Process' method to instruct the module to perform the actual hidden surface removal step on those meshes specified.

```
        // Add all of our meshes to the HSR Processor
        for ( i = 0; i < m_vpMeshList.size(); i++ )
        {
            CMesh *pMesh = m_vpMeshList[i];
            if (!pMesh) continue;
            if ( pMesh->Flags & MESH_DETAIL ) continue;
            ProcessHSR.AddMesh( pMesh );

        } // Next Mesh

        // Begin the HSR Process
        ProcessHSR.Process();
```

When the module's 'Process' function returns, it will have constructed a new mesh object that contains each of the polygons having been merged during the hidden surface removal process. This is of course unless an error had occurred. While the HSR processing class is responsible for reporting the specifics of any errors to the user via the logging class specified, we must still ensure that we take the appropriate action. To determine whether or not an error occurred during the hidden surface removal process, we test the value returned by the modules 'GetResultMesh' function. If this returns a value not equal to NULL then we know that no error occurred and we can continue to process the resulting data.

Before we actually do anything with the mesh generated by the 'Process' method, we must first remove each of the original non-detail objects that were unioned together in this step. As mentioned earlier, we do this in order to ensure that the final scene data set does not contain duplicate information. This is achieved using a method similar to that of the previous loop in which we added meshes to the processor prior to its execution. In this case however, whenever we find a valid pointer to a non detail mesh in the compiler's mesh array, we release that mesh object. Recall that we validated each element in the mesh array earlier to ensure that it did not contain a NULL pointer. The following loop logic demonstrates the reason why this must be done – once the original mesh object has been released, we subsequently set the corresponding array element to NULL. These empty elements will be removed at a later point in the application but at this stage this is done simply to prevent the mesh array from being reshuffled and resized at each step.

```
        // Make way for our result if there is one
        if ( ProcessHSR.GetResultMesh() != NULL )
        {
            // Destroy any loaded meshes
            for ( i = 0; i < m_vpMeshList.size(); i++ )
            {
                CMesh * pMesh = m_vpMeshList[i];
                if ( !pMesh ) continue;
                if ( pMesh->Flags & MESH_DETAIL ) continue;
                delete pMesh;
                m_vpMeshList[i] = NULL;

            } // Next Mesh
```

With each of the original source meshes removed, we can now retrieve the resulting mesh from the 'ProcessHSR' object and store it in the compiler's mesh array ready for the next compilation process. Rather than simply add this mesh to the end of the mesh array however, we have the ability to reuse one of the array elements that we had set to NULL in the previous loop. The following code searches for an array element containing a NULL pointer. If one is found, the index to that element is stored in the local 'MeshIndex' variable before breaking out of the loop.

```
            // Store our single result mesh in the first empty slot
            long MeshIndex = -1;
            for ( i = 0; i < m_vpMeshList.size(); i++ )
            {
                if ( !m_vpMeshList[i] ) { MeshIndex = i; break; }

            } // Next Mesh Slot
```

Notice that the local variable 'MeshIndex' was initialized using a default value of -1 in the previous code. If there were no elements found to contain a NULL pointer, this variable will not have been overwritten with a new index value and should therefore still be in its default state of -1. If an empty slot in the mesh array *was* found, this variable would now contain an index in the range of 0 and above. The following code examines the contents of this variable to determine whether it can reuse one of the available empty array elements, or if it must add the new resulting mesh to the end of the compiler's internal mesh array. If the 'MeshIndex' array contains a value of -1 then no slot was found and a pointer to the new mesh – accessed with a call to the module's 'GetResultMesh' method as before – is added to the end of the mesh array with a call to the STL vector 'push_back' function. If on the other hand the value of 'MeshIndex' is anything other than -1, then we simply overwrite that element in the array with the new mesh pointer.

```
            if ( MeshIndex == -1 )
            {
                m_vpMeshList.push_back( ProcessHSR.GetResultMesh() );

            } // End if No Slot
            else
            {
                m_vpMeshList[ MeshIndex ] = ProcessHSR.GetResultMesh();

            } // End if Free Slot
```

At this stage we have now removed every non-detail mesh originally contained in the compiler's mesh array, merged them together, and finally replaced them with a single new mesh result. With all of the illegal geometry hopefully now removed from the scene data set, we are now ready to have this new mesh processed by the next module in the list – the BSP compiler. As a result, the last part of this function simply informs the user that the HSR process has completed, and then returns to the calling 'CompileScene' function.

```
        } // End if

    } // End if multiple meshes
```

```
    // Log – HSR: Write Success Information

    // Success!!
    return true;
}
```

Although we have not yet covered the code to the hidden surface removal processor at this point, the discussion of this function will serve us well in understanding how this module fits into the larger compilation scheme. In addition to this we should now have a clearer picture of exactly what data is passed to the module class and what pieces of information the compiler is expecting to receive.

CCompiler::PerformBSP

Referring back to the code in the 'CompileScene' function, we know that this 'PerformBSP' function is called directly following the hidden surface removal step. With the HSR process completed, we are now able to compile a solid BSP leaf tree without worrying about the impact that any illegal geometry might have on the validity of the tree structure generated.

This is the stage in which we begin constructing the data that will serve as the foundation for much of the additional information generated by the future modules we will be implementing in both this lesson and the next. As we know, the 'CCompiler' class contains a member variable named 'm_pBSPTree'. This variable will store the pointer to an instance of the 'CBSPTree' class we will be discussing shortly. In the next lesson we will be using much of the information constructed in this step to generate the portal data that describes how the leaves in the tree are connected together. These portal polygons will then allow us to build the inter-leaf visibility information (PVS) which will provide us with scene occlusion culling. All of this information will eventually be stored within the BSP tree we construct in this step which will also be used as the source from which the final scene file is built.

From a high level standpoint, the 'PerformBSP' function undertakes the following tasks:

1) Set up the BSP compiler module ready for its execution.

2) Collect a combined list of all of the polygons from every non detail mesh in the scene and pass that list to the BSP tree compiler. These polygons will be used as the basis for the compilation of the polygon-aligned BSP leaf tree itself.

3) Trigger the BSP compilation process and allow it to run its course.

4) If the BSP compile process was successful, any original non-detail meshes that were used in the construction of the BSP tree should be removed. The polygon data is now owned by the centralized scene BSP tree stored within the compiler object. When exporting the scene at the end of the compilation process, the polygon data will be built using that information contained within the BSP tree.

As we can see from the above overview, the responsibilities of this method are fewer in number than those of the 'PerformHSR' function. We should already be familiar with the types of data required by

the BSP compiler at this point, so we will get straight down to examining the implementation of the 'PerformBSP' function.

```
bool CCompiler::PerformBSP()
{
    ULONG       i;

    // Destroy any old BSP Tree
    if ( m_pBSPTree ) delete m_pBSPTree;

    // Allocate a new BSP Tree
    m_pBSPTree = new CBSPTree;

    // Set our compiler options
    m_pBSPTree->SetOptions( m_OptionsBSP );
    m_pBSPTree->SetLogger( m_pLogger );
    m_pBSPTree->SetParent( this );

    // Log – BSP: Beginning Compilation Process
```

In a similar fashion to the 'PerformHSR' method, there are no parameters that need to be specified when calling this function. As before, everything we need is already contained within the member variables of the compiler class itself. Unlike this previous method however, there is no local variable declared here which serves as the processing module. In the case of hidden surface removal, the processing module class we used was instantiated as a temporary object which simply processed and built data subsequently used as a replacement in one single step. With the BSP tree class, we are building a tree structure that must be retained both for future processing modules, in addition to the requirement that this structure to be exported to file at a later point in the application. As a result, we create an instance of the 'CBSPTree' class and store it within the 'm_pBSPTree' member variable of the compiler class.

After creating the BSP class instance, we specify the compilation options that it must use with a call to the 'CBSPTree::SetOptions' method, passing in the 'BSPOPTIONS' structure stored in the compiler's 'm_OptionsBSP' member variable. We also inform the compiler module of the applications logging class object, in addition to passing the reference to this compiler object with calls to the 'SetLogger' and 'SetParent' calls respectively.

With the main BSP tree member object instantiated and initialized, we are now ready to begin processing the loaded scene information in order to compile the tree structure. In the following code we begin by looping through each of the meshes currently stored within the compiler's mesh array, adding each mesh's polygon data to the tree ready for compilation. If the hidden surface removal process was enabled and executed in the previous step, it is possible that this array will only contain a single valid mesh pointer. With that said, it is not a requirement that the HSR process be enabled in cases where the scene contains no illegal geometry to begin with, or those in which valid solid / empty information is not required. For this reason we must still loop through each mesh rather than simply searching for the first valid mesh pointer. Also recall that we do not want to include those meshes flagged as being detail objects in the compilation of the BSP tree. To this end we skip over any meshes whose 'Flag' variable contains the 'MESH_DETAIL' bit as before. Each time we find a mesh in the array that should be included in the BSP compilation process, we add its polygon data to the BSP compiler object with a call to the 'AddFaces' method. This function accepts two parameters. The first parameter should be passed

an array of ‘CFace’ object pointers – such as those managed by each mesh – each of which will be appended to the internal list of polygons to be used. The second of these two parameters should be passed a simple integer value containing the length of the aforementioned array.

With each mesh’s polygon data passed into the BSP tree object, the process if compiling the tree can now begin. In the case of the ‘CBSPTree’ class, this is done with a call to its ‘CompileTree’ method.

```
    // Add all remaining meshes polys (automatically backup with NSR)
    for ( i = 0; i < m_vpMeshList.size(); i++ )
    {
        CMesh * pMesh = m_vpMeshList[i];
        if ( !pMesh ) continue;
        if ( pMesh->Flags & MESH_DETAIL ) continue;
        m_pBSPTree->AddFaces( pMesh->Faces, pMesh->FaceCount );

    } // Next Mesh

    // Compile the BSP Tree
    m_pBSPTree->CompileTree();
```

Once the BSP tree has been successfully compiled, each of the non-detail meshes used to construct that tree should now be removed from the compiler’s scene database. If we did not perform this step then our export file would contain at least one duplicate of every polygon in the tree – one stored in the source mesh and another in the BSP tree itself. This loop simply searches for any valid non-detail mesh, releases it and finally overwrites the corresponding element in the compiler’s mesh array with a NULL pointer.

```
    // Destroy any loaded scene meshes
    for ( i = 0; i < m_vpMeshList.size(); i++ )
    {
        CMesh * pMesh = m_vpMeshList[i];
        if ( !pMesh ) continue;
        if ( pMesh->Flags & MESH_DETAIL ) continue;
        delete pMesh;
        m_vpMeshList[i] = NULL;

    } // Next Mesh
```

In the final part of this function we unset the BSP tree object’s logging class reference by passing NULL to the ‘SetLogger’ function. This is not strictly necessary within our lab project application. However, in doing so, we ensure that any BSP tree class function that outputs progress information during the main tree compile step does not output this information again in the event that any future module makes a call to it.

```
    // Prevent future logging
    m_pBSPTree->SetLogger( NULL );

    // Log – BSP: BSP Process Completed

    // Success!!
    return true;
```

```
}
```

With the BSP compilation step completed we once again return control back to the 'CompileScene' function that made the original call to this method. The next processing task undertaken by the compiler is the T-junction repair step.

CCompiler::PerformTJR

The 'PerformTJR' function is the primary wrapper around the preparation and execution of the T-junction repair process. This process constitutes the final pre-processing task that we will develop in this lesson.

The process of T-junction repair has been covered in previous lessons, so we should already be familiar with the general concepts involved. We know from experience that – at a high level – this process compares the vertices of every polygon in the scene against the edges of every other polygon that surrounds it. If no vertex is found to have a matching position within the edge being tested then a copy of that vertex must be inserted in the neighboring edge in order to resolve this T-junction situation. With this in mind, it should be clear that we must somehow pass the scene polygon information into the T-Junction repair module in order for it to have access to the level geometry. At this point in the process however, there are two locations in which the scene polygon information may exist. The first is from the mesh data contained within the compiler's internal mesh array. However, this array will only contain applicable mesh data if the BSP compilation step was bypassed. Recall that during the BSP compile step, the 'PerformBSP' function may remove those non-detail meshes that were used to construct the tree if the BSP process has been enabled by the application. As a result, the second case that we must consider is that in which the BSP tree has already been compiled and we must source the polygon data from the compiler's BSP tree object as a result.

As we know, the T-Junction repair process is not concerned with any of the renderable polygon information such as textures or materials, or even the surface normal. All this process needs to be able to function is a list of the vertices that make up each of the polygons in the scene. If we refer back to the discussion of the base 'CPolygon' class – from which each of the extended polygon data classes are derived – it should be clear that this process need only access the information exposed by that base class.

With this situation in mind, the T-Junction repair processing module has been designed to accept a list of *pointers* to one or more 'CPolygon' objects. In doing so, we allow the T-Junction repair process to gain access to the polygons from a wide variety of sources even if they are of different physical types. As long as each of the source polygon objects to be repaired are *derived* from the base 'CPolygon' class, then we can pass this data into the repair module and have the process function regardless of their type.

Before we move onto examining the internal workings of this method, let us quickly summarize the procedure as it will be implemented.

1) Set up the T-Junction repair module ready for its execution.

2) Collect a combined list of all of the polygons from every non detail mesh in the scene, or alternatively from any compiled BSP tree object, and pass that list to the T-Junction repair module ready for processing.

3) Trigger the repair process and allow it to run its course.

As you can see, this function is a relatively simple one. Let us therefore move on to briefly discuss how it has been implemented in this lab project.

```
bool CCompiler::PerformTJR()
{
    ULONG i, k;

    // One time compile process
    CProcessTJR ProcessTJR;

    // Set our process options
    ProcessTJR.SetOptions( m_OptionsTJR );
    ProcessTJR.SetLogger( m_pLogger );
    ProcessTJR.SetParent( this );

    ULONG       PolyCount = 0, Counter = 0;
    CPolygon ** ppPolys   = NULL;

    // Log – TJR: Beginning Process
```

As with each of the tasks before it, the first thing we must do in this function is to instantiate the T-junction repair module object and initialize the various options, logging and parent properties. Similar to the hidden surface removal process, T-junction repair is a one time procedure that simply manipulates any data that already exists in the scene. Once the process has completed, this processing module object is no longer required. As a result, the 'CProcessTJR' class is instantiated as a local variable named 'ProcessTJR'. Once this object has been initialized we can begin to prepare any applicable scene information ready for the T-junction repair module to perform its task.

The first case we deal with in this function is that in which no BSP tree has yet been compiled. In this case there may be one or more non-detail meshes contained within the compiler's internal scene mesh array. Because we cannot know in advance how many polygons are stored within these mesh objects in total, we must first iterate through each non-detail mesh and count up this total. If it turns out that there are no available polygons in the list, this function can simply return without error.

```
    if ( !m_pBSPTree )
    {
        // Count all polys in all active meshes
        for ( i = 0; i < m_vpMeshList.size(); i++ )
        {
            CMesh * pMesh = m_vpMeshList[i];
            if ( !pMesh ) continue;
            if ( pMesh->Flags & MESH_DETAIL ) continue;
            PolyCount += pMesh->FaceCount;

        } // Next Mesh
```

```
        // If no polys exist, bail (no error)
        if (!PolyCount) return true;
```

Now that we know the total number of polygons contained within each of the meshes in the compiler' scene database, we can begin to allocate and build the polygon pointer array discussed earlier. Our first job therefore is to allocate an array of 'CPolygon' base class *pointers* that will store any references to each polygon needed. This pointer returned by this allocation is stored in the local variable 'ppPolys' declared at the top of the 'PerformTJR' function. If this array was allocated successfully, this function subsequently collects a pointer to each polygon, from every valid non-detail mesh, and stores them in this newly allocated array.

```
        // Allocate our polygon pointer array
        if (!(ppPolys = new CPolygon*[PolyCount])) return false;

        // Add all mesh face pointers here
        for ( i = 0, Counter = 0; i < m_vpMeshList.size(); i++ )
        {
            CMesh * pMesh = m_vpMeshList[i];
            if ( !pMesh ) continue;
            if ( pMesh->Flags & MESH_DETAIL ) continue;

            // Loop through faces
            for ( k = 0; k < pMesh->FaceCount; k++ )
                ppPolys[ Counter++ ] = pMesh->Faces[ k ];

        } // Next Mesh
    } // End if Meshes
```

At this stage, assuming no BSP tree had been compiled prior to this function being called, the local 'ppPolys' variable will reference an array that contains a pointer to every polygon, taken from every non-detail mesh in the scene. If a BSP tree had been compiled however then, as we know, there will be applicable meshes remaining in the compiler's mesh array. As a result, we must also cater for the situation in which a BSP tree has been compiled.

In this case, we already know in advance how many polygons are stored in the already compiled BSP tree object. We can gain access to this information by calling the 'CBSPTree::GetFaceCount' method. Again, if the number of polygons is found to be 0 at this stage, then we return from the function without error. With the total number of polygons to hand, we allocate the 'CPolygon' pointer array on the heap and store its pointer in the local 'ppPolys' array in the same fashion as the previous case. If the allocation of this array was successful, we finish up this conditional block by filling the same polygon pointer array with references to each polygon contained in the BSP tree. These polygons are retrieved by calling the 'CBSPTree::GetFace' method.

```
    else
    {
        // Retrieve poly count
        PolyCount = m_pBSPTree->GetFaceCount();

        // If no polys exist, bail (no error)
```

```
        if (!PolyCount) return true;

        // Allocate our polygon pointer array
        if (!(ppPolys = new CPolygon*[PolyCount])) return false;

        // Loop through faces and add
        for ( k = 0; k < PolyCount; k++ )
            ppPolys[ k ] = m_pBSPTree->GetFace( k );

    } // End if BSP Tree
```

So, in either of the cases outlined above we now have an array that contains a list of polygons, referenced by pointers to their base 'CPolygon' class. This will of course be the case regardless of the actual type of the polygon objects being referenced. Armed with all the information we need, we then trigger the T-Junction repair module with a call to the 'ProcessTJR' object's 'Process' function, passing in both the array we have just constructed, along with the number of polygons stored therein. Due to the fact that we have passed in only *references* to the polygon data contained in either the mesh array, or the BSP tree, the T-Junction repair process will manipulate the polygon data without the need to be aware of the location from which they were retrieved. In addition, because the process processes and inserts vertices directly into the source polygon data, there is no need for us to retrieve and interpret any kind of resulting data. Once the repair process has completed, there is nothing further required of this function other than to release the temporary polygon array that we had previously allocated. With this allocated resource released, we finally report the process success to the user and return control to the calling function.

```
    // Repair any T-Junctions
    ProcessTJR.Process( ppPolys, PolyCount );

    // Release the poly pointer array
    if (ppPolys) delete []ppPolys;

    // Log – TJR: Process Completed

    // Success!!
    return true;
}
```

Once this function has returned, we will have come to the end of the entire compilation process for this lab project. In future lessons we will of course add additional processing modules to the compiler core that will add additional steps. In this version of our pre-processing tool however, the front end application would instruct the compiler to save the resulting information at this point. Therefore, let us now examine the compiler method used to save our newly compiled scene information to file.

CCompiler::SaveScene

The final task that our compiler must undertake once the scene data has been successfully processed is to save the compiled information back out to file.

There are several pieces of information that we have imported, compiled or processed that need to be written back out to the final IWF file. These include the texturing, material, shader and entity information we imported earlier in addition to any surviving mesh data that still exists within the compiler's mesh array. Of course, we must also export the BSP tree data to file too should that compiler process have been enabled. Let us briefly refer back to a statement that was made earlier in this chapter regarding the 'BuildFromBSPTree' function exposed by the new 'CMesh' class.

"Although we have not yet discussed our new BSP leaf tree class, we should be familiar enough with the general concepts involved in the construction of leaf trees to know that, once the compilation has completed, the tree will store a list of each of the polygons contained within its leaves. Once the BSP tree has been built, we need to write the polygon information to file in a format that is easy for the application to retrieve. Due to the fact that our application is already capable of loading mesh and polygon data from the IWF file, it makes sense that we export the resulting BSP tree polygon data out to file as a standard mesh. This will prevent us from having to implement another series of polygon import functionality and will allow the BSP tree's polygon data to be loaded seamlessly by any IWF import procedure."

This behavior can be observed in the function code outlined here. Should the BSP tree have been compiled, we take the polygon data contained within the compiled tree object and convert it into a 'CMesh' object such that it is compatible with both the standard mesh saving and loading procedures. This mesh is then added to the IWF file object in a manner that will cause this mesh to **always** be written to the file as the first mesh encountered during any subsequent import operation. Each mesh that follows this first mesh will be the detail objects that have not been processed or compiled into the BSP tree by this application. Moving forward it will be important to bear this in mind as we begin to develop the rendering application that will rely on this exported IWF file.

With all the various pieces of information stored within the compiler, it may seem as if the process involved in exporting the resulting scene data could be a little daunting. In fact, this process is relatively simple as we will discover when we begin to examine the implementation of the 'SaveScene' function below.

```
bool CCompiler::SaveScene( LPCTSTR FileName )
{
    ULONG       i;
    CFileIWF    IWFFile;
    CMesh      *pTreeMesh = NULL;

    try
    {
        // Fill up the IWF's internal structures
        IWFFile.m_vpTextureList  = m_vpTextureList;
        IWFFile.m_vpMaterialList = m_vpMaterialList;
        IWFFile.m_vpShaderList   = m_vpShaderList;
        IWFFile.m_vpEntityList   = m_vpEntityList;
```

This function accepts only a single parameter to which the application should pass the path and filename to the file in which it would like the current scene data to be saved. As with the loading operation undertaken in 'CompileScene', this function makes use of the 'CFileIWF' class to provide much of the

core file handling and export functionality. All we really need to do at this point is to populate the data structures within this class that it will then proceed to interpret and export to the final IWF file. To this end we begin by creating a local instance of this class in the form of the 'IWFFile' object shown at the top of this function.

Recall in our previous discussion of the 'CompileScene' function, we took ownership of several pieces of the imported data simply by performing a shallow copy on the STL vectors contained within the IWF loading class. During this save operation we can do exactly the same thing in reverse. By assigning the 'IWFFile' object's STL vector members to those matching vectors stored within the compiler object, we populate those data structures automatically. However, due to the fact that we must perform additional processing on the mesh information that is to be exported, we can only do this with the static information that was not modified during the compilation process. These include the texture, material, shader and entity vector members demonstrated in the previous code snippet.

With these other four STL vectors now populated, this function then proceeds to construct the all important mesh and polygon data that must also be exported to the IWF file. Depending on whether or not the application chose to enable the BSP tree compilation step, there are clearly two different situations that can arise. Either a BSP tree object has been created, from which we must populate the export file, or no tree was compiled and we simply need consider those meshes contained within the compiler's mesh array. The first of these two cases is shown below. If a BSP tree has been constructed at this point, the function will proceed to generate a compatible 'CMesh' object from the polygon data contained in the BSP tree. We achieve this by calling the 'BuildFromBSPTree' method of the 'CMesh' class covered earlier. To this function we pass the primary instance of our BSP tree class stored within the 'm_pBSPTree' member variable. Once completed, this newly generated mesh is then added to the IWF object's mesh list in exactly the same fashion as if this had been a standard mesh to begin with. Of course, the additional tree information such as the nodes and leaves will not be transferred into this mesh object. This additional information will be handled separately, as we shall see later on in this function.

```
        // If there is a tree, build a mesh from it
        if ( m_pBSPTree )
        {
            // Allocate a new tree mesh
            pTreeMesh = new CMesh;
            if (!pTreeMesh) throw std::bad_alloc();

            // Build the mesh from the bsp tree
            if (!pTreeMesh->BuildFromBSPTree( m_pBSPTree ))
                throw BCERR_OUTOFMEMORY;

            // Add the mesh to the file export list
            IWFFile.m_vpMeshList.push_back( pTreeMesh );

        }
```

The alternate case is executed when the application chose not to construct a BSP tree from the imported mesh data. In this case we simply add each of the **non-detail** meshes directly to the end of the 'IWFFile' object's mesh list ready for export.

```
        else
        {
            // Add any conventional meshes
            for ( i = 0; i < m_vpMeshList.size(); i++ )
            {
                CMesh * pMesh = m_vpMeshList[ i ];
                if ( !pMesh ) continue;

                // Add this if it's not a detail mesh
                if ( !(pMesh->Flags & MESH_DETAIL) )
                    IWFFile.m_vpMeshList.push_back( pMesh );

            } // Next Mesh

        } // End if No Tree
```

Although it may seem strange that we have chosen to add only those non-detail mesh objects to the export list in the previous case, remember that we must export any detail objects back out to file regardless of whether or not we have compiled a BSP tree. As a result, the detail objects are added to the list outside of the conditional if/else statement to ensure that these detail mesh objects are exported in both cases.

```
        // Loop through and add any detail meshes
        for ( i = 0; i < m_vpMeshList.size(); i++ )
        {
            CMesh * pMesh = m_vpMeshList[ i ];
            if ( !pMesh ) continue;

            // Add this if it's a detail mesh
            if ( pMesh->Flags & MESH_DETAIL )
                IWFFile.m_vpMeshList.push_back( pMesh );

        } // Next Mesh
```

Now that each of the 'IWFFile' object's four internal STL vectors have been populated with the appropriate data items, we can now call the 'Save' function to have that data written to file. To this function we pass both the name of the file to which the scene is to be exported, in addition to a pointer to the BSP tree object stored in the compiler's 'm_pBSPTree' member variable. While the purpose of the first parameter should be obvious, we pass the BSP tree object to this function as the second parameter in order for the IWF class to access and export the additional information stored within the tree. These include the nodes, leaves and plane information that may have been generated during the compilation process. In the next lesson, the tree object will also store portal and visibility information that the 'CFileIWF' class will also be responsible for retrieving and exporting.

Assuming the save operation was a success; we must now clear up any items that may have been allocated during this function's execution. The first of these is the mesh pointed to by the local 'pTreeMesh' variable. Recall that if a BSP tree object was constructed during the compilation process, this function was required to generate a new mesh object that could be added to the standard mesh list within the 'IWFFile' object. If this case has occurred, then we must release this temporary mesh object before exiting the function in order to prevent a memory leak. Finally we clear each of the 'IWFFile'

object's internal STL vector items. We must do this to prevent the objects stored within this array from being released prematurely when the 'IWFFile' object goes out of scope as this function returns.

```
        // Export file
        IWFFile.Save( FileName, m_pBSPTree );

        // Clean up
        if ( pTreeMesh ) delete pTreeMesh;
        IWFFile.m_vpMeshList.clear();
        IWFFile.m_vpTextureList.clear();
        IWFFile.m_vpShaderList.clear();
        IWFFile.m_vpEntityList.clear();
        IWFFile.m_vpMaterialList.clear();

    } // End Try Block
```

This function traps any errors encountered using a try/catch block mechanism. Because an exception may be thrown during either the IWF export procedure, or during any of the STL operations we perform in this function, the catch block below attempts to safely release any allocated memory in an identical manner to that outlined in the earlier code. If an exception was thrown within this function then the code in this catch block will be executed before returning a value of 'false' to the calling function. If no exception is thrown then the catch block is skipped and the function will return a value of 'true' denoting a successful export.

```
    catch (...)
    {
        if ( pTreeMesh ) delete pTreeMesh;
        IWFFile.m_vpMeshList.clear();
        IWFFile.m_vpTextureList.clear();
        IWFFile.m_vpShaderList.clear();
        IWFFile.m_vpEntityList.clear();
        IWFFile.m_vpMaterialList.clear();
        return false;

    } // End Catch Block

    // Success!!
    return true;
}
```

CCompiler::Release / ~CCompiler()

With the scene now fully processed, the only two functions that remain for us to examine are those responsible for cleaning up any objects or resources allocated during the import and compilation procedures. The first of these two functions is the 'Release' method. Similar to the functions of this type that we have implemented in the past, this can be called by the application should it wish to reuse any particular instance of the compiler class in a subsequent compilation task.

There is nothing really deep or complex about this function, the majority of which is dedicated to simply looping through each of the STL vectors maintained by the compiler class, and releasing any data storage objects stored in each element. These include meshes, textures, materials, shaders and entities.

Once each of these objects has been correctly released, the STL vectors in which they were contained are cleared in order to ensure that these arrays are cleared of the object pointers that are now invalid.

```
void CCompiler::Release()
{
    unsigned long i;

    // Destroy any loaded meshes
    for ( i = 0; i < m_vpMeshList.size(); i++ )
    {
        if ( m_vpMeshList[i] ) delete m_vpMeshList[i];

    } // Next Mesh

    // Destroy any loaded textures
    for ( i = 0; i < m_vpTextureList.size(); i++ )
    {
        if ( m_vpTextureList[i] ) delete m_vpTextureList[i];

    } // Next Texture

    // Destroy any loaded maerials
    for ( i = 0; i < m_vpMaterialList.size(); i++ )
    {
        if ( m_vpMaterialList[i] ) delete m_vpMaterialList[i];

    } // End If

    // Destroy any loaded shaders
    for ( i = 0; i < m_vpShaderList.size(); i++ )
    {
        if ( m_vpShaderList[i] ) delete m_vpShaderList[i];

    } // End If

    // Destroy any loaded entities
    for ( i = 0; i < m_vpEntityList.size(); i++ )
    {
        if ( m_vpEntityList[i] ) delete m_vpEntityList[i];

    } // End If

    // Clear the vectors
    m_vpMeshList.clear();
    m_vpTextureList.clear();
    m_vpMaterialList.clear();
    m_vpShaderList.clear();
    m_vpEntityList.clear();
```

With each of the scene data items released and cleared, the final task is to release the duplicated file name string contained in the ‘m_strFileName’ variable and to release the compiled BSP tree object should it exist.

```
    // Release strings
```

```
    if ( m_strFileName ) free( m_strFileName );
    m_strFileName = NULL;

    // Destroy any compiled BSP Tree
    if (m_pBSPTree) delete m_pBSPTree;
    m_pBSPTree = NULL;
}
```

The second of these two functions is the standard compiler class destructor. As has been the case in many of the classes we have encountered, this destructor simply calls the 'Release' function to ensure that no resources are leaked when the compiler class is destroyed or goes out of scope.

```
CCompiler::~CCompiler()
{
    // Clean up after ourselves
    Release();
}
```

With the completion of these two functions, we have reached the conclusion of the API exposed by the compiler class as it will commonly be used by any front end application. We have covered each task including the importing of the scene, preparing that scene data for processing, creating and executing each compiler module process and finally saving the data back to file. What remains to be covered is of course each of the compiler process classes that perform the pre-process tasks available in this lab project.

Adding BSP Tree Support – CBSPTree.cpp

Before we can realistically move on to discussing the compiler module classes, we must first discuss the integration of the new polygon-aligned BSP compiler supported into this lab project. Although this class is a compilation module in its own right, much of the functionality contained within this class is also used by other processing modules. In the case of the hidden surface removal process – which is actually executed *before* the main BSP compile step – we must create and compile individual BSP tree objects from each of meshes that we intend to merge before we can perform the union operation. Since this class is a major pre-requisite in many cases, it will be beneficial to us if we step outside of the program flow for a while and examine the entire set of BSP tree classes and compilation procedures.

A Note Regarding Linked Lists

The various compiler classes that we have previously implemented have made extensive use of the STL 'list' template class to provide much of the linked list support required by those applications. In this new compiler application we use manually constructed linked lists almost exclusively. We have encountered these concepts many times in previous lessons, an example of which would be the sibling pointer and iteration logic used extensively in our coverage of the D3DXFRAME and D3DXMESHCONTAINER structures. We have chosen to use manual linked lists in this application due to the many varied situations in which they are used requiring a high degree of flexibility not easily implemented when using the STL list template class.

With that in mind, let us now move on to discuss each of the supporting classes required by the BSP tree compilation process.

The CBSPFace Class

Up until this point we have been using the renderable 'CFace' class during the manipulation of our scene data. This class maintains those pieces of information that our rendering application may require – such as the texturing, material and surface normal data imported from the source IWF file. Recall that the 'CFace' class is also derived from a base of 'CPolygon' that provides much of the vertex management we require such as the 'Split' function we encountered earlier. Due to the fact that we want to compile the same information that we will ultimately be rendering in our run-time application, this class is derived directly from the 'CFace' class. By extending the renderable polygon class in this way, we automatically inherit the variables and functionality exposed by this base class without having to explicitly redeclare such members.

The 'CBSPFace' class is used exclusively by the BSP tree compilation process, and contains several additional member variables that are designed specifically for those tasks undertaken by the BSP tree class.

```
class CBSPFace : public CFace
{
public:

    // Constructors & Destructors
    CBSPFace( );
    CBSPFace( const CFace * pFace );

    // Public Variables for This Class
    bool        UsedAsSplitter;
    long        OriginalIndex;
    bool        Deleted;
    long        ChildSplit[2];
    CBSPFace   *Next;
    long        Plane;

    // Public Virtual Functions for This Class
    virtual HRESULT Split( const CPlane3& Plane, CBSPFace * FrontSplit,
                           CBSPFace * BackSplit, bool bReturnNoSplit = false );

};
```

Let us briefly examine each of the new member variables declared within this extended polygon class.

bool UsedAsSplitter

In the previous lab project 16.1 in which we developed a BSP node tree compiler class, the polygons were removed from consideration and attached to each node at the point of being selected as a separating plane candidate. During the compilation of the leaf based BSP tree however, we are required to pass any surviving polygon fragments through the tree in order for them to be collected in the attached leaf structures that will be created at the terminal nodes. While this could be achieved by

passing the polygons through the tree after the nodes and leaves have been constructed, the most efficient approach is to perform the polygon splitting and classification at the same time as building the tree itself. To this end, we need to be able to determine if a polygon fragment has already been chosen as a node plane candidate in order to remove it from consideration as it is passed through the tree during construction.

The 'UsedAsSplitter' variable is the means by which this is achieved. By testing the value of this member in the splitter selection step, we can determine whether a polygon has already been used to generate a node at a point further up in the recursive building process. With a default value of 'false', each polygon passed into the BSP tree class for compilation can initially be chosen for node plane candidacy. Whenever a polygon has been used in the creation of a node however, this member variable should be set to 'true'. Thus, whenever that polygon is encountered by the splitter selection routine at a point further down the tree, it would not be selected for a second time. This leaves us free to pass as many polygons as we need through the recursive BSP compilation function, creating a leaf only when there are no remaining polygons available for use as splitters in the polygon list specified.

long OriginalIndex

When used in conjunction with the more traditional split type BSP tree compilation process, this variable is used to transfer the index of this polygon's final location within the BSP trees centralized polygon array for storage in the leaf structure. When the application requests that the BSP tree compiler build a structure in which the leaves reference the original unsplit versions of the polygon data however – the non-split resulting tree type – this variable is used to track the index of the original polygon from which this particular fragment was created. Whenever a polygon is split, this original index value is copied into each of the resulting fragments. This enables us to identify the polygon from the original imported data set when any polygon fragment reaches a terminal node. We will explore this topic in greater depth a little later.

bool Deleted

During the hidden surface removal process, there are situations in which a polygon may have been split into multiple fragments of which none have been removed under the clipping rules specified. We will discover shortly how it is possible for us to easily repair these unnecessary splits and restore the polygon to its initial state. To do this however, requires that we do not physically delete the original polygons whenever they are found to span a BSP tree node that subsequently caused it to be split. For this reason, we maintain this 'Deleted' variable that we use to notify the HSR clipping procedure that it should simply be ignored as if it had been removed altogether. This allows us to simply set this variable to 'false', and those of any resulting split fragments to 'true', in order to undo any unnecessary split operations that may have occurred.

long ChildSplit[2]

Used only by the hidden surface removal support functionality provided by the BSP tree class, each element in this array stores indices to the two resulting polygon fragments added to the resulting polygon list should this polygon be split against a node's separating plane. We will examine how this variable is applied when we come to discuss these supporting functions later in this chapter.

CBSPFace * Next

This pointer variable is used to describe the *next* 'CBSPFace' object contained within any individual linked list being maintained by the compiler. This variable is used in several situations, each of which will be explained when they are encountered.

long Plane

Earlier in this chapter we discussed how we might build an array of planes that could be referenced by the nodes of the tree using a simple index. This member variable contains an index that references an element within such a plane array that will later be constructed within the BSP tree class. Recall that using a combined plane array allows us to reduce the amount of memory and file resources required to store the plane information which might otherwise be duplicated for coplanar nodes and polygons. In addition to reducing the memory footprint of this plane data, we will also shortly discuss how the accuracy of the BSP compilation process can be greatly improved by building shared and reusable plane data in this way.

CBSPFace::CBSPFace()

There are two constructors provided by this class. The first of these is the default class constructor shown below.

```
CBSPFace::CBSPFace()
{
    // Initialise anything we need
    UsedAsSplitter  = false;
    OriginalIndex   = -1;
    Next            = NULL;
    Deleted         = false;
    ChildSplit[0]   = -1;
    ChildSplit[1]   = -1;
    Plane           = -1;
}
```

As you can see, this constructor simply initializes each of the extended class member variables with a sensible default value. The only member whose default value is of any real importance here is the 'UsedAsSplitter' variable. Due to the fact that every polygon used in the construction of the BSP tree should be used as a node plane candidate at some point in the process, it is imperative that this variable is defaulted to 'false'. Remember that in C++, each of the base class constructors will be automatically executed in order. As a result, it is not necessary for us to default those member variables declared by the parent 'CFace' or 'CPolygon' classes here.

The second constructor defined by 'CBSPFace' class is an overload that accepts a single parameter of a 'CFace' object pointer type. This constructor is used in cases where the data contained within the polygon passed to this constructor should be duplicated into the new 'CBSPFace' polygon being constructed. This function begins in a similar manner to that of the default constructor by initializing the extended member variables declared by this class.

```
CBSPFace::CBSPFace( const CFace * pFace )
{
    // Initialise anything we need
    UsedAsSplitter  = false;
```

```
    OriginalIndex   = -1;
    Next            = NULL;
    Deleted         = false;
    ChildSplit[0]   = -1;
    ChildSplit[1]   = -1;
    Plane           = -1;
```

Once the ‘CBSPFace’ member variables have been set to their initial state, this function then proceeds to duplicate the information contained within the ‘CFace’ object passed to this constructor. As demonstrated below, this is achieved by first copying the values from those member variables declared by the ‘CFace’ class from the polygon object passed, into the corresponding members inherited by this object. Once this information has been transferred, the constructor then proceeds to duplicate the vertex data contained within the specified polygon object into the internal vertex array of the new polygon object being constructed.

```
    // Duplicate required values
    Normal          = pFace->Normal;
    TextureIndex    = pFace->TextureIndex;
    MaterialIndex   = pFace->MaterialIndex;
    ShaderIndex     = pFace->ShaderIndex;
    Flags           = pFace->Flags;
    SrcBlendMode    = pFace->SrcBlendMode;
    DestBlendMode   = pFace->DestBlendMode;

    // Duplicate Arrays
    AddVertices( pFace->VertexCount );
    memcpy( Vertices, pFace->Vertices, VertexCount * sizeof(CVertex));
}
```

CBSPFace::Split

Just as with the ‘CFace' class from which ‘CBSPFace’ is derived, we must provide an overloaded ‘Split’ function that is responsible for copying any additional member variables maintained by this class into each of the two split fragments. Notice that at the very start of this function we make a call to the base class’ implementation of the ‘Split’ procedure. Recall that in this case, the base from which this polygon class is derived is ‘CFace’ which is in turn derived from ‘CPolygon’. By calling the ‘CFace’ implementation of the split function, which in itself also calls the ‘CPolygon’ implementation, we ensure that all of those pieces of information maintained by either class in the hierarchy are duplicated into the two resulting polygon fragments.

```
HRESULT CBSPFace::Split( const CPlane3& SplitPlane, CBSPFace * FrontSplit,
                         CBSPFace * BackSplit )
{

    // Call base class implementation
    HRESULT ErrCode = CFace::Split( SplitPlane, FrontSplit, BackSplit );
    if (FAILED(ErrCode)) return ErrCode;

    // Copy remaining values
    if (FrontSplit)
    {
```

```
        FrontSplit->UsedAsSplitter = UsedAsSplitter;
        FrontSplit->OriginalIndex  = OriginalIndex;
        FrontSplit->Plane          = Plane;

    } // End If

    if (BackSplit)
    {
        BackSplit->UsedAsSplitter = UsedAsSplitter;
        BackSplit->OriginalIndex  = OriginalIndex;
        BackSplit->Plane          = Plane;

    } // End If

    // Success
    return BC_OK;
}
```

In this function, we copy three main pieces of information into each of the resulting polygon fragments. The first of these is the 'UsedAsSplitter' member. It is important that each of the split fragments inherit the value stored in this member whenever a polygon is split during the BSP compilation process. If this were not the case then, whenever a polygon that has already been selected for node plane candidacy is split, each child fragment would subsequently cause a new node plane to be generated at some point underneath the node originally generated. While this would not necessarily harm the integrity of the BSP tree or the validity of the solid / empty leaf information, creating these additional nodes would be wasteful and would merely increase the time it would take to traverse the hierarchy.

Secondly, we copy the source polygon's 'OriginalIndex' member value into each fragment. Again this is only really important when the application has chosen to construct a non-split resulting BSP tree, but we copy this information regardless of the tree type. As mentioned earlier, this index is used as a reference to the original scene polygon that was initially used to create each 'CBSPFace' object used in the BSP compilation process. Whenever a polygon gets split into two new fragments, each of these resulting polygons should maintain that same 'OriginalIndex' value so that we can correctly process this information when we reach a terminal node.

Finally, we duplicate the plane index into each of the resulting front and back fragments. Since each of the fragments generated by the polygon splitting operation are absolutely **guaranteed** to be coplanar with the source polygon, both of these fragments can share the same plane structure referenced by this polygon.

The CBSPLeaf Class

In the previous implementations of our kD-tree, oct-tree and quad-tree classes, we made extensive use of the 'CBaseLeaf' class to attach various pieces of information to each terminal node. This information included items such as the axis aligned bounding box of the space contained within the leaf, in addition to storing references to any polygon fragments that were contained within that leaf node's interior. The leaf structure used by the new BSP tree compiler class bears a striking resemblance to that original leaf concept.

```
class CBSPLeaf
{
public:

    // Constructors & Destructors
             CBSPLeaf( );
    virtual ~CBSPLeaf( );

    // Public Variables for This Class
    std::vector<long>   FaceIndices;
    CBounds3            Bounds;

    // Public Member Functions Omitted
};
```

Although our previous implementation of the leaf class contained many more run-time specific member variables, the basic premise is the same. This class stores a list of every polygon that was collected at any terminal node by the hierarchy compilation process, in addition to the axis aligned bounding box information that has been so useful to us in the past.

Let us examine each of these member variables before we move on to discuss the methods exposed by this class.

std::vector<long> FaceIndices

Unlike the previous implementation of the 'CBaseLeaf' class in which we stored direct pointers to scene polygon objects, recall that we are using an index based, file friendly mechanism in order to reference the different pieces of information in the tree. The 'FaceIndices' member variable therefore, stores a list of indices that reference individual elements with the BSP tree class's internal polygon array. Because this array need only store simple integer values that do not change after the leaf has been built, this member uses a simple STL vector type to provide an easy means by which to insert and access the polygon index data. Once the tree has been built, the indices stored in each leaf can then be used to retrieve the relevant data from the BSP tree's centralized polygon array.

CBounds3 Bounds

The 'Bounds' member is of the type 'CBounds3' – one of our new math utility classes – and is used to store the world space axis aligned extents of every polygon collected and stored within this leaf. This information will be written out to the export file along with the leaf structure, and can be imported and used in a run-time / rendering application to provide additional frustum culling or broad phase information when collect leaves for further consideration.

CBSPLeaf::BuildFaceIndices

The 'BuildFaceIndices' method is the only function defined within the 'CBSPLeaf' class. This function is designed to populate the polygon index data contained within the 'FaceIndices' STL vector. This function is called only by the BSP compiler's recursive 'BuildBSPTree' function and accepts a single parameter that describes the first item in a linked list of polygons to be stored within this leaf. Prior to calling this function, the 'BuildBSPTree' function updates the 'OriginalIndex' member of each 'CBSPFace' object contained within this list. Each 'OriginalIndex' variable is assigned a value that

describes the final location within the BSP tree's internal polygon array into which the polygon has been inserted. This index information is subsequently used to populate the member 'FaceIndices' array within this function.

The first thing we do in this function is to reset the bounding box member that will be used to describe the world space extents of every polygon stored within this leaf. This bounding box will be constructed incrementally as each polygon within the specified linked list is visited later in this function.

```
bool CBSPLeaf::BuildFaceIndices( CBSPFace * pFaceList )
{

    CBSPFace       *Iterator      = pFaceList;
    unsigned long   OriginalIndex = 0;

    // Reset bounds, will be rebuilt
    Bounds.Reset();
```

With the 'Bounds' member reset, we can now begin to iterate through the specified polygon list. Notice in the previous code snippet how the pointer describing the first element of the list is copied into a local variable named 'Iterator'. This variable will be used as the means by which we iterate through the linked polygon list.

While traversing the linked list of polygon data passed to this function, the first thing we must do is extract the 'OriginalIndex' value from the current polygon that will be added to the 'FaceIndices' member array. Before this happens however, this function includes a test to determine whether or not this index has already been added to the leaf's internal polygon list. This is achieved with a call to the 'std::find' library function that is designed to iterate through an STL vector, searching for an element that contains the specified value. In doing so, we prevent duplicate polygon indices from being added to the same leaf for whatever reason.

If no duplicate was found in the 'FaceIndices', we are now free to add the polygon index to this array. Due to the fact that we are adding many potential polygon indices to the STL vector member within a loop however, we use the capacity threshold resizing logic in order to prevent this array from being resized / reallocated for every index added. We have observed this kind of vector resizing logic in the past, but to summarize the process used here; if the total number of elements in the vector *including* the new index is found to exceed its current internal capacity then we allocate additional space by calling the vector's 'Reserve' method. To this method we specify a capacity equal to the current number of items stored in the vector plus an additional number of slack elements into which the vector can grow. In this way, the vector will only ever be physically resized each time we have added a number of indices equal to this additional slack space. The number of additional elements reserved in this function is defined by the constant shown below.

```
#define BSP_ARRAY_THRESHOLD 100
```

Once we have reserved any required number of elements in the 'FaceIndices' member, we can then add the 'OriginalIndex' value taken from the current polygon with a call to the STL vector's 'push_back' method.

```
    // Iterate building list
    while ( Iterator != NULL )
    {
        // Get the original polygon's index
        OriginalIndex = Iterator->OriginalIndex;

        try
        {
            // Make sure this index does not already exist in the array?
            if ( std::find(FaceIndices.begin(), FaceIndices.end(),
                           OriginalIndex) == FaceIndices.end())
            {

                // Resize the vector if we need to
                if (FaceIndices.size() >= (FaceIndices.capacity() - 1))
                {
                    FaceIndices.reserve( FaceIndices.size() +
                                         BSP_ARRAY_THRESHOLD );
                } // End If

                // Finally add this face index to the list
                FaceIndices.push_back(OriginalIndex);

            } // End If needs adding

        } // End Try Block
```

If an exception occurred during any of the above operations, we need to catch this situation and release any resources that were allocated before returning a failure code to the calling function

```
        catch (...)
        {
            // Clean up and bail
            FaceIndices.clear();
            return false;
        } // End Catch
```

In the final stages of this loop we must now grow the leaf's bounding box to include the current polygon's vertex data. This is done with a call to the 'CalculateFromPolygon' method of the leaf' 'Bounds' member. Recall that, in order for this function to grow the bounding box extent values using the specified vertex data, we must pass a value of false to the final 'reset' parameter.

With this polygon fully considered, we finally move on to the next polygon ready for the following iteration of the while loop. If this polygon was the last item in the linked list, the 'Next' variable will contain a value of NULL that would be subsequently transferred into the local 'Iterator' pointer, causing the while loop to exit.

```
        // Build into current bounding box
        Bounds.CalculateFromPolygon( Iterator->Vertices, Iterator->VertexCount,
                                     sizeof(CVertex), false );
```

```
        // Move to next poly
        Iterator = Iterator->Next;

    } // End While
```

At this stage, the 'FaceIndices' STL vector will contain an index to each polygon passed in to this leaf for storage. When adding each of the polygon indices to this array, recall that we used a capacity threshold technique to prevent the STL vector from having to be reallocated and duplicated every time a new index value was added. As we know, this block resizing technique can result in an STL vector having an internal capacity that is much larger than might actually be required to store the index values. In order to prevent these arrays from needlessly consuming this additional slack memory, the final task undertaken by this function is to optimize the memory allocated by the 'FaceIndices' vector if required.

```
    // Optimize the vector
    if (FaceIndices.size() < FaceIndices.capacity())
        FaceIndices.resize( FaceIndices.size() );

    // Success
    return true;
}
```

The CBSPNode Class

This class is used to represent the individual nodes within the hierarchy of the new BSP leaf tree. Similar to the node class we have previously implemented in both the kD-tree and BSP node tree compiler projects, this node class is represented by a single separating plane used to partition the space on either side into two equal halfspaces. This is a relatively simple class that is based on those we are already familiar with so let us move straight on to examining the class declaration.

```
class CBSPNode
{
public:

    // Constructors & Destructors
             CBSPNode( );
    virtual ~CBSPNode( ) {};

    // Public Variables for This Class
    long            Plane;
    long            Front;
    long            Back;
    CBounds3        Bounds;

    // Public Member Functions Omitted
};
```

At this point, it should be reasonably clear as to the purpose of each of the member variables declared within this class. In the interest of completeness however, let us just briefly examine each member before moving on to discuss the class methods.

long Plane

Just as with the 'CBSPFace' class, the node maintains an index into the BSP tree's internal array in order to describe the plane on which this node lies. This index is taken directly from the polygon object that was used as the candidate plane for the generation of this node. In this way we are able to reuse not only that plane information shared between individual polygons, but also between coplanar nodes and polygons alike.

long Front

This member variable has a dual purpose. Recall from our earlier discussion of the file based BSP data structures; we will use the same front member variable to attach both nodes *and* leaves to the appropriate side of this node. The value stored in this member is used to represent an index into one of the BSP tree's centralized data arrays. The type of data structure that is attached to the front of this node via this member depends on the sign of the value stored here. If this variable contains a negative value, this means that there is a leaf attached to the front of the node and is used to represent an index to an element within the BSP tree's leaf array. If this value is positive, then there is simply another node attached as the front child. This is then used as the index into the BSP tree's node array.

long Back

This purpose and use of this member variable is identical to that of the aforementioned 'Front' member. The only difference here is that this member is used to describe the index of either the node or leaf attached as the child *behind* this node.

CBounds3 Bounds

This member represents the axis aligned world space extents for this node. Recall that the bounding box contained within a BSP tree node is used to describe the world space extents of *every* polygon that will exist in the tree at some point beneath it in the hierarchy.

CBSPNode::CBSPNode()

This class contains only a single default constructor in which each of the primitive typed member variables are defaulted to a value of '-1'. This value is used to signify that the information has not yet been initialized. The only variable that we do not initialize here is the 'Bounds' member. This is due to the fact that the constructor of this object will be called implicitly, whenever an instance of this node class is created.

```
CBSPNode::CBSPNode()
{
    // Initialise anything we need
    Plane   = -1;
    Front   = -1;
    Back    = -1;
}
```

CBSPNode::CalculateBounds

The only member function defined within this class is the 'CaclulateBounds' method shown in the following block of code. Called during the BSP construction process, this is a utility function designed

to populate the ‘Bounds’ member of this object with the world space extents of every polygon that will exist in the tree at some point underneath this node.

This method accepts two parameters. The first of these two describes the first element in a linked list of ‘CBSPFace’ object pointers that will be taken into consideration during the calculation of this bounding box. The second parameter is a simple Boolean value that dictates whether the specified polygon data should be used to simply grow any existing bounding box values, or whether it should first be reset.

```
void CBSPNode::CalculateBounds( CBSPFace * pFaceList, bool ResetBounds )
{
    CBSPFace *Iterator = pFaceList;

    // Reset bounding box and grow from default state?
    if ( ResetBounds ) Bounds.Reset();

    // Calculate bounding box based on the face list passed
    while ( Iterator )
    {
        // Grow the bounding box values
        Bounds.CalculateFromPolygon( Iterator->Vertices, Iterator->VertexCount,
                                     sizeof(CVertex), false );

        // Move on to the next polygon
        Iterator = Iterator->Next;

    } // End If
}
```

The techniques used in the development of this function have been discussed in detail elsewhere in this lesson, so we will not go into any further detail here. We will discuss how and when this function is to be used shortly, as we continue on to discuss the main leaf based BSP tree compilation class in the following section.

The CBSPTree Class

Up until this point we have spent a great deal of time focusing on the specifics of our new pre-processing tool and the various associated framework classes that have been introduced. These discussions were vital in order for us to understand the techniques involved in building the compiler application for lab project 16.2. In addition, this coverage has laid the foundation that will allow us to discuss the various compilation modules, without having to stop and examine any new support and utility functionality utilized in the process. Let us therefore continue on to examine the new polygon aligned BSP leaf tree compiler that we have made reference to several times in this chapter.

While the ‘CBSPTree’ class serves as the basis for many of the compilation modules that are covered in both this lesson and the next, it also acts as a compilation module in its own right. Referring back to our discussion of the ‘PerformBSP’ method of the ‘CCompiler class, we know that a BSP tree is constructed from the scene information in much the same way as we have done in each of our previous spatial hierarchy lab project applications. This has traditionally involved passing scene polygon data into the compiler class, triggering the compilation process and finally interpreting and storing the compiled

information in a manner suitable for rendering. In this pre-processing application, the high level concepts involved in the use of the BSP tree class as a compilation module are very similar. The one exception is that, after compiling the tree we must interpret and store the compiled information in a manner suitable for export. With this in mind, let us now examine the declaration of the new 'CBSPTree' class in order to see just what information will be built.

As before, we have removed the list of member functions in this declaration to improve readability, so check the source code for a full list of methods.

```
class CBSPTree
{
public:

    // Constructors & Destructors for This Class.
             CBSPTree();
    virtual ~CBSPTree();

private:

    // Private Variables for This Class.
    CBSPFace       *m_pFaceList;
    unsigned long   m_lActiveFaces;
    vectorNode      m_vpNodes;
    vectorPlane     m_vpPlanes;
    vectorLeaf      m_vpLeaves;
    vectorBSPFace   m_vpFaces;
    vectorBSPFace   m_vpGarbage;
    CBounds3        m_Bounds;
    BSPOPTIONS      m_OptionSet;
    ILogger        *m_pLogger;
    CCompiler      *m_pParent;
};
```

As you can see, there are many variables declared within this new 'CBSPTree' class. While we are familiar with the types of information stored within many of these members at this point, there are several items in this list that we have not yet encountered. Therefore, before we move on to the discussion of the class implementation, let us first familiarize ourselves with the role of each of these member variables.

CBSPFace * m_pFaceList

Before we can even begin to think about compiling the tree structure, we obviously must have access to the list of polygons to which the nodes of the polygon-aligned BSP tree will be oriented. This member variable contains the first / head element within a linked list of 'CBSPFace' objects that will be used as the source set for the BSP compilation process. In the earlier discussion of the 'CCompiler::PerformBSP' function, we saw how each polygon in the scene was passed into the BSP tree object through a call to its 'AddFaces' method. This function accepted an array of 'CFace' object pointers that were to be considered as valid polygons for use by the BSP tree compilation process. We will discuss how the 'AddFaces' method is implemented shortly, but in summary this function takes each of the specified 'CFace' objects, duplicates that polygon's data into a new 'CBSPFace' object before finally attaching that new polygon to the linked list maintained by this member.

vectorNode m_vpNodes

The ‘m_vpNodes’ member is used as the centralized container array for the *final* list of hierarchy nodes contained within the compiled BSP tree. The information contained within this node array will later be exported to file after each compilation process has been run. This member variable is of the type ‘vectorNode’ which is a typedef of a standard STL vector template designed to store a series of ‘CBSPNode’ object pointers.

```
typedef std::vector<CBSPNode*>   vectorNode;
```

In order to access the data stored within this vector easily and safely, the BSP tree class defines both the ‘GetNode’ and ‘GetNodeCount’ accessor functions for use by the application. Existing elements can also be assigned with the use of the ‘SetNode’ method. A list of these accessor functions can be found and the end of this variable listing if you wish to examine them.

vectorPlane m_vpPlanes

This member variable is intended to store a list of every plane used by both the polygons and nodes contained within this BSP tree. Recall that we will be relying heavily upon shared plane information in this BSP tree implementation in order to save space and – as we will discover shortly – to improve the accuracy of the BSP compilation process. As a result, individual planes stored within this array may be referenced by many different sources before, after and during the compilation process. The information contained within this plane array will also later be exported to file after each compilation process has been run.

The ‘m_vpPlanes’ member is of the type ‘vectorPlane’ which is a typedef of a standard STL vector template designed to store a series of ‘CPlane3’ object pointers.

```
typedef std::vector<CPlane3*>    vectorPlane;
```

In order to access the data stored within this vector easily and safely, the BSP tree class defines both the ‘GetPlane’ and ‘GetPlaneCount’ accessor functions for use by the application. Existing elements can also be assigned with the use of the ‘SetPlane’ method.

vectorLeaf m_vpLeaves

The ‘m_vpLeaves’ member is used as the centralized container array for the *final* list of leaf objects contained within the compiled BSP tree. The information contained within this leaf array will later be exported to file after each compilation process has been run. This member variable is of the type ‘vectorLeaf’ which is a typedef of a standard STL vector template designed to store a series of ‘CBSPLeaf’ object pointers.

```
typedef std::vector<CBSPLeaf*>   vectorLeaf;
```

In order to access the data stored within this vector easily and safely, the BSP tree class defines both the ‘GetLeaf’ and ‘GetLeafCount’ accessor functions for use by the application. Existing elements can also be assigned with the use of the ‘SetLeaf’ method.

vectorBSPFace m_vpFaces
The 'm_vpFaces' member is used as the centralized container array for the *final* list of polygon objects contained within the compiled BSP tree. The information contained within this polygon array will later be exported to file after each compilation process has been run. This member variable is of the type 'vectorBSPFace' which is a typedef of a standard STL vector template designed to store a series of 'CBSPFace' object pointers.

```
typedef std::vector<CBSPFace*>   vectorBSPFace;
```

In order to access the data stored within this vector easily and safely, the BSP tree class defines both the 'GetFace' and 'GetFaceCount' accessor functions for use by the application. Existing elements can also be assigned with the use of the 'SetFace' method.

vectorBSPFace m_vpGarbage
Logically, as the tree compilation process becomes ever more comprehensive, there are likewise more situations in which failures might occur. If a failure does happen, it is always preferable for the application to gracefully handle this situation such that the user might take further action to resolve the source of the problem. This member array is provided in order to make the process of handling such errors a little easier during the recursive BSP compilation procedure. By providing a convenient location for the collection of polygons that should be released at a later point in time, we can actually bypass some significant problems introduced when trying to clean up any allocated polygon data in the middle of this heavily recursive process. The specifics of the error handling and garbage collection scheme will be covered a little later on in this section.

CBounds3 m_Bounds
As with many of the classes to which we have previously been introduced, the BSP tree class also stores an axis aligned bounding box that is used to represent the total world space extents of every node, leaf and polygon contained within the compiled tree. This information will be crucial during the portal compilation process we will develop in the next lesson.

unsigned long m_lActiveFaces
This member is used primarily for the purposes of informing the user about the progress of the compilation process. The value stored here simply maintains a count of the number of polygons currently active within the compilation process. With this information we can determine how far through the BSP compile process we have come simply by comparing this total number of polygons against the number of polygons that have been removed from consideration at each step.

BSPOPTIONS m_OptionSet
This member stores the various settings, specified by the application to inform the compiler how the BSP tree should be compiled. This options structure is set using the 'SetOptions' accessor function outlined on the following page.

ILogger * m_pLogger
In order for the BSP compiler to report progress, error and useful status information to the user, this member variable stores a pointer to the application defined logging class. While the logging feature remains optional, this member can be set with a call to the 'SetLogger' accessor function defined by this

class. In this lab project, the logging class instance is passed to this object by the 'CCompiler::PerformBSP' function.

CCompiler * m_pParent

Each compilation module class maintains a member that stores a reference to the parent compiler class that created it. This member is set with a call to the 'SetParent' accessor function defined by each of these classes. This information is used by each of these processing modules in order to test the current state of the compiler to determine if the compile operation has been either paused or cancelled. Although we have omitted much of the logging and progress functionality from the code listings in this workbook, you should take a look at the source code for lab project 16.2 to see this process in action.

BSP Tree Accessor Functions

There are many accessor functions defined within the BSP tree class. In each case, the body for these functions can be found in the class declaration contained in the header file, rather than in the source module / .CPP file. We include the function bodies in the header mostly for convenience. However, because these functions are very simple and are accessible by any source module that might include this header, these functions are much more likely to be chosen to be inline functions. Due to the fact that these methods are so small, and will be called often, this is an ideal situation.

We will not go into detail about how each of these functions is implemented, for this you should take a look at the 'CBSPTree.h' header file contained in the 'Compiler Source' project directory. Instead we will give a brief overview of each category of accessor function available in this class.

The first series of accessor functions defined within the BSP tree class are those which return the number of elements stored within the STL vector for each type of data stored. These functions wrap a call to the STL vector 'size' method, and simply return that information to the calling function.

```
unsigned long   GetNodeCount  ( ) const
unsigned long   GetLeafCount  ( ) const
unsigned long   GetPlaneCount ( ) const
unsigned long   GetFaceCount  ( ) const
```

The second set of accessor functions defined here are those that actually retrieve a pointer to each specific data class from the member arrays. Each of these functions accepts a single parameter that is used to specify the index to the element in the array which the calling function would like to retrieve. Rather than simply have the underlying STL vector throw an exception if the specified index is out of bounds however, these functions test the value of the index parameter, returning NULL if it exceeded the end of the array. This allows the calling function to retrieve each type of object safely without having to wrap each call with exception handling logic.

```
CBSPNode        *GetNode       ( unsigned long Index ) const
CPlane3         *GetPlane      ( unsigned long Index ) const
CBSPLeaf        *GetLeaf       ( unsigned long Index ) const
CBSPFace        *GetFace       ( unsigned long Index ) const
```

The third set of accessor functions are called in order to *set* an individual element in each of the member arrays. These functions each accept two parameters. The first is the index to the element in the relevant

array that the calling function would like to set. The second is a pointer to the data object that should be stored in that specified array element.

```
void            SetNode       ( unsigned long Index, CBSPNode   * pNode  )
void            SetPlane      ( unsigned long Index, CPlane3    * pPlane )
void            SetLeaf       ( unsigned long Index, CBSPLeaf   * pLeaf  )
void            SetFace       ( unsigned long Index, CBSPFace   * pFace  )
```

The fourth and final set of accessor functions are those that set the various pieces of information required by each compilation process module. These include the process options, a pointer to the parent compiler and a pointer to the class defined logging class. These functions simply store those specified values into the applicable member variables declared by this class.

```
void            SetOptions    ( BSPOPTIONS Options    )
void            SetParent     ( CCompiler * pCompiler )
void            SetLogger     ( ILogger * pLogger     )
```

Now that we have familiarized ourselves with each component of the 'CBSPTree' class declaration, let us move directly on to the implementation of the all important class methods.

CBSPTree::AddFaces

The 'AddFaces' method is the means by which any applicable scene polygon data is added to the tree ready for compilation. We have seen how this method is called in our earlier coverage of the 'CCompiler::PerformBSP' function.

```
HRESULT CBSPTree::AddFaces( CFace ** ppFaces, unsigned long lFaceCount )
{
    CBSPFace *NewFace = NULL;

    // Validate Parameters
    if ( !ppFaces || lFaceCount <= 0 ) return BCERR_INVALIDPARAMS;

    // Release the old tree data (if any)
    if (!m_pFaceList) ReleaseTree();
```

This function accepts two parameters. The first is an array of 'CFace' object *pointers* that contains the list of polygons that have been selected by the application to be included in the BSP compilation process. The second parameter specifies the number of polygons contained within that array.

After ensuring that each of the specified parameters are valid, this function first releases any tree data that already exists within this object should the class have been previously used. This is only done during the first call to the 'AddFaces' function however. We can determine if this is the first time that this function has been called by testing the value stored within the 'm_pFaceList' member variable. If this variable currently contains a NULL pointer, this means that no polygon data has yet been collected. This is something that will no longer be the case after this function has completed its first execution.

At this stage, we begin to loop through each of the polygons passed into this function ready to populate the 'm_pFaceList' linked list member variable. This list will contain the data that is actually used to

construct the BSP tree in the next step. To this end, each valid ‘CFace' polygon object encountered in the array passed to this function is duplicated into a newly allocated ‘CBSPFace’ polygon with a call to the ‘AllocBSPFace’ function. This function wraps much of the allocation and error handling logic on our behalf and is an easy and safe way to create a new BSP specific polygon object. Into this newly duplicated polygon we store the index that describes the order in which this polygon was created. This value is retrieved from the ‘m_lActiveFaces’ member variable which is subsequently incremented.

```
    // First add the mesh polygons to the initial linked list
    for ( unsigned long i = 0; i < lFaceCount; i++ )
    {

        // Add if available
        if (ppFaces[i])
        {
            // Allocate the new BSPFace
            if (!(NewFace = AllocBSPFace( ppFaces[i] )))
            {
                ReleaseTree();
                return BCERR_OUTOFMEMORY;
            } // End If Out of Memory

            // Store original index for later use
            NewFace->OriginalIndex = m_lActiveFaces;
            m_lActiveFaces++;
```

With this source polygon duplicated into the new ‘CBSPFace’ typed object, we attach this new polygon to the head of the internal source polygon linked list referenced by the ‘m_pFaceList’ member.

```
            // Attach this to the list
            NewFace->Next = m_pFaceList;
            m_pFaceList   = NewFace;
```

In the spatial hierarchy concepts developed in previous lab projects, we had the ability to generate trees in which the polygon data stored in its leaves were not split against the separating planes. When the non-split option was selected in these earlier compiler classes, the source polygon data used in the construction of the tree remained in the tree’s internal polygon array from the start. This was in contrast to the splitting method in which the polygon fragments were added to the internal polygon array only when they were being added to a leaf in the tree. This same logic is applied to our new BSP leaf tree compiler.

In the following block of code we can see that the current original source polygon is duplicated and added directly to the tree’s final polygon array if the non-split option was selected by the application. Recall that earlier in this function we stored the current face count in the ‘OriginalIndex’ member of each polygon stored in the linked list. If the non-split resulting tree option has been selected, this ‘OriginalIndex’ value will correspond with the element in which these duplicate polygons have been stored in the tree’s final polygon array. We will examine how all of this is tied together in the coverage of the ‘ProcessLeafFaces’ method later in this section.

```
            // Non Split tree?
            if ( m_OptionSet.TreeType == BSP_TYPE_NONSPLIT )
```

```
            {
                // Allocate some storage space
                if (!IncreaseFaceCount())
                {
                    ReleaseTree();
                    return BCERR_OUTOFMEMORY;
                } // End if out of memory

                // Allocate a duplicate of the original original
                if (!(NewFace = AllocBSPFace( ppFaces[i] )))
                {
                    ReleaseTree();
                    return BCERR_OUTOFMEMORY;
                } // End if out of memory

                // Store this new pointer
                SetFace( GetFaceCount() - 1, NewFace );

            } // End if backup required

        } // End If Face Available
```

With the current polygon now processed, we move onto the next item in the specified array. Once the loop has run its course, this function returns a success code back to the calling function.

```
    } // Next Face

    // Success
    return BC_OK;
}
```

CBSPTree::CompileTree

After having added each of the polygons to be considered by the BSP tree compiler, this function is called in order to begin the actual tree compilation process. Put simply, this method wraps each of the calls to the various pieces of functionality required in order to construct the BSP tree.

The first process that we must undertake when building the BSP tree in this application is to construct the combined plane array into which each ‘CBSPFace’ object’s ‘Plane’ member will reference. This information is used both to reduce the amount of memory consumed for plane data between coplanar polygons, in addition to improving the accuracy of the BSP compilation process as we shall demonstrate shortly.

Once the pre-compiled plane array information has been generated, we are ready to begin the construction of the BSP tree itself. Before we can do this however, we must first allocate the root node that will be passed into the initial call of the main recursive build procedure. This is done with a call to the ‘IncreaseNodeCount’ method discussed later in this section.

```
HRESULT CBSPTree::CompileTree( )
{
    HRESULT ErrCode;
```

```
    // Validate values
    if (!m_pFaceList) return BCERR_INVALIDPARAMS;

    // Calculate our plane array
    if (FAILED(ErrCode = BuildPlaneArray())) return ErrCode;

    // Allocate our root node
    if (!IncreaseNodeCount()) return BCERR_OUTOFMEMORY;

    // Log – BSP: Building BSP Tree
```

At this point, we make a call to the 'BuildBSPTree' function, passing in both the index to the root node we allocated a moment before (the index of the root node will always be zero in this implementation), in addition to the linked list of polygon data referenced by the 'm_pFaceList' member.

```
    // Compile the BSP Tree
    if (FAILED(ErrCode = BuildBSPTree(0, m_pFaceList))) return ErrCode;
```

Assuming no errors occurred during the compilation process above, we should now have compiled a fully functional BSP tree. With each of the polygons in the source linked list now stored within the BSP tree data structures, we no longer own these polygons. As a result, we reset the 'm_pFaceList' with a NULL pointer value to remove all references to those polygons should we attempt to release this list, or append new polygons to it with future calls to 'AddFaces'.

```
    // Reset Face List
    m_pFaceList = NULL;
```

Now that we have populated the internal polygon array with the final set used in the construction of the BSP tree, the final task undertaken by this function is to calculate the tree's overall bounding box. We can do this quickly and efficiently using the 'CalculateFromPolygon' method exposed by the 'm_Bounds' object, passing in the vertex data from each polygon now stored in the tree as a whole.

With this final piece of information built, we finally return back to the calling function, notifying it of our success.

```
    // Build the trees bounding box
    m_Bounds.Reset();
    for ( ULONG i = 0; i < GetFaceCount(); i++ )
    {
        m_Bounds.CalculateFromPolygon( GetFace(i)->Vertices,
                                       GetFace(i)->VertexCount,
                                       sizeof(CVertex), false );

    } // Next Face

    // Log – BSP: Compile Success

    // Success
    return BC_OK;
}
```

CBSPTree::BuildPlaneArray

We have discussed at several points within this lesson just how beneficial the construction of a combined plane array can be during the compilation of a polygon aligned BSP tree. Not only does this pre-building technique provide a much smaller memory and file footprint with respect to the plane data itself, it also allows us to construct a BSP compiler class that is extremely stable and as fault tolerant as possible. Regarding the latter, we will observe later how building this plane array in advance can eliminate hundreds of potentially error prone polygon and vertex classification tests to be replaced with a simple integer equality test. Before we get to that point however, let us first examine how this new combined plane array is constructed. This should give us a better understanding of how these methods employ this information later in this chapter.

```
HRESULT CBSPTree::BuildPlaneArray()
{
    CBSPFace * Iterator = NULL;
    CPlane3    Plane, * TestPlane;
    CVector3   Normal, CentrePoint;
    int        i, PlaneCount;
    float      Distance;

    // Log – BSP: Building Initial Plane Array
```

This function accepts no parameters and employs a simple HRESULT style return code system for reporting any errors that may have occurred.

Given the list of source polygons contained within the ‘m_pFaceList’ member, this function begins by looping through each of these polygons using the standard linked list iteration logic we should already be familiar with. For each polygon in the list, the first job is to construct a ‘CPlane3’ object that describes the plane on which this polygon lies. As we know, in order to construct a plane from a polygon we need two pieces of information. The first is the polygon normal and the second is a point that lies on the intended plane. For the point we might perhaps use the position of the first vertex stored within the polygon vertex array. Due to the limited accuracy of single precision floating point values however, there is no guarantee that every vertex in the polygon lies on *exactly* the same plane. In many cases there will be a very slight twist to the polygon due to the vertices becoming slightly misaligned. As a result, in such a accuracy sensitive situation, it is not really ideal that we select any one vertex as the point used to construct the plane. For this reason, the first thing we do inside the main loop is to sum the position of every vertex in the current polygon, and then divide by the total number of vertices. This will give us an average center point that should provide us with a more accurate point on which to base the plane.

With the surface normal taken directly from the polygon and the averaged center point now computed we construct a new plane object by passing the normal and point information to the relevant overloaded ‘CPlane3’ constructor. This will automatically convert the normal/point information into the normal/distance values maintained by the plane class.

```
    // Loop through each face
    for ( Iterator = m_pFaceList; Iterator; Iterator = Iterator->Next )
```

```
    {
        // Calculate polygons centre point
        CentrePoint = Iterator->Vertices[0];
        for ( i = 1; i < (signed)Iterator->VertexCount; i++ )
              CentrePoint += Iterator->Vertices[i];

        // Average Vertices
        CentrePoint /= (float)Iterator->VertexCount;

        // Calculate polygons plane
        Plane = CPlane3( Iterator->Normal, CentrePoint );
```

Once we have generated the plane based on the information contained within the current polygon, this function then proceeds to check if a similar plane already exists in the plane array constructed so far. We can do this simply by comparing both the normal and the distance values contained within each plane. If both planes are equal – remembering to use a tolerance in order to ensure that we cater for any floating point precision errors – then we simply break from the loop having found a matching plane.

```
        // Search through plane list to see if one already exists
        PlaneCount = GetPlaneCount();
        for ( i = 0; i < PlaneCount; i++ )
        {
            // Retrieve the plane details
            TestPlane = GetPlane(i);

            // Test the plane details
            if ( fabsf(TestPlane->Distance - Plane.Distance) < 1e-5f &&
                 Plane.Normal.FuzzyCompare( TestPlane->Normal, 1e-5f )) break;

        } // Next Plane
```

If the previous loop ran to its conclusion then we know that no plane matching that of the current polygon was found in the plane array. We can test for this case by checking to see if the loop counter variable ‘i' is equal to the number of planes that were to be tested in that loop – ‘PlaneCount’. If this is the case then this function proceeds to add the unique plane described by this polygon the plane array stored within this class.

Now that we have an index to either an already existing plane, or the newly generated plane, this index must finally be stored in the polygon’s ‘Plane’ member ready for use in the BSP compilation process.

```
        // Add plane if none found
        if ( i == PlaneCount )
        {
            if (!IncreasePlaneCount()) return BCERR_OUTOFMEMORY;
            *GetPlane( PlaneCount ) = Plane;

        } // End if no plane found

        // Store this plane index
        Iterator->Plane = i;
```

We mentioned earlier that it was possible for floating point inaccuracies to cause one more of the vertices in this polygon to be slightly misaligned, causing this polygon to twist to a small degree. Herein lies one of the techniques that we have implemented to help improve the accuracy of the BSP tree compiler.

In the following code we begin to loop through each of the vertices contained within the current polygon. For each vertex encountered here we first calculate the distance at which that vertex lies from the new or existing plane we assigned to the polygon in the previous steps. We then use this information to push the vertex back along the plane normal by that distance such that it will now lie exactly on the surface of that plane. As you might imagine, once every vertex in the polygon has been processed in this way, any twisting that may have caused incorrect classification results during compilation should now have been resolved.

With this step completed we then display the updated progress information to the user – via the logging interface – and move on to the next polygon.

```
        // Retrieve the plane details
        Normal   = GetPlane(i)->Normal;
        Distance = GetPlane(i)->Distance;

        // Ensure that all vertices are on the selected plane
        for ( unsigned long v = 0; v < Iterator->VertexCount; v++ )
        {
            float result = Iterator->Vertices[v].Dot( Normal ) + Distance;
            Iterator->Vertices[v] += (Normal * -result);

        } // Next Vertex

        // Log – BSP : Update Progress

    } // Next Face
```

Once every polygon in the ‘m_pFaceList’ linked list member has been tested and assigned a plane index, this function finishes simply by reporting the successful completion to the user, and returning control back to the calling function – ‘CompileTree’.

```
    // Log – BSP: Operation Successful

    // Success
    return BC_OK;

}
```

CBSPTree::BuildBSPTree

This recursive function is the very heart of the polygon aligned BSP leaf tree compiler. It is functionally very similar in many respects to those we have implemented in the past. From a high level perspective, the following list provides a general summary of the polygon aligned leaf BSP tree construction process:

1) The first step is to select a polygon from those passed into this function that will be used as the candidate plane for a new node. This polygon should be removed from further consideration as a node plane candidate.

2) Loop through each polygon in the list, including the one selected in the previous step.

3) Classify the current polygon against the node plane and add it to the appropriate child list depending on the result of the classification.

4) If the polygon was found to span the node plane, split the polygon against this plane in order to generate two new polygon fragments. Add each of these fragments to the appropriate child list and release the original polygon.

5) Once each polygon has been processed, determine if there are any remaining candidates in front or behind and attach a new leaf or node depending on the outcome of that test.

6) If new nodes were generated, recurse down into those nodes and begin the process again.

As you can see the general construction process remains the same in principle as that employed by the node BSP tree, and even the kD-tree in part. There are, however, a few intricacies and additional steps not included in this list that we will discover as we take a look at how this function is implemented.

```
HRESULT CBSPTree::BuildBSPTree( unsigned long Node, CBSPFace * pFaceList )
{
    // 49 Bytes including Parameter list (based on __thiscall declaration)
    CBSPFace     *TestFace   = NULL, *NextFace  = NULL;
    CBSPFace     *FrontList  = NULL, *BackList  = NULL;
    CBSPFace     *FrontSplit = NULL, *BackSplit = NULL;
    CBSPFace     *Splitter   = NULL;
    HRESULT       ErrCode    = BC_OK;
    CLASSIFYTYPE  Result;
    int           v;

    // Log – BSP: Update Progress
```

This function accepts two parameters. The first is the index to the current node being generated at this point in the recursive process. When calling the function for the first time, this parameter will contain a value of 0 signifying the root node. The second parameter is the first (or head) item of the linked list containing each of the polygons to be processed and classified at this level in the tree.

With this information to hand, the first task that this function must undertake is to select an appropriate node plane candidate – or splitter polygon – from the list passed to this level of the recursive build procedure. This is achieved with a call to the ‘SelectBestSplitter’ method that we first encountered in lab project 16.1. To this function we pass the current list of available polygons, the number of polygons that we would like to sample for selection as well as the split heuristic constant. The ‘SelectBestSplitter’ function will search through the list specified and select an appropriate polygon from those that has not already been used as a splitter in the past. If everything was successful, a reference to this selected

polygon will be returned from the selection routine and stored in the local 'Splitter' variable for use throughout the remainder of this function.

Now that we have an appropriate polygon that can be used as the candidate plane for the node at this level, this polygon's 'UsedAsSplitter' member is set to true. This is done in order to remove it from consideration during further calls to the 'SelectBestSplitter' function. The index stored in the 'Plane' member of this polygon is also then copied into the match member within the current node.

```
    // Select the best splitter from the list of faces passed
    Splitter = SelectBestSplitter( pFaceList, m_OptionSet.SplitterSample,
                                   m_OptionSet.SplitHeuristic);
    if (!Splitter) { ErrCode = BCERR_BSP_INVALIDGEOMETRY; goto BuildError; }

    // Flag as used, and store plane
    Splitter->UsedAsSplitter = true;
    GetNode(Node)->Plane     = Splitter->Plane;
```

Once we have selected the candidate splitter polygon used to generate the node at this stage we then begin the process of iterating through the list of polygons passed in to this level of the recursive procedure in the same way as we have done several times in the past.

```
    // Begin face iteration....
    for ( TestFace = pFaceList; TestFace != NULL;
          TestFace = NextFace, pFaceList = NextFace )
    {
        // Store plane for easy access
        CPlane3 * pPlane = GetPlane( TestFace->Plane );

        // Store next face, as 'TestFace' may be modified / deleted
        NextFace = TestFace->Next;
```

One of the most beneficial aspects of storing indices to the shared plane information within each polygon is that we can determine whether two faces or nodes are coplanar with one another simply by testing for equality between their plane indices. As you might imagine, this could potentially save us from having to perform hundreds or even thousands of plane distance calculations that might be required when testing each vertex via the 'ClassifyPoly' method. Of course, if the plane indices do not match then we must still perform the more traditional polygon classification step, but the savings gained make this step more than worthwhile. From an accuracy standpoint the benefits gained by performing this simple check are also significant because we do not need to use the more inaccurate vertex classification process to determine those polygons that are coplanar with the separating plane.

In the following code you can see this technique employed. If the polygon we are testing has a plane index that is equal to that of the splitter chosen earlier, then we simply store a value of 'CLASSIFY_ONPLANE' in the result variable. If the plane indices do not match however, then we call the plane's 'ClassifyPoly' method to perform the more traditional classification step.

```
        // Classify the polygon
        if ( TestFace->Plane == Splitter->Plane )
        {
```

```
            Result = CLASSIFY_ONPLANE;

        } // End if uses same plane
        else
        {
            Result = GetPlane(Splitter->Plane)->ClassifyPoly(TestFace->Vertices,
                                                             TestFace->VertexCount,
                                                             sizeof(CVertex));

        } // End if differing plane
```

The co-planar case is arguably the most critical of each of the classification cases which is one of the reasons why the aforementioned plane index test is so beneficial. In this on-plane case we must first determine if the polygon faces in the same direction as the current node plane. In our implementation we can use the plane's 'SameFacing' method to test for this.

If the polygon is found to face in the same direction as this coplanar node then we can automatically remove that polygon from being considered as a node plane candidate in the future. If it was not marked as used at this point, then any node generated from it would simply describe the same separating plane as that of the current node. Once this is done, we must then add the current polygon to the linked list representing those polygons or polygon fragments contained in the front halfspace of the node – the linked list headed by the local 'FrontList' variable.

If the polygon does not point in the same direction as the plane then, as we know, this polygon should *not* be removed from consideration in the leaf based BSP tree, and must go on to generate its own node. This polygon must be added to the linked list representing those polygons or polygon fragments contained in the back halfspace of the node – the linked list headed by the local 'BackList' variable.

```
        // Classify the polygon against the selected plane
        switch ( Result )
        {
            case CLASSIFY_ONPLANE:

                // Test the direction of the face against the plane.
                if ( GetPlane(Splitter->Plane)->SameFacing( pPlane->Normal ) )
                {
                    // Mark matching planes as used
                    if (!TestFace->UsedAsSplitter)
                    {
                        TestFace->UsedAsSplitter = true;

                        // Log – BSP : Update Progress Details

                    } // End if !UsedAsSplitter

                    TestFace->Next  = FrontList;
                    FrontList       = TestFace;
                }
                else
                {
                    TestFace->Next  = BackList;
                    BackList        = TestFace;
```

```
                } // End if Plane Facing
                break;
```

The front classification case is relatively straight forward. If we step into this case it means that the polygon is contained completely within the front halfspace of the node. As a result, this polygon is attached directly to the linked list referenced by the 'FrontList' variable.

```
            case CLASSIFY_INFRONT:
                // Pass the face straight down the front list.
                TestFace->Next      = FrontList;
                FrontList           = TestFace;
                break;
```

In a similar fashion to the front case, if the polygon we are testing is found to be completely contained within the back halfspace of the node's plane then it is simply attached to the linked list referenced by the local 'BackList' variable.

```
            case CLASSIFY_BEHIND:
                // Pass the face straight down the back list.
                TestFace->Next      = BackList;
                BackList            = TestFace;
                break;
```

If we step into the spanning case, we have of course found a situation in which the polygon intersects the current node plane, with a portion of that polygon found to lie on either side. This being the case, we must split this polygon into those two fragments separated by the plane in order to pass the relevant portion of the polygon down either side of the node. Before we can do this however we must first allocate the two new polygon objects that will contain these split fragments. To make the handling of errors a little easier in this application, we have implemented a function named 'AllocBSPFace' – covered shortly – that can be used to retrieve a new 'CBSPFace' instance. This is called twice, storing the two resulting polygon pointers into the 'FrontSplit' and 'BackSplit' variables respectively.

```
            case CLASSIFY_SPANNING:
                // Ensure this is not an invalid operation
                // Allocate new front fragment
                if (!(FrontSplit = AllocBSPFace()))
                {
                    ErrCode = BCERR_OUTOFMEMORY;
                    goto BuildError;
                }
                FrontSplit->Next    = FrontList;
                FrontList           = FrontSplit;

                // Allocate new back fragment
                if (!(BackSplit     = AllocBSPFace()))
                {
                    ErrCode = BCERR_OUTOFMEMORY;
                    goto BuildError;
                }
                BackSplit->Next     = BackList;
                BackList            = BackSplit;
```

Notice in the above code that we have immediately added the new polygon objects directly to the front and back lists. We do this in order to ensure that these fragments are automatically released – along with the others in each list – should an error occur in the following split operation.

Having allocated these two new polygon objects, we can now call the spanning polygon's 'Split' method, passing in the separating plane along with the two new polygon objects to be generated. Should it be successful, this will result in the 'FrontSplit' and 'BackSplit' polygons describing the portions of the original polygon that lay on either side of the plane.

```
                // Split the polygon
                if (FAILED( ErrCode = TestFace->Split(*GetPlane(Splitter->Plane),
                                                      FrontSplit,
                                                      BackSplit))) goto BuildError;
```

Recall in the earlier coverage of the 'BuildPlaneArray' method, we described a mechanism in which the vertices of each polygon were pushed back such that they always touched the surface of the plane they reference. Because the polygon splitting operation is prone to floating point accuracy errors – like most other operations – we perform this operation once again here on both the new front and back polygon fragments. While this is not a critical step in the generation of a polygon-aligned BSP tree, this step may help to greatly improve the accuracy of the compilation process.

```
                // Ensure that all vertices are on the original plane
                for ( v = 0; v < (signed)FrontSplit->VertexCount; v++ )
                {
                    float result = FrontSplit->Vertices[v].Dot( pPlane->Normal ) +
                                   pPlane->Distance;

                    FrontSplit->Vertices[v] += (pPlane->Normal * -result);

                } // Next Vertex

                // Ensure that all vertices are on the original plane
                for ( v = 0; v < (signed)BackSplit->VertexCount; v++ )
                {
                    float result = BackSplit->Vertices[v].Dot( pPlane->Normal ) +
                                   pPlane->Distance;

                    BackSplit->Vertices[v] += (pPlane->Normal * -result);

                } // Next Vertex
```

At this stage, we have generated the two new polygon fragments that describe those portions of the original polygon that lay on either side of the plane. We have also added them to the front and back lists ready to be processed at the next level in the recursive procedure. As a result, we have no further need for the original polygon from which these two fragments were generated and therefore we simply release it here. Having removed this original polygon, and inserted two additional polygons into the compile process, the number of active faces will have increased by one. To this end we increment the 'm_lActiveFaces' member here to ensure that our progress is accurately reported before moving on to the next polygon in the linked list passed at this level in the recursive process.

```
                // Log – BSP: Update Progress Details

                // + 2 Fragments - 1 Original
                m_lActiveFaces++;

                // Free up original face
                delete TestFace;

                break;

        } // End Switch

    } // End while loop
```

With every polygon now having been processed, and the resulting front and back lists populated we can now begin to process this information.

During the earlier coverage of the settings contained within the 'BSPOPTIONS' structure we discussed a technique that could be employed to help ensure the integrity of the solid/empty leaf information within the tree. As mentioned, the 'RemoveBackLeaves' flag contained within the 'm_OptionSet' member allows the application to specify whether or not it would like the BSP compiler to enforce the removal of any polygon fragments which end up behind a node where solid space should exist.

If this process was enabled then we first test the contents of the back list to determine whether or not any further nodes will be generated behind the current one. This achieved with a call to the 'CountSplitters' method that is responsible for totalling those polygons in the specified linked list that have not yet been used as node plane candidates. If this function returns a value equal to 0 after having been passed the back list, then we know that we have reached a node behind which solid space exists. Given that this is the case, the following code then proceeds to delete each of the polygons contained within the back list that would have ended up in this solid space.

```
    // Should We Back Leaf Cull ?
    if ( m_OptionSet.RemoveBackLeaves )
    {
        // If No potential splitters remain, free the back list
        if ( BackList && CountSplitters( BackList ) == 0 )
        {
            // Release illegal polygon fragments
            for ( TestFace = BackList; TestFace; TestFace = TestFace->Next )
            {
                delete TestFace;
                m_lActiveFaces--;

            } // End if
            BackList = NULL;

        } // End if No Splitters

    } // End If RemoveBackLeaves
```

At this stage in the process we have access to the final front and back polygon linked lists. This is the ideal time for us to generate the final bounding box extents for the current node based on this information. As a result, we make two calls to the current node's 'CalculateBounds' method. In the first call we pass the front polygon list to the first parameter, and specify that the node's bounding box should be reset by passing a value of 'true' to the second. Once this function returns the node's 'Bounds' members will contain extents values which describe those polygons in the front list. We must take into account *every* polygon that will exist at some point below the node however. As a result we call this method again, passing in the back polygon list and a value of false to the second parameter which instructs the 'CalculateBounds' function that it should not reset the extents. Instead it will grow the current extents to include those polygons passed.

```
    // Calculate the nodes bounding box
    GetNode(Node)->CalculateBounds( FrontList, true );
    GetNode(Node)->CalculateBounds( BackList, false );
```

When processing the front of the node, we know that there can never be a situation in which no polygon data exists within the linked list referenced by the 'FrontList' variable. This is due to the fact that the polygon used as the node plane candidate will always at least be added to the front list. In the following code block therefore we begin by counting the number of splitters that remain in that list.

Recall that a leaf is normally created at the point when there are no further nodes that can be generated from those polygons contained in the appropriate list – e.g. each polygon has its 'UsedAsSplitter' member set to true or the list contains no polygon data at all. Since the latter of these two cases is not possible in front of the node, this means that there must be at least one polygon stored here but it has already been used.

The first case in the conditional if/else statement in the following code block creates a new leaf structure should there have been no available splitter polygons contained in the front list. This leaf is attached to the current node's 'Front' member in the manner outlined in the 'File Based Data Structures' section in which we discussed how leaves and nodes are referenced in this application. After the leaf has been attached to the node in this way, we then make a call to the 'ProcessLeafFaces' method. To this call we pass the newly generated leaf structure and the front polygon list in order to have this function insert those polygons into the leaf structure on our behalf.

```
    // Is the front list empty?
    if ( CountSplitters( FrontList ) == 0 )
    {
        // Add a new leaf and store the resulting faces
        if (!IncreaseLeafCount())
        {
            ErrCode = BCERR_OUTOFMEMORY;
            goto BuildError;
        }

        GetNode(Node)->Front = -((long)GetLeafCount());
        if (FAILED(ErrCode = ProcessLeafFaces( GetLeaf( GetLeafCount() - 1 ),
                                               FrontList ))) goto BuildError;
    }
```

The second case in this conditional if/else statement is executed if there were polygons in the front list that are still available for use as node plane candidates – e.g. at least one of these polygons has a 'UsedAsSplitter' member set to 'false'. In this case there are obviously further nodes that can be generated in front of this node. As a result, we generate a new node structure, store the index to that new node in the 'Front' member of the current node and finally step down the front of this node by recursively calling the 'BuildBSPTree' function here.

```
    else
    {
        // Allocate a new node and step into it
        if (!IncreaseNodeCount())
        {
            ErrCode = BCERR_OUTOFMEMORY;
            goto BuildError;
        }

        GetNode(Node)->Front = GetNodeCount() - 1;
        ErrCode = BuildBSPTree( GetNode(Node)->Front, FrontList );

    } // End If FrontList

    // Front list has been passed off, we no longer own these
    FrontList = NULL;
    if ( FAILED(ErrCode) ) goto BuildError;
```

If you have read the textbook at this point you should be aware that whenever the list of available polygons that fall *behind* a particular node are depleted, then the space behind this node will describe solid space. Recall that a leaf is normally created at the point when there are no further nodes that can be generated from those polygons contained in the appropriate list – e.g. each polygon has its 'UsedAsSplitter' member set to true or the list contains no polygon data at all. In either case, when the back list is empty, we must attach a leaf to the back of the current node that denotes this solid area. Due to the fact that there are no polygons which remain to be collected into the leaf however, it would be wasteful if we allocated and store a new leaf structure here. Instead, we take advantage of the fact that we are using *indices* to reference any leaves attached to either side of the node in order to store a special case 'solid leaf' constant code defined as follows.

```
#define BSP_SOLID_LEAF 0x80000000
```

This value is equal to the largest *negative* value that can be stored in a signed 32 bit variable. Because this constant defines a negative value, the application will still be able to test for the existence of a leaf attached to the back of a node with a simple '<0' comparison test. In order to determine if a leaf is solid however, the 'Back' member of the node must be tested explicitly for equality with this solid leaf define.

In the following code we first check to see if the list of polygons is empty simply by testing the 'BackList' variable to see if it contains a zero or NULL value. If this is found to be the case then we know that solid space must exist behind this node and as a result we set the current node's 'Back' member value to the 'BSP_SOLID_LEAF' constant defined earlier.

```
    // Is the back list empty?
    if ( !BackList )
```

```
    {
        // Set the back as a solid leaf
        GetNode(Node)->Back = BSP_SOLID_LEAF;
    }
```

If the back list *does* contain polygon data at this stage then either the 'RemoveBackLeaves' compile option was disabled by the application, or this backlist simply contains no remaining splitters. In either case, we treat this situation in exactly the same manner as we did with the front list – e.g. create, attach and populate a new leaf structure to the back of this node if there were no splitters remaining or; create and attach a new node behind the current, and recurse into the back of the current node with a further call to the 'BuildBSPTree' function.

```
    else
    {
        // No splitters remaining?
        if ( CountSplitters( BackList ) == 0 )
        {
            // Add a new leaf and store the resulting faces
            if (!IncreaseLeafCount())
            {
                ErrCode = BCERR_OUTOFMEMORY;
                goto BuildError;
            }

            GetNode(Node)->Back = -((long)GetLeafCount());
            if (FAILED(ErrCode = ProcessLeafFaces( GetLeaf( GetLeafCount() - 1 ),
                                                   BackList ))) goto BuildError;

        } // End if no splitters
        else
        {
            // Allocate a new node and step into it
            if (!IncreaseNodeCount())
            {
                ErrCode = BCERR_OUTOFMEMORY;
                goto BuildError;
            }

            GetNode(Node)->Back = GetNodeCount() - 1;
            ErrCode = BuildBSPTree( GetNode(Node)->Back, BackList);

        } // End if remaining splitters

    } // End If BackList

    // Back list has been passed off, we no longer own these
    BackList = NULL;
    if ( FAILED(ErrCode) ) goto BuildError;

    // Success
    return BC_OK;
```

There were several cases within the 'BuildBSPTree' function in which we jumped to the section of code referenced by the label 'BuildError' by using a goto statement. While some might argue that using a

try/catch exception handling method would be more compatible with the C++ standards specification, we have chosen this method within this recursive procedure purely for reasons of efficiency and convenience.

Regardless of how we reach this block of error handling logic, the important point is how each of the front and back lists maintained by this function are being handled in addition to the list of polygons passed into this function. In the following code you can see that each linked list is passed into the 'TrashFaceList' utility function that is designed to add each polygon in the specified list to the 'm_vpGarbage' member array in order for them to be released at a later time. We will discuss why this is the case in the coverage of the 'TrashFaceList' function later in this section.

The final part of this error handling logic returns the error information currently stored in the local 'ErrCode' variable – specified by the main portion of this code – to the calling function. Remember, that because this is a recursive procedure, the function responsible for making the call might actually be this very same one. As a result, we must remember to pay attention to any error codes returned from these recursive calls. If an error was returned from a child recursion, then that call must also begin to clean up and return any applicable error to its parent. This would therefore be repeated until we return all the way back out of each level in the call recursion.

```
BuildError:
    // Add all currently allocated faces to garbage heap
    TrashFaceList( pFaceList );
    TrashFaceList( FrontList );
    TrashFaceList( BackList  );

    // Failed
    return ErrCode;
}
```

CBSPTree::SelectBestSplitter

We encountered the 'SelectBestSplitter' function during our coverage of lab project 16.1. There are however several minor modifications that we must discuss in order to make this function compatible with the BSP leaf tree and our new pre-processing tool.

```
CBSPFace * CBSPTree::SelectBestSplitter( CBSPFace * pFaceList,
                                         unsigned long SplitterSample,
                                         float SplitHeuristic )
{
    unsigned long Score, Splits, BackFaces, FrontFaces;
    unsigned long BestScore = 10000000, SplitterCount = 0;
    CBSPFace *Splitter = pFaceList, *CurrentFace = NULL, *SelectedFace = NULL;
```

Other than using slightly different types (CBSPFace instead of CPolygon for instance) the parameters, local variable list and return value remain similar to that of our previous implementation of this function.

One thing that has changed however is the data that will be passed in to this function. In the previous implementation of the BSP node tree class, the 'SelectBestSplitter' function would be passed a list of only those polygons that had not been linked to nodes in the tree and removed from further processing.

In the BSP leaf tree information, remember that the polygon data is now being passed through the tree in order for it to be collected within the leaves. As a result, this function will now receive even those polygons already used as node plane candidates. For this reason, in the following while loop, this function must ignore any polygon that has its 'UsedAsSplitter' member set to 'true'.

```
    // Traverse the Face Linked List
    while ( Splitter != NULL )
    {

        // If this has NOT been used as a splitter then
        if ( !Splitter->UsedAsSplitter )
        {
            // Create testing splitter plane
            CPlane3 SplittersPlane( Splitter->Normal, Splitter->Vertices[0] );
```

The only remaining difference of any significance within this function is the way in which the splitter plane is generated and tested. In our previous implementation we made use of the D3DXPLANE structure in conjunction with our collision library's 'PolygonClassifyPlane' function. In this lab project however, we make use of the new 'CPlane3' math utility class and its associated 'ClassifyPoly' routine to do the same job.

Other than these minor differences, the mechanism by which a polygon is selected as a potential splitter remains the same. As a result the remainder of this function is included only in the interest of completeness.

```
            // Test against the other poly's and count the score
            CurrentFace = pFaceList;
            Score = Splits = BackFaces = FrontFaces = 0;
            while ( CurrentFace != NULL )
            {
                CLASSIFYTYPE Result =
                         SplittersPlane.ClassifyPoly(CurrentFace->Vertices,
                                                     CurrentFace->VertexCount,
                                                     sizeof(CVertex) );
                switch ( Result )
                {
                    case CLASSIFY_INFRONT:
                        FrontFaces++;
                        break;

                    case CLASSIFY_BEHIND:
                        BackFaces++;
                        break;

                    case CLASSIFY_SPANNING:
                        Splits++;
                        break;

                    default:
                        break;

                } // switch
```

```
                CurrentFace = CurrentFace->Next;

            } // Next Face

            // Tally the score (modify the splits * n )
            Score = (unsigned long)((long)abs( (long)(FrontFaces - BackFaces) ) +
                                                    (Splits * SplitHeuristic));
            // Is this the best score ?
            if ( Score < BestScore)
            {
                BestScore    = Score;
                SelectedFace = Splitter;
            } // End if better score

            SplitterCount++;

        } // End if this splitter has not been used yet

        Splitter = Splitter->Next;

        // Break if we reached our splitter sample limit.
        if (SplitterSample != 0 && SplitterCount >= SplitterSample && SelectedFace)
            break;

    } // Next Splitter

    // This will be NULL if no faces remained to be used
    return SelectedFace;
}
```

CBSPTree::CountSplitters

This method serves as utility function utilized by the 'BuildBSPTree' function to quickly count the number of polygons that have not yet been selected for node plane candidacy within the specified 'CBSPFace'object linked list.

Using the same linked list iteration logic we have employed several times before in this class, the 'CountSplitters' function simply tests the value of each polygon's Boolean 'UsedAsSplitter' member. If this member contains a value of 'false' this indicates that the polygon has not yet been used in the generation of a node. Should this be the case, the counter describing the total number of *unused* polygons is then incremented. This value is maintained within the local 'SplitterCount' variable declared at the top of this function and initialized with a default value of 0. Once each polygon within the linked list has been tested, this function then returns to the calling function passing back this total number of unused polygons.

```
unsigned long CBSPTree::CountSplitters( CBSPFace * pFaceList ) const
{
    unsigned long SplitterCount = 0;
    CBSPFace     *Iterator      = pFaceList;

    // Count the number of splitters
    while ( Iterator != NULL )
```

```
    {
        if ( !Iterator->UsedAsSplitter ) SplitterCount++;
        Iterator = Iterator->Next;

    } // End If

    // Return number of splitters remaining
    return SplitterCount;
}
```

CBSPTree::ProcessLeafFaces

As we already know at this point, the 'ProcessLeafFaces' method is called by the 'BuildBSPTree' function in order to have the polygons contained within the linked list (passed into the second parameter) added to the specified leaf (passed into the first). However, what may not initially have been clear is the reason behind why this was necessary.

As we know, there are two types of results which we can obtain from the BSP tree compiler. Either the leaves reference those polygons that may have been split during the compilation process, or they reference the original unsplit polygons stored in the tree's final polygon array at the start of the process.

This function wraps the logic required for both of these types of tree result. The first of these cases is the non-split resulting tree type. If this type of tree was selected by the application then the polygon linked list passed to this function is sent straight through to the leaf's 'BuildFaceIndices' function. Recall that the polygon list sent to us from the 'BuildBSPTree' function contains those polygons that have been split against and passed through the tree during the compilation process. These polygon fragments each store a value in their 'OriginalIndex' member that references the original unsplit polygon already stored in the tree's polygon array. As a result, the indices for the original unsplit polygons are added directly to the leaf. Because of the fact that we are only interested in the original unsplit versions of those polygons passed to this function in the non-split case, the polygons contained in this list are released with a call to the 'FreeFaceList' utility method.

```
HRESULT CBSPTree::ProcessLeafFaces( CBSPLeaf * pLeaf, CBSPFace * pFaceList )
{
    HRESULT ErrCode = BC_OK;

    // Depending on the tree type we may need to store these resulting faces
    if ( m_OptionSet.TreeType == BSP_TYPE_NONSPLIT )
    {
        // Add these faces to the leaf
        if ( FAILED( ErrCode = pLeaf->BuildFaceIndices( pFaceList )))
             return ErrCode;

        // Release the faces
        FreeFaceList( pFaceList );

    } // End if NSR Type
```

The alternative case is the standard split resulting tree in which the polygon data that has been passed through the tree – and potentially split into many additional polygons – is to be stored in the tree's final

polygon array. As we loop through the list of polygons passed to this function in the split treetype case, we simply allocate a new element in the 'm_vpFaces' array with a call to the 'IncreaseFaceCount' method. Into this element we place the actual pointer to the current polygon object that has been used in the tree compilation process. Finally we update its 'OriginalIndex' member with its own position in the tree's polygon list before passing each of these polygons into the leaf's 'BuildFaceIndices' function as before.

```
    else
    {
        // Split tree, we need to store the face pointers
        CBSPFace * Iterator = pFaceList;
        while ( Iterator != NULL )
        {
            if (!IncreaseFaceCount()) return BCERR_OUTOFMEMORY;
            SetFace( GetFaceCount() - 1, Iterator );

            // Set our original index to the final position it
            // is stored in the array (Split type only)
            Iterator->OriginalIndex = GetFaceCount() - 1;
            Iterator = Iterator->Next;

        } // Next Face

        // Add these faces to the leaf
        if ( FAILED( ErrCode = pLeaf->BuildFaceIndices( pFaceList )))
                    return ErrCode;

    } // End if Split Type

    // Success
    return BC_OK;
}
```

CBSPTree::IncreaseNodeCount / IncreaseLeafCount / IncreasePlaneCount

There are four main utility functions defined within the 'CBSPTree' class that are responsible for resizing the various STL vector members maintained by each instance of this class. The three functions outlined here are each responsible for increasing the size of the node, leaf and plane arrays by one element in each call. The fourth function of this type is responsible for resizing the polygon array but this is implemented in a slightly different manner and is covered independently.

The first of these is the 'IncreaseNodeCount' method. This function is used to allocate and insert a new node object at the end of the BSP tree's internal node array. Due to the fact that this function may be called many times to add a large number of nodes during the BSP compilation process, we use the standard capacity threshold resizing logic in order to prevent this array from being resized / reallocated for every node we add. Put simply, if the total number of elements in the vector *including* the new node is found to exceed its current internal capacity, then we will proceed to allocate additional space by calling the vector's 'Reserve' method. To this method we specify a capacity equal to the current number of items stored in the vector plus an additional number of slack elements into which the vector can grow.

In this way, the vector will only ever be physically resized each time we have added a number of nodes equal to this additional slack space. The number of additional elements reserved in this function is defined by the constant shown below.

```
#define BSP_ARRAY_THRESHOLD 100
```

Once we have reserved any required number of elements in the 'm_vpNodes' member, we can then allocate the new node, and add it to this member with a call to the STL vector's 'push_back' method.

```
bool CBSPTree::IncreaseNodeCount()
{
    CBSPNode *NewNode = NULL;

    try
    {
        // Resize the vector if we need to
        if (m_vpNodes.size() >= (m_vpNodes.capacity() - 1))
        {
            m_vpNodes.reserve( m_vpNodes.size() + BSP_ARRAY_THRESHOLD );
        } // End If

        // Allocate a new Node ready for storage
        // Note : VC++ new does not throw an exception on failure (easily ;)
        if (!(NewNode = new CBSPNode)) throw std::bad_alloc();

        // Push back this new Node
        m_vpNodes.push_back(NewNode);
    } // Try vector ops
```

Each of these functions also implements exception handling logic similar to that shown below. This prevents the BSP compiler from having to wrap each insert operation with its own exception handling logic because any exceptions will have been handled already.

```
    // Catch Failures
    catch (std::bad_alloc)
    {
        return false;
    }
    catch (...)
    {
        if (NewNode) delete NewNode;
        return false;
    } // End Catch

    // Success
    return true;
}
```

We won't go into detail about the remaining two 'Increase*' methods as their functionality is essentially identical. In the interest of completeness however the code to the 'IncreaseLeafCount' method is shown below. This function is used to allocate and insert a new leaf object at the end of the BSP tree's internal leaf array.

```
bool CBSPTree::IncreaseLeafCount()
{
    CBSPLeaf *NewLeaf = NULL;

    try
    {
        // Resize the vector if we need to
        if (m_vpLeaves.size() >= (m_vpLeaves.capacity() - 1))
        {
            m_vpLeaves.reserve( m_vpLeaves.size() + BSP_ARRAY_THRESHOLD );
        } // End If

        // Allocate a new leaf ready for storage
        // Note : VC++ new does not throw an exception on failure (easily ;)
        if (!(NewLeaf = new CBSPLeaf)) throw std::bad_alloc();

        // Push back this new leaf
        m_vpLeaves.push_back(NewLeaf);
    } // Try vector ops

    // Catch Failures
    catch (std::bad_alloc)
    {
        return false;
    }
    catch (...)
    {
        if (NewLeaf) delete NewLeaf;
        return false;
    } // End Catch

    // Success
    return true;
}
```

Finally, the BSP tree class also defines the 'IncreasePlaneCount' method. This function is used to allocate and insert a new plane object at the end of the BSP tree's combined plane array.

```
bool CBSPTree::IncreasePlaneCount()
{
    CPlane3 *NewPlane = NULL;

    try
    {
        // Resize the vector if we need to
        if (m_vpPlanes.size() >= (m_vpPlanes.capacity() - 1))
        {
            m_vpPlanes.reserve( m_vpPlanes.size() + BSP_ARRAY_THRESHOLD );
        } // End If

        // Allocate a new plane ready for storage
        // Note : VC++ new does not throw an exception on failure (easily ;)
        if (!(NewPlane = new CPlane3)) throw std::bad_alloc();
```

```
        // Push back this new plane
        m_vpPlanes.push_back(NewPlane);
    } // Try vector ops

    // Catch Failures
    catch (std::bad_alloc)
    {
        return false;
    }
    catch (...)
    {
        if (NewPlane) delete NewPlane;
        return false;
    } // End Catch

    // Success
    return true;
}
```

CBSPTree::IncreaseFaceCount

As with each of the memory management functions covered so far, this function increases the capacity of the BSP trees internal polygon array using a similar threshold mechanism. There is one major difference with this function when compared to those discussed previously. In this function we do *not* allocate and insert a new 'CBSPFace' object. Instead we simply push a NULL pointer value onto the end of the 'm_vpFaces' STL vector. This behavior was selected due to the fact that in the majority of cases, any polygon data that will be stored within the 'm_vpFaces' array has already been allocated prior to the compilation step. As a result, any existing polygon objects would simply need to be transferred into this array with a call to the 'SetFace' accessor function.

```
bool CBSPTree::IncreaseFaceCount()
{

    try
    {
        // Resize the vector if we need to
        if (m_vpFaces.size() >= (m_vpFaces.capacity() - 1))
        {
            m_vpFaces.reserve( m_vpFaces.size() + BSP_ARRAY_THRESHOLD );

        } // End If

        // Push back a NULL pointer
        m_vpFaces.push_back( NULL );

    } // Try vector ops

    // Catch Failures
    catch (...)
    {
        return false;

    } // End Catch
```

```
    // Success
    return true;
}
```

CBSPTree::AllocBSPFace

The ‘AllocBSPFace’ method is yet another utility function designed to make the job of implementing the more comprehensive BSP leaf tree compilation process a little less clumsy. This function is designed simply to allocate a single ‘CBSPFace’ object that will be passed back via the return value. This could of course be achieved simply by allocating the polygon object within the calling function using the ‘new’ operator. However, rather than have the compiler wrap each allocation attempt in exception handling logic, this function does that on its behalf.

The single parameter accepted by this function is used to specify any ‘CFace' object that should be duplicated into the new ‘CBSPFace’ instance using the overloaded constructor of that class.

```
CBSPFace * CBSPTree::AllocBSPFace( const CFace * pDuplicate )
{
    CBSPFace * NewFace = NULL;

    try
    {
        // Call the corresponding constructor
        if (pDuplicate != NULL)
        {
            NewFace = new CBSPFace( pDuplicate );
        }
        else
        {
            NewFace = new CBSPFace;
        } // End If pDuplicate

        // Note : VC++ new may not throw an exception on failure (easily ;)
        if (!NewFace) throw std::bad_alloc();

    } // End Try

    catch (...) { return NULL; }

    // Success!
    return NewFace;
}
```

CBSPTree::FreeFaceList

The ‘FreeFaceList’ method is a utility function designed to **immediately** release any polygon data stored within the linked list of ‘CBSPFace’ object pointers passed to its single parameter. We observed this method being used during the earlier coverage of the ‘ProcessLeafFaces’ function.

In the following code we can see how this function simply iterates through each element in the specified linked list using the traversal logic we have seen throughout this application. For each polygon encountered in this loop we must first make a duplicate of the pointer stored within that polygon's 'Next' member used to iterate to the next polygon in the list. We must take this action first due to the fact that the current iterator polygon will be deleted in the very next step, rendering that polygon and its members invalid. Before moving on to the next polygon using this duplicated 'NextFace' pointer, we decrement the BSP tree's 'm_lActiveFaces' member due to there now being one less active polygon within the BSP compilation process.

Once the loop completes, this function simply returns control back to the calling function having released every polygon in the list passed.

```
void CBSPTree::FreeFaceList( CBSPFace * pFaceList )
{
    // Free up the linked list
    CBSPFace * TestFace = pFaceList, *NextFace = NULL;
    while ( TestFace != NULL )
    {
        NextFace = TestFace->Next;
        delete TestFace;
        m_lActiveFaces--;
        TestFace = NextFace;
    } // Next Face
}
```

CBSPTree::TrashFaceList

Whenever an error occurs during the construction of the tree, there are most likely many references to the original polygons and new polygons alike that exist in one or more of the lists contained on the stack at each level in the recursion. Under failure conditions, it will be difficult to safely release any allocated polygon data as the recursion unwinds due to the fact that we may attempt to release the same polygon instance on more than one occasion. This would of course cause an illegal memory access and a whole new problem to deal with.

To ensure that we can safely release each of the polygon objects referenced or created by the compile process up to the point of failure, any remaining 'CBSPFace' object pointers can be inserted into the garbage collection member array by passing them to this function. As the code iterates through each of the polygons passed into this procedure, we first check to see if a pointer to that particular polygon already exists within the 'm_vpGarbage' STL vector. Only if no duplicate pointer is found to exist will this function add that polygon to the list. Once the recursive compile process has returned all the way back out to the original calling function, each of the polygons added to the garbage collection list by this function can then safely be released.

```
void CBSPTree::TrashFaceList( CBSPFace * pFaceList )
{
    CBSPFace * Iterator = pFaceList;

    while ( Iterator != NULL )
    {
```

```
        // If it doesn't already exist then add it to the list
        if (std::find(m_vpGarbage.begin(), m_vpGarbage.end(),
            Iterator) == m_vpGarbage.end())
        {

            try
            {
                // Resize the vector if we need to
                if (m_vpGarbage.size() >= (m_vpGarbage.capacity() - 1))
                {
                    m_vpGarbage.reserve( m_vpGarbage.size() +
                                         BSP_ARRAY_THRESHOLD );
                } // End If

                // Push back this new item
                m_vpGarbage.push_back(Iterator);

            } // End Try

            // On exception, we can do nothing but bail and leak
            catch (std::exception&) { return; }

        } // End If Exists

        Iterator = Iterator->Next;

    } // Next Face
}
```

The CProcessHSR Module Class

With the BSP compilation topics out of the way, we can now move onto our coverage of the hidden surface removal processing class that is actually executed in advance of the BSP compile process. It was important that we first discussed the core functionality within the BSP compiler class before moving on to this topic because the HSR process relies so heavily on the information generated by the BSP tree compilation process.

```
class CProcessHSR
{
public:
    // Constructors & Destructors for This Class.
             CProcessHSR();
    virtual ~CProcessHSR();

    // Public Member Functions Omitted

private:
    // Private Variables for This Class.
    vectorMesh      m_vpMeshList;       // List of meshes for HSR Processing.
    CMesh          *m_pResultMesh;      // The resulting unioned mesh

    HSROPTIONS      m_OptionSet;        // HSR Options Set
    ILogger        *m_pLogger;          // Logging output interface
    CCompiler      *m_pParent;          // Parent Compiler Pointer
```

```
};
```

Looking at the declaration for the HSR module class, we can see that this one-off processing module is relatively simple when compared to the BSP compiler class / module covered earlier. This class declaration is a more typical example of the kind of one-time processing module classes that we might develop within this application. There are only a few member variables declared here, so let us cover them very briefly.

vectorMesh m_vpMeshList
This member maintains a list of references to each mesh to be merged together within the hidden surface removal process. It should be populated by the application using the 'AddMesh' method defined by this class. This member variable is of the type 'vectorMesh' which is a typedef of a standard STL vector template designed to store a series of 'CMesh' object pointers.

```
typedef std::vector<CMesh*>    vectorMesh
```

CMesh * m_pResultMesh
Once the hidden surface removal process has run to its conclusion, this member variable will store a pointer to the new mesh that resulted from the union operation. This mesh object can subsequently be retrieved by the compiler class with a call to the 'GetResultMesh' method covered shortly.

HSROPTIONS m_OptionSet
This member stores the various settings, specified by the application to inform the compiler how the hidden surface removal operation should be executed. Although this structure contains no settings outside of the 'Enabled' Boolean, this options structure should be set using the 'SetOptions' accessor function in case of future enhancement.

ILogger * m_pLogger
In order for the HSR processor to report progress, error and useful status information to the user, this member variable stores a pointer to the application defined logging class. While the logging feature remains optional, this member can be set with a call to the 'SetLogger' accessor function defined by this class. In this lab project, the logging class instance is passed to this object by the 'CCompiler::PerformHSR' function.

CCompiler * m_pParent
Each compilation module class maintains a member that stores a reference to the parent compiler class that created it. This member is set with a call to the 'SetParent' accessor function defined by each of these classes. This information is used by each of these processing modules in order to test the current state of the compiler to determine if the compile operation has been either paused or cancelled. Although we have omitted much of the logging and progress functionality from the code listings in this workbook, you should take a look at the source code for lab project 16.2 to see this process in action.

HSR Module Accessor Functions

There are only a few accessor functions defined within the HSR processing module class. In each case, the body for these functions can be found in the class declaration contained in the header file, rather than in the source module / .CPP file. We will not go into detail about how each of these functions is implemented, for this you should take a look at the 'CProcessHSR.h' header file contained in the 'Compiler Source' project directory.

The only accessor functions defined by the 'CProcessHSR' class are those that set the various pieces of information required by each compilation process module. These include the process options, a pointer to the parent compiler and a pointer to the class defined logging class. These functions simply store those specified values into the applicable member variables declared by this class.

```
void            SetOptions    ( HSROPTIONS Options    )
void            SetParent     ( CCompiler * pCompiler )
void            SetLogger     ( ILogger * pLogger     )
```

Now that we are familiar with each of this class's member variables, let us move on to examine the main process functionality.

CProcessHSR::AddMesh

If we refer back to the discussion of the 'CCompiler::ProcessHSR' function, we saw how the 'AddMesh' function was called in order to add each of the scene's non-detail meshes to this hidden surface removal module. This method accepts a single parameter into which is passed a single pointer to a 'CMesh' object. This mesh object pointer will simply be added to the end of the 'm_vpMeshList' member vector using the same capacity threshold mechanism that is used within several other functions in this application. Any meshes that are to be considered by this processing module must be specified in advance, prior to calling this object's 'Process' function.

```
bool CProcessHSR::AddMesh( CMesh * pMesh )
{
    try
    {
        // Resize the vector if we need to
        if (m_vpMeshList.size() >= (m_vpMeshList.capacity() - 1))
        {
            m_vpMeshList.reserve( m_vpMeshList.size() + HSR_ARRAY_THRESHOLD );

        } // End If

        // Finally add this mesh pointer to the list
        m_vpMeshList.push_back( pMesh );

    } // End Try Block

    catch (...)
    {
        // Clean up and bail
        m_vpMeshList.clear();
        return false;

    } // End Catch
```

```
    // Success
    return true;
}
```

CProcessHSR::Process

After having added each of the non-detail scene meshes to this module's source mesh array, this function is called in order to begin the actual hidden surface removal process. Before we move onto examine the implementation for this class, let us once again examine the procedure from a high level overview.

The steps involved in performing the hidden surface removal process are as follows:

1) Allocate and compile a BSP tree object for each individual mesh being processed by this module.

2) Step through each mesh (A) within an outer loop.

3) Step through each mesh (B) within an inner loop.

4) Inside the inner loop, skip any meshes that have already been processed. If the current mesh 'B' has not yet been processed, then test for intersection between mesh 'A' and mesh 'B' using a simple broad phase AABB test. If no intersection occurred, these meshes do not need to be unioned.

5) If the bounding boxes of both meshes intersected, perform an accurate intersection test between these two meshes using the BSP tree information.

6) If mesh 'A' and mesh 'B' were found to intersect with one another then first clip mesh 'A' against mesh 'B's tree, removing any parts of that mesh that exist in solid space. Then do the same in reverse such that mesh 'B' is clipped against mesh 'A's tree.

7) Repair any unnecessary splits that occurred during the clipping process for each mesh, and then exit the inner loop.

8) As the last step of the outer loop, add the surviving polygons from mesh 'A' to the resulting mesh being constructed in this process.

9) Move on to the next mesh in the outer loop and return to step 3 until all meshes have been processed in the outer loop.

Now that we are armed with a general idea of how this process should function, let us take a look at how this has process has actually been implemented in this lab project.

```
HRESULT CProcessHSR::Process()
{
    HRESULT     hRet;
```

```
    BSPOPTIONS  Options;
    int         i, a, b;
    CBSPTree ** BSPTrees  = NULL;
    long        MeshCount = m_vpMeshList.size();
    CBounds3    BoundsA, BoundsB;
```

This function accepts no parameters and simply returns an HRESULT value used to report the success or failure of this process to the calling function.

At the start of this function we start by setting up a temporary 'BSPOPTIONS' structure. These will be the settings that we use to compile each of the mini-BSP trees built for every mesh undergoing the union operation. Within this structure we specify that we would like each tree to use the non-split compilation process. This will ensure that each tree stores an identical set of unsplit polygons as those contained in the original mesh. We also enable the 'RemoveBackLeaves' option. Recall that this setting causes the BSP compiler to forcibly remove any polygons that fall behind a terminal node. This effectively guarantees that a solid space indicator is inserted in place of each empty back leaf that might previously have been created. Should a mesh be slightly malformed, this will help to correct any problems that might arise due to the existence of illegal geometry. The remaining options are set to defaults that will provide a reasonable structure and a fast compile time.

```
    // Build the option set which will be used for all Mini-BSP Trees
    ZeroMemory( &Options, sizeof(BSPOPTIONS));
    Options.TreeType          = BSP_TYPE_NONSPLIT;
    Options.Enabled           = true;
    Options.RemoveBackLeaves  = true;
    Options.SplitHeuristic    = 3.0f;
    Options.SplitterSample    = 60;

    // Log – HSR: Building BSP Trees
```

With these options values initialized, we must now allocate the array in which each mesh' BSP tree will be contained. This array of BSP tree pointers is stored in the local 'BSPTrees' variable declared at the top of the function. The mesh into which all the resulting polygon data can be placed must also be created at this point. Recall that this mesh object is stored within the 'm_pResultMesh' member variable.

```
    try
    {
        // Allocate memory for an array pf BSP Trees
        BSPTrees = new CBSPTree*[ MeshCount ];
        if (!BSPTrees) throw BCERR_OUTOFMEMORY;

        // Set all pointers to NULL
        ZeroMemory( BSPTrees, MeshCount * sizeof(CBSPTree*));

        // Allocate our result mesh
        m_pResultMesh = new CMesh;
        if (!m_pResultMesh) throw BCERR_OUTOFMEMORY;
```

The next step in this process is to compile a BSP tree for every mesh. The following block of code demonstrates how this is achieved.

For each mesh in the 'm_vpMeshList' array we allocate a new 'CBSPTree' object instance, and store its pointer in the newly allocated 'BSPTrees' container array. If the allocation was successful, the 'BSPOPTIONS' structure we set up at the start of this function is then passed into the new BSP tree object with a call to its 'SetOptions' method. Before we can compile the BSP tree, we must first pass in the polygon data from the current mesh object via the 'CBSPTree::AddFaces' method. With this process completed, we can finally call the BSP tree 'CompileTree' method in order for the mesh data to be compiled.

```
        // Build a BSP Tree for each mesh.
        for ( i = 0; i < MeshCount; i++ )
        {
            // Allocate a new tree
            BSPTrees[i] = new CBSPTree;
            if (!BSPTrees[i]) throw BCERR_OUTOFMEMORY;
            BSPTrees[i]->SetOptions( Options );

            // Add the faces from this mesh ready for compile
            hRet = BSPTrees[i]->AddFaces( m_vpMeshList[i]->Faces,
                                          m_vpMeshList[i]->FaceCount );
            if (FAILED(hRet)) throw hRet;

            // Compile the BSP Tree
            hRet = BSPTrees[i]->CompileTree();
            if (FAILED(hRet)) throw hRet;

            // Log – HSR : Update Progress

        } // Next Mesh
```

Now that the BSP tree data for each mesh has been compiled, the next task is to determine which of the mesh objects should be unioned together. While it is certainly possible for us to simply pass the polygon data of one mesh through the BSP tree of another, this could potentially cause hundreds of polygons to be split unnecessarily. This might be the case even if those two mesh objects were on opposite sides of the level. It is logical to assume therefore that if we can find any two meshes that intersect with one another then these two meshes should be unioned.

We search for these intersecting cases by first creating an outer loop that iterates through each of the meshes currently stored in the processor class. We will call this the source mesh. For each source mesh, we must then proceed to iterate through the mesh list once again in order to search for a another mesh that might intersect with the source. We should obviously ignore any cases in which both meshes are the same. However, it is also important to skip over any mesh that has already been processed – e.g. it was a source mesh at an earlier point and has already clipped and been clipped by every other mesh in the scene. Whenever a mesh has been fully processed within the outer loop, the BSP tree for this mesh will be released and set to NULL. If this is found to be the case in the inner loop, then we can safely ignore that mesh.

```
        // Log – HSR: Clipping Meshes for HSR
```

```
        // Now do the actual Union (HSR) clipping operations
        for ( a = 0; a < MeshCount; a++ )
        {
            // Log – HSR: Update progress

            // Skip any NULL bsp objects
            if (!BSPTrees[a] || BSPTrees[a]->GetFaceCount() == 0) continue;

            // Clip against all other meshes
            for ( b = 0; b < MeshCount; b++ )
            {
                // Skip any NULL bsp objects (i.e. has already been clipped)
                if (!BSPTrees[b] || BSPTrees[b]->GetFaceCount() == 0) continue;

                // Don't Boolean Op the mesh with itself
                if (a == b) continue;
```

At this stage we have a reference to two different meshes, neither of which has ever been clipped against the other. To get a rough idea of whether or not these two meshes intersect, we perform a quick broad-phase rejection step by testing for intersection between the bounding boxes of each mesh's BSP tree. If no intersection between these larger bounding boxes was found to have occurred, then we know that the meshes cannot possibly be intersecting. In this case we can continue on to test the next mesh in the inner loop.

If an intersection was found during this broad-phase test, then it is possible that the two meshes also intersect. To make sure that these two meshes really do intersect, we then perform a more accurate intersection test with a call to the 'CBSPTree::IntersectedByTree' function. We will cover this in detail shortly. For now all we need to know is that this test provides a more accurate result, using the BSP tree information constructed from the mesh data itself. Again, if this function indicated that there was no intersection, we can ignore this mesh combination and continue on to the next iteration of the inner loop.

```
                // Skip if the two don't intersect
                BoundsA = BSPTrees[a]->GetBounds();
                BoundsB = BSPTrees[b]->GetBounds();
                if ( !BoundsA.IntersectedByBounds( BoundsB,
                                                   CVector3( 0.1f, 0.1f, 0.1f )))
                    continue;

                if ( !BSPTrees[a]->IntersectedByTree( BSPTrees[b] ) )
                    continue;
```

If we reached this point in the function then it is safe to assume that these two meshes were likely to be intersecting and should be clipped. This is done in such a way that the portions of each mesh are removed if they are contained within the solid space of the other. We perform this clipping operation using the 'ClipTree' method of each BSP tree object. Notice however that the 'ClipTree' procedure accepts a pointer to another BSP tree as its first parameter. In fact we will not be touching any of the original mesh data during the HSR process because these meshes still belong to the compiler object. Instead we will be manipulating only the polygon data stored within each BSP tree object. Once the tree has been compiled, the data stored in its internal polygon array has no bearing on the actual structure of

the tree itself. As a result we can clip and manipulate this data as many times as we like without compromising the integrity of the tree.

If we look at the two calls made to the 'ClipTree' function, we can see that we first call this function on the tree created from the mesh selected in the outer loop, passing in the tree from the inner loop. In the next call this situation is reversed. In both cases we pass a value of 'true' to the second 'ClipSolid' parameter which forms the basis of the CSG union operation. Finally, pay special attention to the value passed to the final 'RemoveCoPlanar' parameter in each case. This will be important when we come to discuss the ClipTree function shortly.

If you have read through the textbook at this point, you should be aware that the CSG process can sometimes split polygons even if neither of the resulting fragments are ever deleted. For this reason we call each BSP tree objects' 'RepairSplits' method which is designed to undo these unnecessary splits. Again, we will examine this function a little later on.

```
                // Clip tree a to tree b and vice versa
                BSPTrees[a]->ClipTree( BSPTrees[b], true, false );
                BSPTrees[b]->ClipTree( BSPTrees[a], true, true  );

                // Repair Unrequired Splits
                BSPTrees[a]->RepairSplits();
                BSPTrees[b]->RepairSplits();

            } // Next Mesh b
```

With the BSP tree selected in the outer loop having now been clipped by each intersecting mesh in the scene, we can add the surviving polygons contained within this BSP tree object to the resulting mesh. This is achieved by calling the 'BuildFromBSPTree' we covered earlier. By specifying a value of false to the final parameter in this method, this will result in the polygon data being appended to those polygons already stored in the 'm_pResultMesh' object. Once the polygon data has been extracted from the tree, we then release it in order to free up any allocated resources that are no longer required. The applicable element in the 'BSPTrees' array is also finally set to a value of NULL. This is to ensure that we do not try and access the recently released BSP tree object at some point in the future.

```
            // Append all faces to the result brush
            m_pResultMesh->BuildFromBSPTree( BSPTrees[a], false );

            // Tree a has now been clipped by all other meshes
            delete BSPTrees[a];
            BSPTrees[a] = NULL;

        } // Next Mesh a

    } // End Try Block
```

The following catch block is designed to release any memory allocated by this method before returning the applicable error code to the calling function should an exception have been thrown at any point.

```
    catch ( HRESULT &e )
```

```
    {
        if ( BSPTrees )
        {
            for ( i = 0; i < MeshCount; i++ )
                if ( BSPTrees[i] ) delete BSPTrees[i];
            delete []BSPTrees;

        } // End if we allocated

        // Release the result mesh
        if ( m_pResultMesh ) { delete m_pResultMesh; m_pResultMesh = NULL; }

        // Log – HSR : Report Failure

        return e;

    } // End Catch Block
```

The final step in this process is simply to release any temporary objects and resources that remain allocated at the end of the process. Once this is complete, we finally return to the calling function with a code indicating success.

```
    // Release the BSP Trees
    if ( BSPTrees )
    {
        for ( i = 0; i < MeshCount; i++ ) if ( BSPTrees[i] ) delete BSPTrees[i];
        delete []BSPTrees;

    } // End if we allocated

    // Log – HSR : Report Success

    // Success!
    return BC_OK;

}
```

Once this entire process has been completed, the ‘m_pResultMesh’ mesh object will contain a copy of every polygon fragment that existed only within an empty area of space. With those fragments existing in solid space having been clipped away, this resulting mesh should now contain a valid set of scene polygon data with all hidden surfaces / illegal geometry removed.

CProcessHSR::GetResultMesh

As we know, the goal of the HSR processing module is to merge each of the specified meshes into one single result mesh. In the previous coverage of the ‘Process’ function defined by this class, we saw how the mesh referenced by the ‘m_pResultMesh’ member variable was constructed. This function is designed to be called by the compiler class in order to retrieve this mesh pointer ready for BSP compilation.

```
CMesh * CProcessHSR::GetResultMesh() const
```

```
{
    return m_pResultMesh;
}
```

CBSPTree – Additional CSG Functionality

With the general concepts involved in performing the hidden surface removal process behind us, let us take a look at that additional support functionality provided by the 'CBSPTree' class for performing CSG operations.

CBSPTree::ClipTree

The 'ClipTree' method of the BSP tree class provides the hidden surface removal processor with the functionality needed to perform the union operation used to merge each of the scene meshes together. Much like the 'BuildBSPTree' method discussed earlier in this chapter, this function is a recursive procedure that passes polygon data through the tree, classifying and splitting against each node until it reaches a terminal node within the hierarchy.

```
HRESULT CBSPTree::ClipTree( CBSPTree * pTree, bool ClipSolid, bool RemoveCoPlanar,
                            ULONG CurrentNode, CBSPFace * pFaceList )
{
    // 50 Bytes including Parameter list (based on __thiscall declaration)
    CBSPFace     *TestFace   = NULL, *NextFace  = NULL;
    CBSPFace     *FrontList  = NULL, *BackList  = NULL;
    CBSPFace     *FrontSplit = NULL, *BackSplit = NULL;
    unsigned long Plane      = 0;
    HRESULT       ErrCode    = BC_OK;

    // Validate Params
    if (!pTree) return BCERR_INVALIDPARAMS;

    // Did Someone use or pass in a silly tree ?
    if (pTree->GetFaceCount() < 1 || GetFaceCount() < 1 )
        return BCERR_BSP_INVALIDGEOMETRY;
```

Although there are 5 parameters declared by this function, only the first three should be passed to the initial call. The final two parameters are used only within this function to pass data between recursive calls. Let us briefly examine the purpose of each of these parameters and what should be passed to each of them.

*CBSPTree * pTree*

The first of these parameters is a pointer to another BSP tree object. The actual tree structure of the object passed to this parameter will *not* be used in this call. Only the polygon data stored within this tree will be manipulated. Recall that in order to perform any type of CSG operation on mesh data; each source mesh must have a BSP tree. With the tree also storing the mesh polygon information, it makes sense that we simply accept a pointer to the tree itself rather than the original mesh.

bool ClipSolid

This parameter is used by the calling function to control the circumstances under which clipped polygon fragments will be removed. If a value of ‘true’ is specified, then any source polygon fragments that end up in the solid space of this tree will be discarded. Conversely, if a value of ‘false’ is specified then those fragments ending up in *empty* space will be discarded. This parameter is the primary means by which we can adapt this same procedure for use with any of the CSG operations.

bool RemoveCoPlanar

This third parameter is used by the calling function to control the manner in which coplanar polygons are treated. If you have read the textbook at this point you should be familiar with the problems associated with the coplanar case in CSG operations. If you were performing the union of two meshes that had overlapping coplanar polygons, were you to remove both polygons you would be left with a hole. If however you were to keep both polygons you would introduced illegal geometry into the new mesh. By removing only one and keeping the other however, the overlapping fragment of the one mesh covers the gap left by the one removed. By alternating this value between the two calls needed to clip both meshes, this same behavior will be observed.

ULONG CurrentNode

This parameter contains the index of the current node in this BSP tree against which we are classifying the source polygon data. This parameter is optional and defaults to a value of 0 (the root node). It should not be specified in the initial call to this function.

*CBSPFace * pFaceList*

This fifth and final parameter is the head / root element in the linked list containing those polygons being clipped during this procedure. In much the same way as the construction of the BSP tree, the front and back lists collected at each step will be passed down to further recursions using this parameter. These polygons are actually references to those owned by the BSP tree object passed in as the first parameter. As with the ‘CurrentNode’, this parameter is optional and defaults to a value of NULL. It should not be specified in the initial call to this function.

With each of the parameters covered, let us move on to the primary implementation of this function.

The first real task with which this function is charged is to construct a linked list from each of the polygons contained in the BSP tree passed in as the first parameter. This is only performed if this is the first time in to this function (determined by the default NULL pointer contained with the pFaceList parameter) and will not take place in subsequent recursions. This is achieved simply by looping through each polygon in the tree using its ‘GetFaceCount’ and ‘GetFace’ accessor functions and attaching each polygon to the ‘Next’ pointer of the one before. Building a list of polygons from the source tree in this way allows us to work directly with its polygon data while maintaining the ability to reuse much of the functionality already designed to work with linked lists. Notice in the following code block that we also reset the ‘ChildSplit’ elements of each face to a default value of -1 in this same loop.

```
    // Automatically build lists
    if ( pFaceList == NULL )
```

```
    {
        // Build our sequential linked list
        for ( UINT i = 0; i < pTree->GetFaceCount(); i++ )
        {
            pTree->GetFace(i)->ChildSplit[0]= -1;
            pTree->GetFace(i)->ChildSplit[1]= -1;
            if ( i > 0 ) pTree->GetFace(i - 1)->Next = pTree->GetFace(i);

        } // Next Face

        // Reset last face just to be certain
        pTree->GetFace(i - 1)->Next = NULL;
        pFaceList = pTree->GetFace(0);

    } // End If No Faces
```

Now that we have access to either the linked list that has just been built in the first call to this function, or the linked list passed in subsequent recursive calls, we now begin to iterate through each polygon in this list. The first thing we must do in this loop is to make a backup of the pointer stored in that polygons 'Next' member. It is important that we do this here because the current polygon may be deleted or modified during this operation. It is also imperative that we ignore any polygons in the list that have been marked as deleted.

```
    // Select node plane and classify / send the list through the tree
    Plane = GetNode( CurrentNode )->Plane;

    for ( TestFace = pFaceList; TestFace; TestFace = NextFace )
    {
        // Store next face, as 'TestFace' may be modified / deleted
        NextFace = TestFace->Next;

        // Skip this polygon it has been deleted in some previous csg op
        if ( TestFace->Deleted ) continue;
```

The next step in the operation, much as in the BSP compile process, is to classify this polygon against the current node's plane and take any appropriate action based on the result.

The first case we deal with here is those polygons from the source BSP tree that are coplanar with the current node. If this polygon is found to be coplanar with the node and points in the same direction, then there is some additional logic that must be applied here to resolve the overlapping polygon problem we outlined earlier. Thankfully however, the solution is relatively simple. If the value passed to the 'RemoveCoPlanar' parameter is true then we simply attach this polygon to the back list being constructed in this call. If the value is false then we add it to the front list instead. Hopefully you can see why this is the case but in summary; should the polygon used to create the node in this tree overlap with the current polygon from the source tree, this source polygon would eventually end up in solid space and be clipped away. Conversely, passing it down the front would push it into an empty area and it would survive. In either case, should the polygon and the node face in opposite directions, the polygon should be added to the back list regardless.

```
        // Classify the polygon against the selected plane
        switch ( GetPlane(Plane)->ClassifyPoly( TestFace->Vertices,
```

```
                                                TestFace->VertexCount,
                                                sizeof(CVertex) ) )
        {
            case CLASSIFY_ONPLANE:
                // Test the direction of the face against the plane.
                if ( GetPlane(Plane)->SameFacing( TestFace->Normal ) )
                {
                    if ( RemoveCoPlanar )
                    {
                        TestFace->Next = BackList;
                        BackList       = TestFace;
                    }
                    else
                    {
                        TestFace->Next = FrontList;
                        FrontList = TestFace;
                    }
                }
                else
                {
                    TestFace->Next = BackList;
                    BackList       = TestFace;

                } // End if Plane Facing
                break;
```

If the polygon fragment was classified as being contained completely within the front halfspace of the node, we simply add it to the current front list in this case.

```
            case CLASSIFY_INFRONT:
                // Pass the face straight down the front list.
                TestFace->Next     = FrontList;
                FrontList          = TestFace;
                break;
```

In a similar fashion as the in-front case, should the polygon fragment be completely behind the node then it is added straight to the back list.

```
            case CLASSIFY_BEHIND:
                // Pass the face straight down the back list.
                TestFace->Next     = BackList;
                BackList           = TestFace;
                break;
```

The initial stages of the spanning case are almost identical to that of the ‘BuildBSPTree’ function. The only real difference here is that the split polygon fragments that we generate are added to the *source* BSP tree passed in to the first parameter. Notice how we call the ‘IncreaseFaceCount’ and ‘SetFace’ methods of the ‘pTree’ object, rather than those local to this object.

```
            case CLASSIFY_SPANNING:
                // Allocate new front within the passed tree
                if (!(FrontSplit = AllocBSPFace()))
```

```
                {
                    ErrCode = BCERR_OUTOFMEMORY;
                    goto ClipError;
                }
                if (!pTree->IncreaseFaceCount())
                {
                    ErrCode = BCERR_OUTOFMEMORY;
                    goto ClipError;
                }

                pTree->SetFace( pTree->GetFaceCount() - 1, FrontSplit );

                // Allocate new back fragment within the passed tree
                if (!(BackSplit     = AllocBSPFace()))
                {
                    ErrCode = BCERR_OUTOFMEMORY;
                    goto ClipError;
                }
                if (!pTree->IncreaseFaceCount())
                {
                    ErrCode = BCERR_OUTOFMEMORY;
                    goto ClipError;
                }
                pTree->SetFace( pTree->GetFaceCount() - 1, BackSplit );
```

With these two new polygon objects created, we can now proceed to split the polygon against the node plane, generating the two new polygon fragments from those portions of the original source polygon that lay on either side.

In the spanning case of the BSP compiler, we follow the split operation by deleting the original polygon. During the process of clipping polygons for CSG however, there are cases in which the splitting of polygon data can occur even when neither fragment will end up being deleted. As a result, it is possible to repair the unnecessary splits but only if the original polygon remains in-tact and accessible. For this reason we simply set the polygon's 'Deleted' member to true in this function. This will still have the effect of causing this polygon to be ignored by this function due to the initial check above. The last piece of information we need to update in the original polygon are the 'ChildSplit elements. Into these we place the indices to the two new polygons as they exist in the **source** BSP tree object. This information will be used during the 'RepairSplits' method we will discuss shortly. Finally we add each of the two new fragments to the relevant front or back list ready for future processing.

```
                // Split the polygon
                if (FAILED( ErrCode = TestFace->Split(*GetPlane(Plane),
                                                      FrontSplit,
                                                      BackSplit))) goto ClipError;

                // Just flag as deleted and mark for potential repair
                TestFace->Deleted    = true;
                TestFace->ChildSplit[0] = pTree->GetFaceCount() - 2;
                TestFace->ChildSplit[1] = pTree->GetFaceCount() - 1;

                // Add it to the head of our recursion lists
                FrontSplit->Next = FrontList;
                FrontList        = FrontSplit;
```

```
                BackSplit->Next  = BackList;
                BackList         = BackSplit;

                break;

        } // End Switch

    } // Next Face
```

With every polygon in the face list now processed, we should have fully populated the 'FrontList' and 'BackList' with all relevant data. At this point in the function we begin the actual process of removing any applicable polygons should we have arrived at a leaf.

We begin with those tests performed when the 'ClipSolid' parameter was set to a value of 'true'. As we know, the only place that solid space can exist within our polygon-aligned BSP leaf tree is behind a node. As a result we test the value of the 'Back' member of the current node to see if it is equal to the 'BSP_SOLID_LEAF' constant value. If this is the case then we know that the space behind this leaf is solid and therefore the polygons contained within the back list can be deleted. Remember that we must not physically release the polygon data at any point in this clipping process; we simply set each polygon's 'Deleted' member to a value of 'true'. Once we have finished iterating through each of the polygons in the list, we must finally clear the 'BackList' variable by overwriting it with a value of NULL. This should be done in order to prevent this list of now deleted polygons from being passed down the back of the node later in this function.

```
    // Now onto the clipping
    if ( ClipSolid )
    {
        if ( GetNode(CurrentNode)->Back == BSP_SOLID_LEAF )
        {
            // Iterate through and flag all back polys as deleted
            for ( TestFace = BackList; TestFace; TestFace = TestFace->Next )
                TestFace->Deleted = true;

            // Empty Back List
            BackList = NULL;

        } // End if Back == Solid

    }  // End if clipping solid
```

If the value passed to the 'ClipSolid' parameter is equal to 'false', then we have been instructed to remove those polygon fragments that may have ended up in any *empty* leaf. Unlike the solid leaf case, if the 'RemoveBackLeaf' BSP compilation option has been disabled then empty leaves can exist both in front of and behind any node. For this reason we must test both the 'Front' and 'Back' members of the current node in this case. If an empty leaf is found to be attached to the back of this node, then again each of the polygons in the back list should be marked as deleted. Conversely, if an empty leaf is found to be attached to the front of this node, then each of the polygons in the *front* list should be marked as deleted. In either case, to prevent any further recursion with this data, we must also remember to clear the applicable 'FrontList' or 'BackList' variable once the polygons have been processed as before.

```
    else
    {
        if ( GetNode(CurrentNode)->Back < 0 )
        {
            // Iterate through and flag all back polys as deleted
            for ( TestFace = BackList; TestFace; TestFace = TestFace->Next )
                TestFace->Deleted = true;

            // Empty Back List
            BackList = NULL;

        } // End if Back == Empty

        if ( GetNode(CurrentNode)->Front < 0 )
        {
            // Iterate through and flag all front polys as deleted
            for ( TestFace = FrontList; TestFace; TestFace = TestFace->Next )
                TestFace->Deleted = true;

            // Empty Front List
            FrontList = NULL;

        } // End if Front == Empty

    } // End if clipping empty
```

It is not necessarily the case that we would have encountered leaves at this stage in the recursive process. As a result, our front and back lists may still be fully populated. Due to the fact that we are actually passing data through the tree in order to determine the leaves in which they are contained, it is necessary for us to traverse into any front and back child nodes at this point. In each case we pass in the same parameter information as was passed to this call with the exception of the last two parameters. Into these we pass the relevant front & back node indices, along with the matching 'FrontList' or 'BackList' variable. Once each side of the node have been fully traversed, we finally return from this function and pass control back to the caller.

```
    // Pass down the front of the node
    if ( FrontList && GetNode(CurrentNode)->Front >= 0 )
            ErrCode = ClipTree( pTree, ClipSolid, RemoveCoPlanar,
                                GetNode(CurrentNode)->Front, FrontList);

    if ( FAILED( ErrCode ) ) goto ClipError;

    // Pass down the back of the node
    if ( BackList && GetNode(CurrentNode)->Back >= 0 )
            ErrCode = ClipTree( pTree, ClipSolid, RemoveCoPlanar,
                                GetNode(CurrentNode)->Back, BackList);

    if ( FAILED( ErrCode ) ) goto ClipError;

    // Success!
    return BC_OK;
```

Because this function is not responsible for creating or deleting any polygon objects that exist only within the stack based linked lists, we do not need to perform any kind of garbage collection in the error handling case. Instead, whenever this function skips to this piece of code we simply return the current error code maintained within the 'ErrCode' variable.

```
ClipError:
    // Failed
    return ErrCode;
}
```

Once this function has completed its recursive execution, any polygons that were contained within the source BSP tree passed to the first parameter of this function will now contain a list of all the newly clipped fragments, in addition to the original polygons simply marked as 'Deleted'. However, no modification of the object in which the 'ClipTree' method was called has occurred. For this tree to subsequently be clipped, the HSR processing module would now perform the same operation again but with the trees reversed. This tree should now be passed in to the first parameter of the 'ClipTree' method of the other.

CBSPTree::RepairSplits

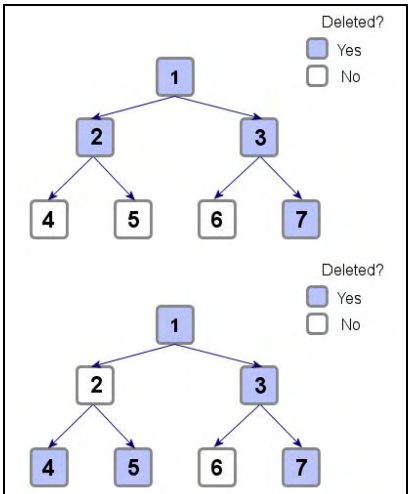

Figure 16.5

The 'RepairSplits' function is an extremely small and yet very fast and elegant way of repairing any unnecessary splits that may have been introduced during the constructive solid geometry clipping process. During the 'ClipTree' process, recall that we store the indices to those polygons created whenever a polygon was split. In addition to this, the original polygon is simply marked as deleted rather than being physically removed.

Referring to the uppermost diagram in figure 16.5, we demonstrate a situation in which the original polygon – shown with an index of 1 – has been split into two child fragments – 2 & 3. This original polygon has then been marked as deleted. Later in the process, each of these child fragments has been split into a further two. Again the source polygons have been flagged as deleted. Finally, polygon 7 gets flagged as deleted during the clipping process. At this point we have a situation in which there are only three polygon fragments that are not marked as deleted. These are the polygons 4, 5 and 6. Notice that polygons 4 and 5 both originated from the same parent – polygon 2. This clearly demonstrates an unnecessary split because both child fragments have survived.

If we now examine the bottom diagram in this same figure we can see what might happen if we repair the unnecessary splits in this scenario. We can see that the child fragments 4 and 5 have now been marked as deleted, and their parent polygon 2 has been resurrected. Its sibling polygon 3 however remains in the deleted state because only one of its child fragments survived.

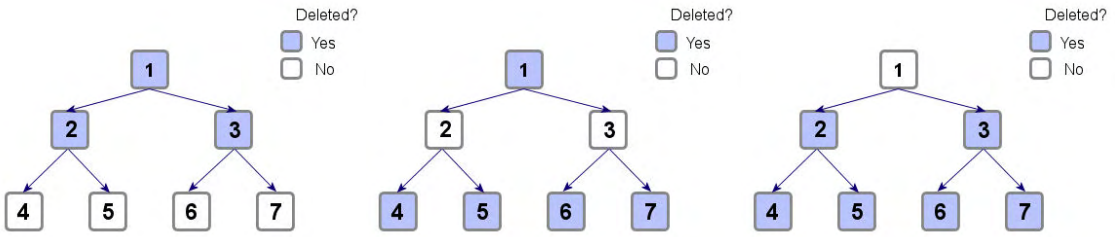

Figure 16.6

Figure 16.6 shows a series of diagrams that demonstrate an alternative scenario. In this case, all 4 of the bottom most children have survived. Both splits generated against polygons 2 and 3 were clearly therefore unnecessary and can be repaired. At this stage, the four child fragments have been marked as deleted and the original fragments 2 & 3 have been restored. Again in this case, these two polygons are fragments resulting from the original polygon 1 being split. Since both child fragments are no longer deleted we can go one step further and restore the original polygon.

As you might imagine, this simple repair process could greatly reduce the number of polygons that might result from an extensive, high-resolution clipping operation. With the theories discussed, let us see how this process is implemented in our 'CBSPTree' class.

The first thing we must do in this function is set up a loop that starts with the last polygon in the BSP tree's polygon array, and works **backwards** to the beginning. If you think back to figure 16.6 remember that we were able to perform multiple levels of repair when starting at the four child fragments and working our way up. In the BSP tree's 'ClipTree' function, whenever new polygon fragments are generated they are added to the *end* of the tree's polygon array with the earliest originals at the start.

Once inside this loop, we first test the contents of one of the 'ChildSplit' elements of the current polygon to see if it makes reference to any split fragment. If either of these elements contains a value other than -1 then this means that this fragment was split at some point. Once we know that a polygon was split into two child fragments, we can then retrieve those fragments and test their 'Deleted' member value. If *neither* fragment is marked as deleted then we will be able to repair this fragment. As a result we set the current polygon's 'Deleted' member to false, and each of the child fragments 'Deleted' members to true.

```
void CBSPTree::RepairSplits()
{
    // For each face
    for ( int i = GetFaceCount() - 1; i >= 0; i--)
    {
        // If one isn't -1, neither is the other
        if ( GetFace(i)->ChildSplit[0] != -1)
        {
            // If the two children are valid this split should be repaired
            if ( !GetFace( GetFace(i)->ChildSplit[0] )->Deleted &&
                 !GetFace( GetFace(i)->ChildSplit[1] )->Deleted )
            {
                // Restore the parent, and delete the children
                GetFace( i )->Deleted = false;
```

```
                GetFace( GetFace(i)->ChildSplit[0] )->Deleted = true;
                GetFace( GetFace(i)->ChildSplit[1] )->Deleted = true;

            } // End if Both Valid

        } // End if Has Children

    } // Next Face
}
```

With this polygon repaired, we continue working backward through the array. Eventually we might come to an earlier polygon that references the polygon we had just repaired. This might be deleted once again, along with a sibling, have *its* parent restored. Once this entire process has completed, we should find that in most cases this repair process is extremely effective because of the fact that it is able to perform partial repairs on original polygons.

CBSPTree::IntersectedByTree / IntersectedByFace

The 'IntersectedByTree' method is the first of two companion functions outlined here. This function is designed to be called by the application in order to test for intersection between two BSP tree objects. The first is the object into which the application is calling, and the second is passed in as the single parameter to this function. This is achieved by passing each polygon contained within the specified BSP tree, through the local tree structure to determine if any of those polygons fall into solid space.

This function is however just a wrapper for the second of these two functions – the 'IntersectedByFace' method. Iterating through each polygon in the BSP tree object passed, this function passes that polygon directly into that method and immediately returning a value of true should it report an intersection.

```
bool CBSPTree::IntersectedByTree( const CBSPTree * pTree ) const
{
    // Loop through each face testing for intersection
    for ( ULONG i = 0; i < pTree->GetFaceCount(); i++ )
    {
        if ( IntersectedByFace( pTree->GetFace(i) ) ) return true;

    } // Next Face

    // No Intersection
    return false;
}
```

The 'IntersectedByFace' method is a recursive procedure and serves as the core of this intersection testing process. This function accepts two parameters. The first is a pointer to the single polygon object to be tested and the second is the index to the current node at this level in the hierarchy. The premise of this function is to pass the specified polygon through the tree, and return an 'intersection' result if that polygon was found to exist in solid space.

> **Note:** This intersection test is not 100% accurate and is designed this way for reasons of efficiency. In order to accurately detect when a polygon falls into solid space it should be split against any node plane it was found to be spanning. Because we do not split the polygon in this way, it is possible for a false

intersection to be returned in certain cases. However, this technique should never return a non-intersection result in cases where an intersection definitely occurred.

```
bool CBSPTree::IntersectedByFace( const CFace * pFace, ULONG Node /* = 0 */ ) const
{
    // Validate Params
    if (!pFace || Node < 0 || Node >= GetNodeCount() ) return false;

    int NodeFront = GetNode( Node )->Front;
    int NodeBack  = GetNode( Node )->Back;
```

The first thing we do at the top of this function is to retrieve the values contained in the front and back members of the current node. This is done for convenience purposes so that we don't have to retrieve them each time we need them.

The next step in the operation is to classify this polygon against the current node's plane and take any appropriate action based on the result.

The first case we deal with here occurs when the polygon we are testing is either co-planar with the node plane, or is found to be spanning. It might seem a little strange to combine both the onplane and spanning case as we have below, but in this function we will not be splitting the test polygon. Instead, all we are interested in is whether there is any part of the polygon in front, behind or on both sides of the node plane. If the polygon is found to be spanning or coplanar then it will be considered to exist both in front and behind. As a result, we check the back of the node to see if it describes solid space. If it does then we immediately return true because we have found a potential intersection. If there is no solid leaf behind, we simply pass this polygon first down the front of the current node and then down the back should a child node exist there in each case. If the recursive call to either 'IntersectedByFace' function returns true, we must also return true such that we will step all the way back out of the recursive procedure.

```
    // Classify this poly against the nodes plane
    switch ( GetPlane(GetNode(Node)->Plane)->ClassifyPoly( pFace->Vertices,
                                                           pFace->VertexCount,
                                                           sizeof(CVertex) ) )
    {
        case CLASSIFY_SPANNING:
        case CLASSIFY_ONPLANE:
            // Solid Leaf
            if (NodeBack == BSP_SOLID_LEAF ) return true;
            // Pass down the front
            if (NodeFront >= 0 )
            {
                if ( IntersectedByFace( pFace, NodeFront ) ) return true;
            }
            // Pass down the back
            if (NodeBack  >= 0 )
            {
                if ( IntersectedByFace( pFace, NodeBack  ) ) return true;
            }
            break;
```

The next case is that in which the polygon is contained completely in the front half space of the current node. Since no solid leaf can exist in front of a node, we simply pass the current polygon down the front of this node should another child node exist there. Again, we return true immediately if this recursive informed us of an intersection.

```
        case CLASSIFY_INFRONT:
            // Pass down the front
            if (NodeFront >= 0 )
            {
                if ( IntersectedByFace( pFace, NodeFront ) ) return true;
            }
            break;
```

Similar to the front case, this case occurs when the polygon is completely contained in the back half space of the node. Solid space can exist *behind* a node however, so we test for this and return true if solid space is found to exist there. If not, we pass the polygon down the back of the current node should another child node exist there.

```
        case CLASSIFY_BEHIND:
            // Solid Leaf
            if (NodeBack == BSP_SOLID_LEAF ) return true;
            // Pass down the back
            if (NodeBack  >= 0 )
            {
                if ( IntersectedByFace( pFace, NodeBack  ) ) return true;
            }
            break;

    } // End Classify Switch
```

If we get here then we did not find any intersections at this level in the tree / recursion. As a result we simply return false from this function in this case.

```
    // No Intersection at this level
    return false;
}
```

This function concludes our coverage of the additional CSG support functionality provided by the ‘CBSPTree’ class. Being the only module that remains to be covered, let us now examine the T-Junction repair process module.

The CProcessTJR Module Class

The T-Junction repair process is the last of the three compiler modules we will implement in this lab project. It is thankfully also the most simple. Because the majority of the code within this process is taken directly from our previous implementation of the T-Junction repair process, we will not dwell on this topic for too long. Before we move on to the modifications that we have made to the procedures, let us take a look at the module class declaration.

```
class CProcessTJR
{
public:
    // Constructors & Destructors for This Class.
             CProcessTJR();
    virtual ~CProcessTJR();

    // Public Member Functions Omitted

private:
    // Private Variables for This Class.
    TJROPTIONS      m_OptionSet;        // The TJR option set
    ILogger        *m_pLogger;          // Log output interface.
    CCompiler      *m_pParent;          // Parent Compiler Pointer

    // Private Member Functions Omitted

};
```

The declaration for the CProcessTJR module class is very similar to that of the hidden surface removal class we looked at earlier. Due to the fact that this module works directly on the existing scene data however, there are even fewer member variables.

Although the member variables declared within this class are only those required by every processing module, let us quickly examine how they apply to this class.

TJROPTIONS m_OptionSet
This member stores the various settings, specified by the application to inform the compiler how the T-Junction repair operation should be executed. Although this structure contains no settings outside of the 'Enabled' Boolean, this options structure should be set using the 'SetOptions' accessor function in case of future enhancement.

ILogger * m_pLogger
In order for the TJR processor to report progress, error and useful status information to the user, this member variable stores a pointer to the application defined logging class. While the logging feature remains optional, this member can be set with a call to the 'SetLogger' accessor function defined by this class. In this lab project, the logging class instance is passed to this object by the 'CCompiler::PerformJTR' function.

CCompiler * m_pParent
Each compilation module class maintains a member that stores a reference to the parent compiler class that created it. This member is set with a call to the 'SetParent' accessor function defined by each of these classes. This information is used by each of these processing modules in order to test the current state of the compiler to determine if the compile operation has been either paused or cancelled. Although we have omitted much of the logging and progress functionality from the code listings in this workbook, you should take a look at the source code for lab project 16.2 to see this process in action.

TJR Module Accessor Functions

There are only a few accessor functions defined within the TJR processing module class. In each case, the body for these functions can be found in the class declaration contained in the header file, rather than in the source module / .CPP file. We will not go into detail about how each of these functions is implemented, for this you should take a look at the 'CProcessTJR.h' header file contained in the 'Compiler Source' project directory.

The only accessor functions defined by the 'CProcessTJR' class are those that set the various pieces of information required by each compilation process module. These include the process options, a pointer to the parent compiler and a pointer to the class defined logging class. These functions simply store those specified values into the applicable member variables declared by this class.

```
void            SetOptions    ( TJROPTIONS Options    )
void            SetParent     ( CCompiler * pCompiler )
void            SetLogger     ( ILogger * pLogger     )
```

Now that we are familiar with each of this class's member variables, let us move on to examine the main process functionality.

CProcessTJR::Process

This function is called by the compiler's 'PerformTJR' function in order to begin the actual T-Junction repair process. This process has no pre-requisites in the form of data being added to the module class in advance. Instead, this method will work directly with that scene data passed into its parameters.

Earlier we discussed the fact that this process is not concerned with any of the renderable polygon information such as textures or materials, or even the surface normal. All we need to have access to are the vertices stored within the scene polygons. As a result, the first parameter declared by this function accepts a list of *pointers* to one or more base 'CPolygon' objects. The second parameter specifies the number of polygons contained in that array.

```
HRESULT CProcessTJR::Process( CPolygon ** ppPolys, ULONG PolyCount )
{
    ULONG      i, k;
    CBounds3  *pBounds = NULL;
    CPolygon  *pCurrentPoly, *pTestPoly;

    // Validate values
    if (!ppPolys || !PolyCount) return BCERR_INVALIDPARAMS;
```

In our previous implementation, we took advantage of the compiled tree in order to rapidly retrieve a list of neighbors for any polygon currently being tested. In this case however we cannot guarantee that a BPS tree has even been compiled. As a result, this function must make its own adjacency arrangements. In order to provide a relatively quick means by which we can determine these neighboring polygons, we first build a list of bounding boxes for every polygon passed into this function using the bounding box's 'CalculateFromPoly' function. We also increase the size of each bounding box by a small amount. This is in order to ensure that the neighbor polygon bounding boxes safely overlap.

```
    try
```

```
    {

        // Allocate space for bounding boxes
        if (!(pBounds = new CBounds3[PolyCount])) return BCERR_OUTOFMEMORY;

        // Log – TJR: Pre-compiling adjacency information

        // Calculate polygon bounds
        for ( i = 0; i < PolyCount; i++ )
        {
            // Log – TJR: Update Progress

            // Build polygon bounds
            pBounds[i].CalculateFromPolygon( ppPolys[ i ]->Vertices,
                                             ppPolys[ i ]->VertexCount,
                                             sizeof(CVertex) );

            // Increase bounds slightly for tolerance
            pBounds[i].Min.x -= 0.1f;
            pBounds[i].Min.y -= 0.1f;
            pBounds[i].Min.z -= 0.1f;
            pBounds[i].Max.x += 0.1f;
            pBounds[i].Max.y += 0.1f;
            pBounds[i].Max.z += 0.1f;

        } // Next Bounds
```

With this bounding box information constructed, we can begin the process of searching for two polygons whose bounding boxes intersect. In a similar manner to the hidden surface removal process, we construct two loops here. The first iterates through each polygon in the outer loop, and another iterates through each polygon in the inner loop. Assuming these aren't both the same polygon, we test for intersection between both polygon bounding boxes with a call to the 'CBounds3::IntersectByBounds' method.

```
        // Log – TJR: Repairing T-Junctions

        // Loop through Faces
        for ( i = 0; i < PolyCount; i++ )
        {
            // Log – TJR: Update Progress

            // Get the current poly to test and its vertex array
            pCurrentPoly = ppPolys[ i ];
            if (!pCurrentPoly) continue;

            // Test against every other face in the tree
            for ( k = 0; k < PolyCount; k++ )
            {
                // Don't against test self
                if (i == k) continue;

                // Get the test face and its vertices
                pTestPoly = ppPolys[ k ];
                if (!pTestPoly) continue;
```

```
                // If the two do not intersect then there is no need for testing.
                if ( !pBounds[i].IntersectedByBounds( pBounds[k] ) ) continue;
```

If the two bounding boxes did intersect at this point then we attempt to run the repair process between each of these polygons, first in one direction and then in the other. We then move on to the next polygon in the inner loop.

```
                // Repair against the testing poly
                if (!(RepairTJunctions( pCurrentPoly, pTestPoly )))
                    throw BCERR_OUTOFMEMORY;

                // Now we do exactly the same but in reverse order
                if (!(RepairTJunctions( pTestPoly, pCurrentPoly )))
                    throw BCERR_OUTOFMEMORY;

            } // Next Test Face
```

At this stage, the current polygon in the outer loop has been processed and repaired against every other polygon in the scene and it need not be considered again in the future. As a result, we overwrite its element in the array with a NULL pointer causing the each loop to bypass this element.

```
            // Completely processed
             ppPolys[i] = NULL;

        } // Next Current Face

    } // End Try Block
```

The final part of this function simply implements the exception handling and clean up code common to most of the functions in this application. Assuming no exception is thrown, the T-Junction repair process has now completed successfully and can return a success code to the calling function.

```
    catch ( HRESULT &e )
    {
        // Clean up and return (failure)
        if (pBounds) delete []pBounds;

        // Log – TJR: Report Failure

        return e;

    } // End Catch Block

    // Release used memory
    if (pBounds) delete []pBounds;

    // Log – TJR: Report Success

    // Success!
    return BC_OK;

}
```

Although this wrapper function contains a reasonable amount of logic on its own, the actual process of repairing the T-Junctions is implemented in the 'RepairTJunctions' method covered in earlier lessons.

CProcessTJR::RepairTJunctions

The 'RepairTJunctions' method outlined below is identical to that we have previously covered and implemented. This is with the exception of it having been adapted for use with the new math support classes. As a result of these minor alterations, we have included this code again here for your convenience.

```
bool CProcessTJR::RepairTJunctions( CPolygon *pPoly1, CPolygon *pPoly2 ) const
{
    CVector3   Delta;
    float      Percent;
    ULONG      v1, v2, v1a;
    CVertex    Vert1, Vert2, Vert1a;

    // Validate Parameters
    if (!pPoly1 || !pPoly2) return false;

    // For each edge of this face
    for ( v1 = 0; v1 < pPoly1->VertexCount; v1++ )
    {
        // Retrieve the next edge vertex (wraps to 0)
        v2 = ((v1 + 1) % pPoly1->VertexCount);

        // Store verts (Required because indices may change)
        Vert1 = pPoly1->Vertices[v1];
        Vert2 = pPoly1->Vertices[v2];

        // Now loop through each vertex in the test face
        for ( v1a = 0; v1a < pPoly2->VertexCount; v1a++ )
        {
            // Store test point for easy access
            Vert1a = pPoly2->Vertices[v1a];

            // Test if this vertex is close to the test edge
            // (Also returns out of range value if the point is past the line ends)
            if ( Vert1a.DistanceToLine( Vert1, Vert2 ) < EPSILON )
            {
                // Insert a new vertex within this edge
                long NewVert = pPoly1->InsertVertex( v2 );
                if (NewVert < 0) return false;

                // Set the vertex pos
                CVertex * pNewVert = &pPoly1->Vertices[ NewVert ];
                pNewVert->x = Vert1a.x;
                pNewVert->y = Vert1a.y;
                pNewVert->z = Vert1a.z;

                // Calculate the percentage for interpolation calcs
                Percent = (*pNewVert - Vert1).Length() / (Vert2 - Vert1).Length();
```

```
                // Interpolate texture coordinates
                Delta.x      = Vert2.tu - Vert1.tu;
                Delta.y      = Vert2.tv - Vert1.tv;
                pNewVert->tu = Vert1.tu + ( Delta.x * Percent );
                pNewVert->tv = Vert1.tv + ( Delta.y * Percent );

                // Interpolate normal
                Delta            = Vert2.Normal - Vert1.Normal;
                pNewVert->Normal = Vert1.Normal + (Delta * Percent);
                pNewVert->Normal.Normalize();

                // Update the edge for which we are testing
                Vert2 = *pNewVert;

            } // End if on edge

        } // Next Vertex v1a

    } // Next Vertex  v1

    // Success!
    return true;
}
```

Lab Project Conclusion

This has been a very interesting but difficult lab project to cover. With the introduction of a completely new framework came new and interesting challenges to overcome. With that said, we now have at our disposal a strong foundation application that can be greatly enhanced as you progress further in your studies with us. With the introduction of the polygon-aligned leaf BSP tree and hidden surface removal processes too, we now have some very exciting opportunities opening up to us. In the next lesson we will be taking these concepts even further with the introduction of portals for leaf connectivity information, and PVS for occlusion culling and visibility which is certainly a topic to look forward to.

Lab Project 16.3: BSP Leaf Tree Loading & Rendering

In lab project 16.3, we begin to put together the rendering application that will make use of the information that has been compiled and exported by the new pre-processing tool developed in the previous lab project. In this application we will move back to our integrated spatial partitioning framework which we have been developing in previous lessons and add a new type of tree responsible for handling the solid BSP leaf tree information. Due to the fact that the compilation of the spatial hierarchy is now delegated to an external application, this new tree class will not perform any physical compile process. Instead it will be responsible only for the loading of the tree data from the compiled IWF file and reconstructing that information into a format compatible with our current spatial hierarchy rendering and utility classes.

The Loading Process

Because we have already developed a full scale scene import process within the 'CScene' class, it would be ideal if we could find a way to have this class remain responsible for loading and processing all level geometry and scene entities. If we can achieve this then no large scale modifications will have to be made within the application itself or any part of our existing spatial partitioning framework. In this lab project we will develop a process in which the scene object first processes the selected IWF file in the same manner as it has always done. Any polygon data imported from that file will simply be added to this new tree *loading* object via the 'ISpatialTree' interface as was the case with the tree *compiler* classes. With this polygon data already in place, the new loading class which will be developed in this lesson will simply be responsible for processing the IWF file for a second time. During this stage, the loading code will retrieve and reconstruct **only** the custom BSP tree information contained therein. As far as the application will be concerned, it would appear as if this new tree class has performed a full compilation of the scene geometry in a similar fashion to the quad-tree class for instance. However, all it has really done is to load the hierarchy data from an external file.

Enhanced Visibility State Recording

In addition to developing this new tree loading concept, we will also enhance the mechanism by which we record the visible state of each of the leaves contained in the tree. In previous applications, during the 'ProcessVisibility' update traversal, we visited every leaf in the tree to update its visibility state with a call to its 'SetVisible' method even if that leaf was not visible. In this tree class, we will be adopting a frame counter system similar to that used by our collision detection and response classes, such that the leaf visibility information is invalidated automatically simply by incrementing a centralized counter variable. Whenever a leaf is found to be visible, a new leaf variable will be updated with the current counter value that can simply be tested during rendering to see if it was marked as visible at any point in this frame of the rendering loop. If the 'SetVisible' call was not made during this frame, then the leaf's internal copy of the counter will be out of date and as such we can take this as a sign that the leaf is not visible. This new mechanism unfortunately prevents the application from making a call to the default 'IsVisible' method of any leaf due to us no longer always updating the 'm_bVisible' member of the 'CBaseLeaf' class. As a result we will need to derive a new leaf class from this base leaf, so that we can

override this behaviour and once again restore this function to a working state. This situation will be discussed in more detail as we move on to discuss the new 'CBSPTreeLeaf' class.

As a direct result of using this new counter mechanism however, we no longer have to visit every single leaf in the spatial hierarchy just to mark it as invisible. As you might image this should have a dramatic effect on the performance of the BSP tree rendering process specifically because it often has many more leaves than the previous types of spatial hierarchy we have developed.

This should be a very interesting use of our existing spatial hierarchy technology. So, without further ado, let us move on to cover the implementation of this new type of tree loader object and its associated support classes and routines.

The CBSPTreeNode Class

As we know, the BSP leaf tree is a *binary* partitioning construct that is designed to separate space into two parts – one portion on either side of a separating plane. This principal is of course identical to that of the kD-tree concept we are already familiar with.

Recall that the node structures within both spatial partitioning schemes are required to maintain similar information. Such information includes a separating plane, front and back child nodes and an optional child leaf. There are also some additional pieces of data that are common to both systems – such as the node's bounding box extents – that serve as the basis for the various rendering and traversal optimizations we have integrated in the past.

If we take a look at the declaration for the new 'CBSPTreeNode' class we should notice that it bears a striking resemblance to the 'CKDTreeNode' class we have previously developed.

```
class CBSPTreeNode
{
public:
    // Constructors & Destructors for This Class.
     CBSPTreeNode( );
    ~CBSPTreeNode( );

    // Public Variables for This Class
    D3DXPLANE       Plane;              // Splitting plane for this node
    CBSPTreeNode *  Front;              // Node in front of the plane
    CBSPTreeNode *  Back;               // Node behind the plane
    CBSPTreeLeaf *  Leaf;               // Leaf may be stored here
    D3DXVECTOR3     BoundsMin;          // Minimum bounding box extents
    D3DXVECTOR3     BoundsMax;          // Maximum bounding box extents
    signed char     LastFrustumPlane;   // The frame-to-frame coherance index.

    // Public Members Omitted
};
```

Due to the fact that this node structure is almost identical to that used by both the kD-tree and BSP node tree, we will only briefly recap on each of the member variables declared here.

D3DXPLANE Plane
This member describes the separating plane used in the creation of this node. In the case of the polygon-aligned BSP tree, this will be oriented such that it matches the plane of at least one polygon in the scene. In this new rendering application, the plane data is pulled from our combined plane array – stored in the import file – and placed into the D3DXPLANE typed member that we have relied upon throughout. We will examine this procedure shortly.

CBSPTreeNode * Front
Each node in the BSP tree partitions the scene into pieces which represent the space contained in both its front and back halfspaces. If there are further polygons available to be selected in front of the current node, then our compiler will have recursed into the front list and continued to generate new nodes from that data. The first of these nodes would be attached to this member in exactly the same manner with which we are familiar. In contrast to our compiler tool, our rendering application does not combine the concept of attached child leaves and nodes into one member variable and as such only a child node can be attached here. This is similar to the previous run-time tree types we have implemented prior to this, represented with a type that contains a pointer to another 'CBSPTreeNode' object.

CBSPTreeNode * Back
This member is similar to the previous in that it stores a pointer to any child node that might exist in the back halfspace of the current. Again this is identical in principal to the kD and BSP node tree types we have implemented in the past.

CBSPTreeLeaf * Leaf
Should this be a terminal node, this member will store the child leaf that should be attached here. In the earlier lab projects dealing with spatial hierarchies, we found that *every* terminal node would have a leaf attached to it. In this application we are implementing the run-time portion of the **solid** leaf BSP tree. Recall in lab project 16.2, there were cases in which a particular area of space within the scene was found to be solid. In these cases, no leaf was created or inserted into the tree. These leaves were simply replaced with an indicator that allowed us to identify this fact. As a result, when reconstructing the BSP tree in this application, there may be cases where this member is assigned a value of NULL that is used to signify the same thing. More details will be provided on this subject as we move into covering the actual reconstruction of the hierarchy from file.

D3DXVECTOR3 BoundsMin
This member stores the value that describes the minimum extents of the node's bounding box. Recall that this bounding box will be large enough to contain every node, leaf and polygon that is found to exist anywhere beneath the current node.

D3DXVECTOR3 BoundsMax
Like the previous, this member stores part of the data required to describe the node's axis-aligned bounding box. In this case however, this member stores the *maximum* extents of the box that describes each of the elements contained in this node's subtree.

signed char LastFrustumPlane
We have encountered and discussed this member in previous lessons. Recall that it is used during the 'ProcessVisibility' traversal process when testing the node bounding box against the camera's frustum

planes. This member stores the last frustum plane found to intersect this node's parent bounding box. This is an optional value that can be passed into the camera's 'BoundsInFrustum' function to allow it to optimize the order in which it tests the frustum planes during the processing of a hierarchy such as this.

With each of the member variables discussed, it should be clear that this node class does not declare anything that we have not encountered before with the kD-tree node type. Similar to the 'CKDTreeNode' class, this exposes only a single method. Let us take a look at this now.

CBSPTreeNode::SetVisible

The only method defined by this node class is the 'SetVisible' function. As we know, this function is traditionally called during the 'ProcessVisibility' traversal in each of our previous tree types. This implementation of the BSP tree is no different in that regard. It accepts a single Boolean parameter that specifies whether or not this node and its children are visible, this function then passes that information on to any applicable children. At the top of the function we can see that if there is a leaf stored in this node, that leaf's own 'SetVisible' function will be called – passing in the same visibility status – before returning. If there was no leaf stored here, then this recursive procedure calls the 'SetVisible' function of both its front and back child nodes should either be available. This has the effect of traversing through the tree and updating the visibility status of every leaf contained anywhere beneath the initial node on which this function has been called.

```
void CBSPTreeNode::SetVisible( bool bVisible )
{
    // Set leaf property
    if ( Leaf  ) { Leaf->SetVisible( bVisible ); return; }

    // Recurse down front / back if applicable
    if ( Front ) Front->SetVisible( bVisible );
    if ( Back  ) Back->SetVisible( bVisible );
}
```

As we can see, this simple recursive function remains unchanged from each of the four node classes we have created within the previous spatial hierarchy types.

The CBSPTreeLeaf Class

This class provides the data structures required to represent the leaf items contained within the spatial hierarchy. Again the concepts involved in attaching objects of this type to the tree should be very familiar to us already. However, there is a key difference between the implementation of the leaf concept used in previous spatial hierarchies and that of this new BSP loading class. In each of the previous tree types, recall that we used instances of the 'CBaseLeaf' class exclusively within the tree structure. This base class provides much of the functionality required to store the various pieces of information – such as the polygons and objects contained within that leaf – in addition to the functionality required for rendering much of that data.

As we move forward with the BSP leaf tree concepts, the leaf structure will be required to store and process much more information that is specific to this type of tree. As a result, within the implementation of this spatial hierarchy type, we will begin to create a new leaf class that *derives* from

‘CBaseLeaf’. This is done in order to extend that base with the additional members and functionality required in both this lesson and the next.

With this in mind, let us take a look at this new leaf class declaration before moving on to the initial methods that will be exposed.

```
class CBSPTreeLeaf : public CBaseLeaf
{
public:
    // Constructors & Destructors for This Class.
             CBSPTreeLeaf( CBSPTreeLoader * pTree );
    virtual ~CBSPTreeLeaf( );

    // Public Virtual Functions for This Class (from base).
    virtual bool    IsVisible  ( ) const;
    virtual void    SetVisible ( bool bVisible );

    // Public Variables for This Class
    ULONG           m_nVisCounter;
};
```

As you can see, there is only one member variable declared by this class outside of those inherited from the base ‘CBaseLeaf’ class that we are already familiar with. The purpose of this variable is described below.

ULONG m_nVisCounter
This member relates to the new visibility counting mechanism mentioned earlier in this lesson. Should the leaf be visible in any given render call, this variable will be updated such that it contains the same value as that currently stored within the main tree object. If at any point the leaf is found to be outside of the viewing frustum, this member will *not* be updated and will automatically become out of date as the main counter has been incremented. Because the tree’s counter is incremented every frame, if the value of this member differs from that of the tree object at any point, we know that this leaf was found not to be visible within **this** frame of the render loop.

With this new visibility counting scheme we must alter the way that the ‘CBaseLeaf’ class detects and reports this leaf’s visibility status to the user. This is achieved by overloading the virtual ‘IsVisible’ method such that when the application requests the leaf’s visibility information through a pointer to the ‘ILeaf’ superclass, the function defined in this new ‘CBSPTreeLeaf’ will be called. In addition, we must also provide an overload of the ‘SetVisible’ function. This method is *not* declared within the ‘ILeaf’ interface and should never be called by the application. However, we must overload the ‘CBaseLeaf::SetVisible’ function in order to perform the additional processing that is now required.

CBSPTreeLeaf::CBSPTreeLeaf( )

The first function we need to discuss is the single constructor for this class. This constructor accepts a single parameter as input. This parameter is a pointer to the tree object into which this leaf will be attached. Recall from our earlier discussion of the ‘CBaseLeaf’ class, this *parent* information is placed into an internal member variable and is used to allow the leaf object to access information stored within

the tree itself. Both the member variable and the code to store the input parameter are inherited from this class's base. As a result, we must ensure that the base class constructor is also called, passing to it the same information that this constructor received. The easiest way to achieve this is to simply call the relevant 'CBaseLeaf' constructor by using the initialization list portion of the 'CBSPTreeLeaf' constructor shown below.

```
CBSPTreeLeaf::CBSPTreeLeaf( CBSPTreeLoader * pTree ) : CBaseLeaf( pTree )
{
    // Reset / Clear all required values
    m_nVisCounter   = 0;
}
```

With the information inherited from 'CBaseLeaf' fully initialized by the base class constructor, we can then simply continue to initialize those members added by this class. In this lab project, the only variable we need to reset here is the 'm_nVisCount' member. This is set to '0' in order to ensure that every leaf starts its life in an *in*visible state.

CBSPTreeLeaf::SetVisible

Earlier we talked a little bit about the new mechanism by which we are recording information about whether or not a leaf is visible. This scheme uses a counter variable that describes whether or not the leaf was marked as visible within the most recent call to the tree class's 'ProcessVisiblity' method. In this function and the next, we can see just how this is achieved. Recall that this is the first spatial hierarchy type in which we are deriving a new class in order to customize some of the core functionality provided by the base 'CBaseLeaf'. Because we want to add an additional mechanism by which the visibility status of the leaf is recorded we need to overload the base class' 'SetVisible' function.

In the code block that follows we have included additional code that updates the member variable responsible for recording the most recent frame in which this leaf was found to be visible. If this leaf was specified as being visible then the current visibility frame counter value is requested of the parent tree object to which this leaf is attached. The value returned is subsequently stored in the leaf's 'm_nVisCounter' member variable. If a value of 'false' was passed to this method's single parameter, then we simply reset the visibility counter to 0. Although in this application we will never explicitly call the 'SetVisible' method when a leaf is **not** visible – due to our new updated counter mechanism automatically invalidating such leaves – we include the latter case in order to ensure that the system exhibits the correct behaviour should we need to do so in the future.

```
void CBSPTreeLeaf::SetVisible( bool bVisible )
{
    // Update our current vis counter
    if ( bVisible )
    {
        // Store the current visibility counter
        m_nVisCounter = ((CBSPTreeLoader*)m_pTree)->GetVisCounter();

    } // End if visible
    else
    {
        // Reset the visibility counter
```

```
        m_nVisCounter = 0;

    } // End if not visible
```

With the ‘m_nVisCounter’ member variable either having been updated with the current frame counter, or reset to a value of 0 depending on the state of the ‘bVisible’ parameter, we must now pass on this message to the base class implementation of this function. This is done to allow the ‘CBaseLeaf’ version of this method to perform any necessary steps for adding this leaf to the tree’s internal visible leaf array as well as populating the appropriate buffers prior to rendering.

```
    // Call base class implementation
    CBaseLeaf::SetVisible( bVisible );
}
```

Given this relatively simple logic it should be clear that the ‘m_nVisCounter’ member of any given leaf will only be updated to match that of the tree if this method has been invoked in any specific visibility update traversal. Because the *tree’s* internal visibility counter is automatically incremented with each subsequent call to the ‘ProcessVisibility’ function in every frame, this of course means that if the leaf was not found to be visible at any point, the ‘m_nVisCounter’ variable maintained by that leaf will no longer match. This effectively allows us to mark every leaf as invisible at the start of each frame simply by incrementing that single counter value maintained by the main tree object. This negates the need to explicitly call the ‘SetVisible’ method for each leaf, passing a value of ‘false’ during the visibility traversal as we have done in the past. We will take a closer look at the changes we can make to the ‘ProcessVisibility’ method of the main tree class to improve its efficiency a little later in this lesson.

Due to the fact that we still want the application to be able to query the visibility state of each leaf, we must also override the ‘IsVisible’ method to take this new frame counter mechanism into account.

CBSPTreeLeaf::IsVisible

Should the leaf’s counter variable have been updated in a call to its ‘SetVisible’ method then logically the value stored in the leaf’s visibility counter should match that maintained by the associated tree object. Of course, this will only be the case for the duration of time until the next call to ‘ProcessVisibility’ is made. If the leaf is not subsequently marked as visible in that frame as well, then the value stored in the leaf’s ‘m_nVisCounter’ variable will be out of date. This removes the need for us to traverse every part of the tree simply to set a leaf as *not* being visible.

Given these facts, the ‘IsVisible’ method has been overloaded in this class to return a status of ‘true’ **only** if the leaf was set to visible in this frame of the applications main rendering loop – or more accurately the most recent call to the tree’s ‘ProcessVisibility’ method. This is done by comparing the visibility counter value stored here, to the value currently maintained by the parent tree object we set in the class constructor. If these two values match, then we know that the leaf has been updated in the current frame and the comparison operation shown below will result in a value of true being returned. If this is not the case, then the function will return false.

```
bool CBSPTreeLeaf::IsVisible( ) const
{
```

```
    return (m_nVisCounter == ((CBSPTreeLoader*)m_pTree)->GetVisCounter());
}
```

With our newly overridden leaf tree and node classes implemented in their entirety, let us now begin to examine the core derived tree class that we will by using in this lab project.

The CBSPTreeLoader Class

Like each of the spatial tree classes we have developed in the past, this new class is derived from 'CBaseTree' from which we inherit a large portion of the required storage, management and rendering functionality. The only task that each of these spatial hierarchy classes has essentially been responsible for is to populate the leaf, node and polygon arrays maintained by the base class itself. As we know this was previously achieved by taking the polygon data that has been loaded and passed in to the tree class and compiling that information into a given type of spatial hierarchy. In the case of lab project 16.3, the compilation process has already taken place and we are simply reconstructing that tree into a format compatible with our already existing spatial hierarchy utility and rendering classes. As a result, the majority of the code that we will be implementing within this class revolves around the loading and interpreting of the BSP tree information contained within the source IWF file and simply storing it in the appropriate base class container members. With this in mind, let us take a look at the new 'CBSPTreeLoader' class declaration to see how we might integrate such a concept into the existing hierarchy system.

```
class CBSPTreeLoader : public CBaseTree
{
public:
    // Constructors & Destructors for This Class.
    virtual ~CBSPTreeLoader( );
             CBSPTreeLoader( LPDIRECT3DDEVICE9 pDevice, bool bHardwareTnL,
                             LPCTSTR FileName );

protected:
    // Typedefs, Structures and Enumerators.
    struct iwfNode
    {
        long        PlaneIndex;
        D3DXVECTOR3 BoundsMin;
        D3DXVECTOR3 BoundsMax;
        long        FrontIndex;
        long        BackIndex;
    };

    // Protected Variables for This Class
    CBSPTreeNode * m_pRootNode;         // The root node of the tree
    LPTSTR         m_strFileName;       // File to load

    CBaseIWF       m_FileLoader;        // The IWF parsing object
    iwfNode       *m_pFileNodes;        // Node data loaded from file
    D3DXPLANE     *m_pFilePlanes;       // Plane data loaded from file.
    ULONG          m_nFileNodeCount;    // Number of nodes loaded from file
    ULONG          m_nFilePlaneCount;   // Number of planes loaded from file
```

```
    // Protected Functions Omitted

};
```

There are several new members declared here that we have not yet encountered in any of the spatial hierarchy classes that we have previously developed. Each of these member variables are outlined below.

CBSPTreeNode * m_pRootNode
The 'm_pRootNode' member stores a pointer to the root 'CBSPTreeNode' object of the constructed spatial hierarchy. This is the entry point into the tree and is used to start any traversal operation as we know. This member will be assigned during the tree reconstruction step in the 'BuildTree' function discussed shortly.

LPTSTR m_strFileName
This member stores a duplicated copy of the path and file name for the file to be imported. This filename string should reference the IWF file that has been compiled and exported by the pre-processing tool developed in lab project 16.2. This member is populated in this class's constructor and later used by the 'Build' function during the file import step (covered shortly).

CBaseIWF m_FileLoader
Due to the fact that this tree type does not perform a tree compilation process and instead simply loads the data from the IWF file, we need access to the file data. For this we use the 'CBaseIWF' class provided to us by the 'libIWF' import library. The 'm_FileLoader' member stores an object of this type. Put simply, this object will be used to perform all of the actual parsing of the IWF file and its structure.

By using a series of callback functions, the 'CBaseIWF' object will notify us whenever it encounters a chunk of a type within the file that we are interested in. With the file automatically positioned at the beginning of that applicable data, we can simply read the information using the stream functions provided by the 'CBaseIWF' class. For more information on this class and its methods, refer to appendix A in this chapter. We will see how this can be used to help us load the custom tree data as we move on to discuss the overloaded 'Build' function in addition to the registered callbacks that we must supply in order to read that information.

iwfNode * m_pFileNodes
During the import of the tree information contained in the IWF file, there are cases where we must load the data into temporary structures. The file data that describe the nodes within the BSP tree is just such a case. As we know, each node item stored within the file has a number of dependencies. These include the planes that are contained in the file's combined plane array, the leaf objects that may be attached to the node and of course the front and back child nodes. At the point in which we are loading the data for any given node, we may not yet have imported any plane or leaf items that may be attached to that node. More importantly than either of these is the fact that, until the entire node array has been loaded, the build procedure will not have access to the front and back child node information and will be unable to rebuild the physical tree structure. As a result, we must import the node data into a temporary area until such time as every node has been loaded. Once this has been done, we will then have full access to each node that is contained in the tree in order for us to reconstruct it.

Because of the fact that the structure of the node data stored within the file is different to that of the run-time application, and uses an indexing scheme to reference the applicable node, leaf and plane information, we must create a new structure that will hold the file's information temporarily. Let us take a quick look at the iwfNode structure we have defined in order to achieve this.

struct iwfNode

- *long PlaneIndex*

  As with each of the variables declared within this 'iwfNode' structure, the data stored in this member is loaded directly from the IWF file that is being processed. In particular, this member stores an index into the file's combined plane array that describes the plane on which this particular node lies. This information will be used to retrieve the correct plane data during the reconstruction of the tree into a format suitable for this application.

- *D3DXVECTOR3 BoundsMin*

  This member stores the value that describes the minimum extents of the node's bounding box. Recall that this bounding box will be large enough to contain every node, leaf and polygon that is found to exist anywhere beneath it in the tree.

- *D3DXVECTOR3 BoundsMax*

  Like the previous, this member stores part of the data required to describe the node's axis-aligned bounding box. In this case however, this member stores the *maximum* extents of the box that describes each of the elements contained in this node's subtree.

- *long FrontIndex*

  This member represents the index of the item attached to the front side of the current node stored within the appropriate array. Recall from our earlier discussion of lab project 16.2 that this can either be another child node or a leaf. If the sign of the index is positive then this member references a child node. If it is negative, this signifies that a leaf is attached to this side of the node. Our run-time tree hierarchy is constructed in a slightly different manner, providing additional leaf-nodes to which we attach the physical leaf data, simplifying the traversal process. This is yet another reason why ensuring that the node data is fully loaded and stored in a temporary array before reconstructing the tree is useful to us.

- *long BackIndex*

  The 'BackIndex' member is identical in principal to the aforementioned 'FrontIndex'. The only difference here is that this member is used to reference any leaf or node child that may be attached to the *back* of the current node. Also recall that in the solid tree – such as that compiled by the new pre-processing tool – this member may also store a value equal to that defined by the 'BSP_SOLID_LEAF' constant if the space behind this node is to be considered solid. It is

important to bear this in mind because we will need to recognize this situation when reconstructing the tree hierarchy.

With each of the individual elements in the temporary node structure defined, let us now continue on to discuss the remainder of the member variables declared within the 'CBSPTreeLoader' class.

D3DXPLANE * m_pFilePlanes
This member stores the array of plane data that was compiled and stored in the scene IWF file. Due to the fact that the plane information is stored in a separate linear block from the node data, this member also acts as a temporary container much like the 'm_pFileNodes' array. This array will be populated during import and will be used during the reconstruction of the spatial hierarchy as the basis for the plane data stored at each node. Recall that the node structure within the file stores an index to a specific plane within the combined plane array stored in the file. Since this array will represent that same plane data it should be used as the source for the plane referenced by the 'PlaneIndex' value stored in each temporary 'iwfNode' structure.

ULONG m_nFileNodeCount
This member stores the total number of nodes loaded from file and subsequently stored in the array referenced by the 'm_pFileNodes' member variable. This information is not used directly during the reconstruction of the tree, but it can be used for the purposes of validation to ensure that node data was actually loaded from the source file. This information might also be used to check each node's front and back index variables such that we return gracefully if any index exceeds the boundaries of the array, indicating that the node data stored in the file is malformed or corrupted.

ULONG m_nFilePlaneCount
As with the previous variable, this member stores the total number of planes loaded from file and subsequently stored in the 'm_pFilePlanes' array. Again, this information is not used directly during the reconstruction of the tree but it might be used to provide an extra layer of validation to protect against file corruptions or invalid information.

As we can see, with the exception of the 'm_pRootNode' variable, each of the members contained within this *loader* class exist primarily for the purpose of handling the import and processing of the scene hierarchy data. This information will then be used to reconstruct the hierarchy in a manner compatible with the 'ISpatialTree' interface concept we have been developing. Now that we have a rough understanding of each of the new class member variables, let us now move on to discuss the various methods of this class that are responsible for performing these operations.

CBSPTreeLoader::CBSPTreeLoader( )

We are already familiar with the steps involved in setting up a constructor for a new tree type that has been derived from 'CBaseTree'. As in each of our earlier tree classes, the constructor must accept both a valid Direct3D device, in addition to a boolean flag indicating whether hardware transform and lighting can and should be used when rendering any scene geometry. These two pieces of information must be passed to the base class constructor to allow any vertex and index buffer resources to be created using the correct parameters. In this new 'CBSPTreeLoader' class, this is achieved in a similar manner to those we have previously implemented, by passing these two parameters to the base constructor using

the initialization list portion of the function. The only additional piece of information that is required specifically by our new BSP tree loading class is the name of the file from which the tree data should be imported. This is passed by the application as the third argument to this constructor.

The body of this constructor is very simple and is responsible for initializing the class member variables with their default values. In this particular constructor we must also make a copy of the filename specified by the application. We do this using the '_tcsdup' runtime function in the same way as we have done many times before. It is important that we make a copy of this string here rather than simply storing the specified string pointer in order to ensure that the memory referenced by the 'FileName' parameter is not altered or released before we get a chance to begin importing and building the tree information.

```
CBSPTreeLoader::CBSPTreeLoader( LPDIRECT3DDEVICE9 pDevice, bool bHardwareTnL,
                                LPCTSTR FileName ) :
                                CBaseTree( pDevice, bHardwareTnL )
{
    // Clear required variables
    m_pRootNode       = NULL;
    m_pFileNodes      = NULL;
    m_pFilePlanes     = NULL;
    m_nFileNodeCount  = 0;
    m_nFilePlaneCount = 0;
    m_nVisCounter     = 0;

    // Make a copy of the file name
    m_strFileName = _tcsdup( FileName );
}
```

Once an object of this type has been instantiated, and the relevant pieces of information initialized and stored, the application can then instruct that object to begin building the spatial hierarchy information.

CBSPTreeLoader::GetVisCounter

The 'GetVisCounter' function is a publically accessible class method that allows other methods and objects to gain access to the tree's current visibility 'call' counter. This method is used by the 'SetVisible' and 'IsVisible' methods of the new 'CBSPTreeLeaf' class in order to retrieve the current counter value that has been incremented by a call to 'ProcessVisibility'. This function simply returns the value currently stored in the 'm_nVisCounter' member variable and takes no further action.

```
ULONG CBSPTreeLoader::GetVisCounter( ) const
{
    return m_nVisCounter;
}
```

CBSPTreeLoader::Build

The 'Build' function in the 'CBSPTreeLoader' class is a virtual function declared initially by the base 'ISpatialTree' interface. In each of the tree classes we have developed to date, the application has used this function to trigger the actual tree compilation process after the scene data has been added. However,

as we mentioned earlier, this class will not actually implement any kind of compile behavior. At this point, the information associated with the tree has already been compiled by our pre-processing tool and written to file. As a result, the 'Build' function of this class is primarily responsible only for setting up and calling the various import and reconstruction procedures that will create and populate the appropriate tree data structures.

One thing that you may notice as we move through the code in this class is that it only imports a small portion of the source IWF file specified in the class constructor. At no point does this class ever load or manipulate any type of scene polygon data for instance. This is due to the fact that the application will already have imported much of this information on our behalf. With the polygon data in particular, these will have already been loaded from the file in the 'CScene' class, and added to the member arrays inherited by this class using the 'CBaseTree::AddPolygon' function. With the scene responsible for loading much of the physical level data, this class needs only to import and process the BSP tree information that was exported by the tool developed in lab project 16.2. Any other information that may be stored in the file will simply be ignored. Thanks to the 'CBaseIWF' class exposed by the libIWF library, this is actually made very simple.

As defined by the 'ISpatialTree' super-class, the 'Build' method accepts a single parameter as input. This parameter is named 'bAllowSplits' and is a simple Boolean value that traditionally instructed the compiler as to whether the resulting polygon data should be split against the node planes or left whole. In the case of the 'CBSPTreeLoader' class, the tree and its associated polygon data have already been constructed and written to file based on the parameters specified in the pre-processing step. As a result this parameter will be ignored and the geometry will instead simply be used in its existing form.

```
bool CBSPTreeLoader::Build( bool bAllowSplits /* = true */ )
{
    try
    {
        // Open the file
        m_FileLoader.Open( m_strFileName, CBaseIWF::MODE_READ );

        // Set up the author ID for custom chunk reading
        m_FileLoader.SetAuthorID( "BSPC1", 5 );
```

Earlier we mentioned the 'm_FileLoader' member which is an instance of the 'CBaseIWF' class exported by the libIWF import library. This class handles the majority of the processing and navigating of an IWF file's structure and provides us with an easy means to gain access to the data stored within that file. In order to have this object process a specific file, the first thing we must do in this function is to open the file that we are interested in importing. This is achieved by calling the 'Open' method of the 'm_FileLoader' object passing in the name of the file to be processed. Recall that when an instance of this 'CBSPTreeLoader' class is created, the name of the IWF file that we are loading is passed to the constructor and duplicated into the 'm_strFileName' member variable. Therefore, this is the string that is passed as the first argument to the 'Open' method of the 'm_FileLoader' object. In addition, we must also instruct this object that the file should be opened for the purpose of *reading* data rather than writing. To this end, we also pass the 'CBaseIWF::MODE_READ' enumerator item as the second argument to this same function.

During the call to the ‘Open’ method, the file will be tested to ensure that it is of a format supported by the import library. Should this be the case, any appropriate file header information will be processed automatically and the ‘m_FileLoader’ object will be initialized such that we can begin reading data immediately. If an error occurred – such as the file being of an unrecognized format – the ‘CBaseIWF’ class will throw an exception that must be handled by our application such that we can return a failure code and potentially exit from the application if necessary. For this reason, the entire file loading logic is wrapped in a ‘try’ block that is used to this end.

In addition to specifying the source file that we would like this object to process, we must also inform the file object of the information that identifies any custom chunk data contained in the file as belonging to this application. Recall from our earlier discussions of the author ID with respect to entities and other custom data stored with the IWF, each of these items have a configurable signature that can be specified by the exporting application. This is done to ensure that only the application(s) that are specifically aware of its format ever try to import it. When loading custom chunks from the IWF file using the ‘CBaseIWF’ class, we can request that the object notifies us of these custom data chunks by specifying this signature with a call to the ‘SetAuthorID’ method of the ‘CBaseIWF’ class. This method accepts two parameters that require an arbitrary byte or character array – which denotes the author signature to verify against – and its associated length in bytes. Assuming that we pass in the same combination of signature bytes to this function as was specified during export, the IWF processing object will step into these custom data areas and correctly process the information instead of ignoring it.

In order to inform the ‘CBaseIWF’ object of the types of custom chunk we are interested in, we make use of the provided ‘RegisterChunkProc’ method. This function accepts the chunk ID value as the first of its three parameters. Recall that when exporting the plane, node and leaf data in the pre-processing tool we used the following three defines to identify each type of custom chunk written to file:

```
#define CHUNK_CTM_PLANES    0x2000
#define CHUNK_CTM_NODES     0x2001
#define CHUNK_CTM_LEAVES    0x2002
```

By re-using these same identifier values we are instructing the IWF processing object that we are interested in being notified whenever these three chunk types are encountered within the file. The means by which the IWF library notifies us of these occurances is by using the same callback mechanism we have used many times before in our lab project framework. By passing a function pointer to the second parameter of the ‘RegisterChunkProc’ method for each type of chunk, those static callback functions will be executed after the file has been positioned at the start of the appropriate data area.

As we know, due to the fact that these types of callback functions are static, it is also useful for the calling function to specify a context pointer. This is often a piece of custom data that can be used to pass any required information on to the callback procedure. In this application we pass in the pointer to the ‘CBSPTreeLoader’ class instance which is currently being processed. This context value is passed to the third parameter of this function to which we simply specify the ‘this’ pointer in each case. In doing so we allow each callback function that is executed to access the members of this specific tree object such that it might store any information that may have been loaded.

```
        // Load leaf and node data
        m_FileLoader.RegisterChunkProc( CHUNK_CTM_PLANES, ReadBSPPlanes, this );
```

```
        m_FileLoader.RegisterChunkProc( CHUNK_CTM_NODES , ReadBSPNodes, this );
        m_FileLoader.RegisterChunkProc( CHUNK_CTM_LEAVES, ReadBSPLeaves, this );
```

The callback functions that we register with the file loader object must be static and should each have a function signature that matches exactly with the one expected by this class. The function pointer typedef for the chunk callback procedures is shown below.

```
typedef void (*CHUNKPROC)(LPVOID pContext,CHUNKHEADER& Header,LPVOID pCustomData);
```

As we can see, each callback procedure will be passed three parameters and is not expected to provide any sort of return value. Given this specification we might imagine any given chunk procedure to be declared similar to the following:

```
static void MyProc( LPVOID pContext, CHUNKHEADER& Header, LPVOID pCustomData );
```

We will shortly discuss the specific details of each of the chunk callback functions that we registered here and will discuss the function parameters and their purpose in each case.

Now that we have registered the callback functions for each of the custom chunk types we would like to be informed of we can instruct the ‘m_FileLoader’ object to begin the processing of the currently open file. This is achieved by calling the ‘ProcessIWF’ method which will proceed to step through the various chunks in the file and call the appropriate procedure should any registered chunk type be encountered. Once the file has been processed in its entirety by this method and the registered callback procedures, we can then close the open file handle with a simple call to the ‘m_FileLoader.Close()’ method.

```
        // Load the additional BSP specific data
        m_FileLoader.ProcessIWF( );

        // Close the file
        m_FileLoader.Close();

    } // End Try Block

    catch ( ... )
    {
        // Complete Failure
        return false;

    } // End Catch Block
```

At this point, the registered chunk procedures should have loaded any node, leaf and plane data required for us to reconstruct the BSP tree. If there was no relevant tree data found to exist in the file, or a problem occurred for whatever reason, we should not continue with the reconstruction process. To this end we must verify that the tree data was indeed loaded by checking both the value contained in the ‘m_nFileNodeCount’ variable, in addition to the size of the ‘m_Leaves’ STL vector inherited from the base ‘CBaseTree’ class. If either of these members indicates that no relevant data was loaded then we return a failure code back to the calling function. Again, we will see the importance of checking these two variables specifically when we move on to discuss the actual chunk procedures registered earlier.

Should the required data have been imported successfully, we are now able to put together the various components to construct the spatial hierarchy. This is achieved with a call to the 'BuildTree' function which is a method of this class. We have encountered this function several times in previous lessons whereby it was traditionally responsible for the actual compilation and processing of the scene data in order to compile a particular type of spatial hierarchy. With the information having already been loaded from file, this function will simply be responsible for taking that information and rebuilding the tree structure in a compatible format. We will examine this function in a little while, but for now all that is important at this stage are the arguments that are being passed in to this function.

```
    // No BSP tree data loaded?
    if ( m_nFileNodeCount == 0 || m_Leaves.size() == 0 ) return false;

    // Reconstruct the tree structure from that loaded
    BuildTree( &m_pFileNodes[0], NULL );
```

The first parameter declared by the 'BuildTree' function is the current *source* node of the type 'iwfNode' (our temporary file based structure). Due to the fact that the node data is currently stored in a flat linear array, each of which contain only indices to inform us of the various parent/child relationships, it might not be instantly apparent exactly where to begin with the reconstruction process. Recall from our earlier coverage of the centralized node array in lab project 16.2 however, we always allocated the root node such that it would be located in the first element of that array. Therefore, using the temporary node information we loaded from the source IWF file, we begin this process by passing in that first element to the 'BuildTree' function. The second parameter is the current *destination* node that we will be constructing from the loaded source data during the recursive process. Since we have no root node at this point we simply pass NULL to this first call of the 'BuildTree' method. We will see how this information is used later in this lesson.

During the import of the spatial hierarchy data, recall that we used temporary arrays in order to store the node and plane information ready for processing. Now that we have fully reconstructed the BSP tree, this information is no longer required. As a result, we call a new method of this class called 'ReleaseFileData'. This function simply releases any memory associated with those temporary arrays to ensure that we don't consume any more memory than is necessary during the lifetime of the application.

```
    // Release the file data we had loaded.
    ReleaseFileData();

    // Allow our base class to finish any remaining processing
    return CBaseTree::PostBuild( );
}
```

At this stage we have imported, built and populated the arrays and hierarchy structures for each of the node and leaf items required. This is all of the information we need in order to begin using the BSP tree we compiled separately. With all of the pre-requisite information now available, we finally call the 'PostBuild' function of the base tree class to allow it to perform any additional processing on the tree data we have built. Recall that the 'PostBuild' procedure is responsible for constructing the vertex and index buffers that will be used during the rendering of the scene. The result of the 'PostBuild' function is returned directly to the calling function in order to signify the final success or failure of the build operation.

With the primary build interface function now covered, let us move on to take a look at the chunk procedure callbacks we registered in order to allow us to load the relevant components of the BSP tree hierarchy.

CBSPTreeLoader::ReadBSPPlanes

The first registered chunk procedure that we come to is the 'ReadBSPPlanes' function. As with all such registered procedures this function is defined as being static and must conform precisely to the function signature we discussed in the coverage of the 'Build' function earlier. This callback function accepts three parameters. The first of these is a void pointer that is used to inform each callback function of the context in which it is being executed. We have seen this type of callback system used many times throughout previous lessons, so the concept of a callback context should be nothing new to us. When registering this callback function with the 'CBaseIWF' object in the 'Build' function, recall that we passed a value of 'this' to the context parameter of the 'RegisterChunkProc' method. This of course means that the underlying object to which this first parameter will point is an instance of the 'CBSPTreeLoader' class that we are currently in the process of initializing. In this function, the loader class instance referenced by the context parameter will be the destination for any plane data that may be encountered in this part of the file. It is generally a good idea to cast this pointer to the expected type early on in the callback function to ensure that the code remains as simple and clean as possible.

The second and third parameters are not used by this application and are reserved mostly for use by the internal functionality of the 'CFileIWF' class exported by the libIWF library. As a result we will not spend too much time discussing their purpose. Put simply however, these parameters are used to pass additional file chunk information to the various callback procedures registered with the system. The 'Header' parameter for instance references a structure that contains various chunk properties such as the type of chunk being processed and the length in bytes of the chunk data area. For more information on the various pieces of additional chunk information available here, please refer to the IWF specification and SDK which should be available to you in your class supplemental download area.

At the point at which any registered chunk procedure is called by the IWF processing class, the file being processed should be positioned at the start of the relevant chunk data area within the file. What this essentially means is that we can begin reading the data relevant to this particular type of chunk immediately on entering this function. In order to do so however, we must gain access to the 'CBaseIWF' object instance that is being used to load the tree information. At the start of this function therefore, we cast the specified context pointer to that of our 'CBSPTreeLoader' class instance that we are populating, and then retrieve from that object a pointer to the 'm_FileLoader' member that specifies the 'CBaseIWF' object for the file we are currently reading from.

```
void CBSPTreeLoader::ReadBSPPlanes( LPVOID pContext, CHUNKHEADER& Header,
                                    LPVOID pCustomData )
{
    ULONG i;

    // Retrieve context pieces.
    CBSPTreeLoader * pLoader = (CBSPTreeLoader*)pContext;
    CBaseIWF *pFile = &pLoader->m_FileLoader;
```

Now that we have access to both the source file object and the destination 'CBSPTreeLoader' class instance, we can begin to load the plane data from the file. We achieve this directly through the file / stream handling methods exposed by the 'CBaseIWF' class which include functions such as 'Read', 'Write' and 'Seek'. A full list of each of these methods and their usage can be found in appendix A of this chapter's workbook. The first item we come to is a simple four byte 'unsigned long' that specifies how many planes – in total – are stored within the file. We read this value with a call to the 'CBaseIWF::Read' method, passing in a pointer to the 'm_nFilePlaneCount' member of the 'pLoader' object into which the plane count will be loaded directly, bypassing the need for a temporary variable.

Next on the agenda is to allocate enough room in our loader class' temporary 'm_pFilePlanes' array to store every plane contained within this chunk. The number of planes is of course described by the 'm_nFilePlaneCount' variable we initialized prior to this step and is used to correctly size the array with the new operator. Before we move on, this new array is cleared with a call to the Win32 'ZeroMemory' function such that we begin with a sensible set of default values.

```
    // Retrieve the Plane Count
    pFile->Read( &pLoader->m_nFilePlaneCount, sizeof(ULONG) );

    // Allocate storage for the planes
    pLoader->m_pFilePlanes = new D3DXPLANE[ pLoader->m_nFilePlaneCount ];
    ZeroMemory( pLoader->m_pFilePlanes,
                pLoader->m_nFilePlaneCount * sizeof(D3DXPLANE) );
```

With the temporary plane array allocated, the actual plane information can now be loaded and stored ready for the reconstruction step which occurs once the file has been completely processed. The code used to achieve this is shown below in which a loop is created that iterates through each of the planes in the new temporary plane array. These planes are used as the destination into which each subsequent plane contained within this file chunk is loaded and stored. Similar to loading the simple unsigned long value we encountered earlier, this is achieved with a call to the 'CBaseIWF::Read' method passing in a pointer to the destination plane structure stored in the temporary array. In addition we also pass a value which indicates the number of bytes that must be read from the file in order to load the plane in its entirety. This process is repeated for each plane indicated by the 'm_nFilePlaneCount' member until all planes have been loaded from the file and stored in the temporary 'm_pFilePlanes' member array.

```
    // Read Planes
    for ( i = 0; i < pLoader->m_nFilePlaneCount; i++ )
    {
        D3DXPLANE * pPlane = &pLoader->m_pFilePlanes[i];

        // Load the plane information from file
        pFile->Read( pPlane, sizeof(D3DXPLANE) );

    } // Next Plane
}
```

At this stage, the 'm_pFilePlanes' array contained within the 'CBSPTreeLoader' class has been allocated and fully populated with that data exported by the pre-processing tool developed in lab-project 16.2. The plane data is left in its combined form to ensure that the plane indices maintained by each

node remain valid. Of course, in order for the plane information to be of any use to us, we must also import the node data. Therefore, let us now examine the chunk callback procedure responsible for loading that information.

CBSPTreeLoader::ReadBSPNodes

As we observed with the 'ReadBSPPlanes' function, the static callbacks we must implement in order to load the custom tree data from the IWF file are relatively straight forward. The same is true when loading the node data into our temporary array of 'iwfNode' structures.

The majority of the code in this function is identical to that of the plane loading callback we discussed previously so we will not spend much time discussing the details here. This function simply reads the value describing the total number of nodes into the 'm_nFileNodeCount' member variable and allocates the temporary node array in much the same way as we did in the 'ReadBSPPlanes' callback. Due to the fact that we have defined the interim 'iwfNode' structure using the same format and layout of the node items contained in the file, we then simply read the node data one item at a time storing that information directly into each element in that temporary node array.

```
void CBSPTreeLoader::ReadBSPNodes( LPVOID pContext, CHUNKHEADER& Header,
                                   LPVOID pCustomData )
{
    ULONG i;

    // Retrieve context pieces.
    CBSPTreeLoader * pLoader = (CBSPTreeLoader*)pContext;
    CBaseIWF *pFile = &pLoader->m_FileLoader;

    // Retrieve the Node Count
    pFile->Read( &pLoader->m_nFileNodeCount, sizeof(ULONG) );

    // Allocate storage for the nodes
    pLoader->m_pFileNodes = new iwfNode[ pLoader->m_nFileNodeCount ];
    ZeroMemory( pLoader->m_pFileNodes,
                pLoader->m_nFileNodeCount * sizeof(iwfNode) );

    // Read Nodes
    for ( i = 0; i < pLoader->m_nFileNodeCount; i++ )
        pFile->Read( &pLoader->m_pFileNodes[i], sizeof(iwfNode) );

}
```

CBSPTreeLoader::ReadBSPLeaves

The 'ReadBSPLeaves' callback is by far the most complex of the tree import procedures implemented here. This is primarily due to the fact that there is much more information to be loaded, processed and stored in each leaf than in either of the other two cases. Similar to the other two callbacks defined within this class, this method is responsible for loading the leaf data from file. However, unlike those procedures, this method will load and populate an instance of a 'CBSPTreeLeaf' object rather than a temporary data structure. As we know, the reason we loaded the node and plane data into temporary arrays was due to the dependency that exists between them and the fact that we could not be certain

which of the two data chunks would be encountered first within the IWF file. In the case of the leaf however, all pre-requisite information has already been loaded by the scene import process, or is contained directly within the file leaf chunk we are reading from in this function.

As with each of the previous two functions, this is a static callback that accepts a void context pointer along with any appropriate chunk and custom data information neither of which is used by this application. Again, we cast the specified context pointer to that of our 'CBSPTreeLoader' class instance that we are populating, and retrieve the 'm_FileLoader' member that specifies the 'CBaseIWF' object for the file we are currently processing.

```
void CBSPTreeLoader::ReadBSPLeaves( LPVOID pContext, CHUNKHEADER& Header,
                                    LPVOID pCustomData )
{
    ULONG       i, j, LeafCount, PolygonCount, PortalCount, ReservedCount;
    D3DXVECTOR3 vecMin, vecMax;
    long        PolygonIndex;

    // Retrieve context pieces.
    CBSPTreeLoader * pLoader = (CBSPTreeLoader*)pContext;
    CBaseIWF *pFile = &pLoader->m_FileLoader;
```

Now that we have access to the source and destination objects we can begin to read the leaf data from file. The first item we come to is a simple four byte 'unsigned long' that specifies how many leaves – in total – are stored within the file. We read this value with a call to the 'CBaseIWF::Read' method, passing in a pointer to the local 'LeafCount' variable declared at the top of this function. We don't need to store this information directly as the tree class's internal leaf count will be incrememented as each leaf is finally added. If no leaves are found to be contained within the file we simply return.

Now we have the information that describes the total number of leaves in the tree, we can reserve the 'm_Leaves' member STL vector of the tree object using the vector's 'reserve' method. This will prevent any subsequent 'CBaseTree::AddLeaf' call from having to resize / reallocate the leaf array.

```
    // Retrieve the Leaf Count
    pFile->Read( &LeafCount, sizeof(ULONG) );
    if ( LeafCount == 0 ) return;

    // Allocate storage for the leaves
    pLoader->m_Leaves.reserve( LeafCount );
```

With this step completed, we can now begin to read the leaf information from file. The 'CHUNK_CTM_LEAVES' chunk stores all of the leaves in the tree together in one linear block. The size of this block of leaves is indicated by the 'LeafCount' variable that was read from the file a moment ago. At this point therefore we create a loop that will execute for this same number of iterations as each leaf is loaded.

The first thing we must do within this loop is to allocate a new 'CBSPTreeLeaf' object that will eventually be inserted at some point into the tree hierarchy. This leaf object will be used to store the information read directly from the file rather than into a temporary structure as with the node type. Remember from our earlier discussion that each leaf must have access to a pointer of the tree object in

which it is contained. This is done in the following code – in a similar manner to the previous compilation classes – by passing the tree object's pointer into the single parameter of the 'CBSPTreeLeaf' constructor. Unlike previous applications however, the 'ReadBSPLeaves' function is static and, as a result, we do not have access to the 'this' pointer. If you refer back to the earlier discussion of the 'Build' function, you will remember that when we registered each callback the 'this' pointer was specified as the callback context at that time. At the start of this function we cast the context pointer to the correct tree class type and copied it over into the 'pLoader' variable. Therefore, we can instead simply pass in the 'pLoader' variable to the leaf's constructor.

What follows this allocation is the reading of the various pieces of leaf data contained in the file. The majority of this information is loaded into temporary variables due to the fact that the actual leaf properties will be updated as we perform the various operations such as adding polygon data or setting the leaf's bounding box via the 'AddPolygon' or 'SetBoundingBox' methods inherited from the 'CBaseLeaf' class. The first two values to be loaded here are the minimum and maximum bounding box vectors that describe the absolute world space extents of the polygon data contained in this leaf. These are stored in the local 'vecMin' and 'vecMax' variables. Following these vectors is a value that is currently reserved for a later lab project. This is a single unsigned long that will eventually be used to store an index into the main visibility array that we will be constructing in the next lesson. For now we simply seek over this value.

The next two values contained in the file describe the total number of elements for both the polygon and portal index data that we will shortly encounter in the file. Again, the 'PortalCount' variable is not used by this application and is reserved for the visibility compiler we will build in the next lesson. However, it is important that we read this information in case we attempt to import a file built by the later version of our pre-processing tool such that we can skip over any portal data that may be contained in this file for this leaf. We will discuss the means by which this is achieved a little further on, but for now just know that these two variables describe the total number of indices maintained by the leaf for both the polygons and portals that are attached to this leaf.

The final of these count variables is the 'ReservedCount' item. Again this is not used by any of our current lab projects, but this reserved concept can be used by an application to store custom information along with the leaf data. The value retrieved by this read operation will describe the amount of space reserved for this custom data that will allow us to skip that portion of the leaf should it not be of any interest to us. Again we will talk about this more specifically further on in this function's coverage.

```
    // Read Leaves
    for ( i = 0; i < LeafCount; i++ )
    {
        CBSPTreeLeaf * pNewLeaf = new CBSPTreeLeaf( pLoader );

        // Read initial part of structure
        pFile->Read( &vecMin, sizeof(D3DXVECTOR3) );
        pFile->Read( &vecMax, sizeof(D3DXVECTOR3) );
        pFile->Seek( sizeof(ULONG) ); // Seek over PVSIndex
        pFile->Read( &PolygonCount, sizeof(ULONG) );
        pFile->Read( &PortalCount, sizeof(ULONG) );
        pFile->Read( &ReservedCount, sizeof(ULONG) );
```

With this first part of the leaf now loaded and stored we can begin to initialize the actual leaf object we created in the initial stages of this loop. The first thing we do here is to set the leaf's bounding box using the local 'vecMin' and 'vecMax' variables that were populated in the first two read operations for this leaf. Once this has been done we then begin to link any appropriate polygon data to the leaf object itself. To do this, we create a loop that will execute for the total number of iterations specified by the value stored in the 'PolygonCount' variable we loaded earlier. Recall that this value describes the total number of indices stored in this particular leaf that indicate which polygons we should attach here. At each step we then read in a single 4 byte value from the file that describes the index of the polygon to be attached to this leaf. Due to the fact that the polygon data has been loaded by the scene class and added to the 'CBSPTreeLoader' polygon array in advance we can simply retrieve the pointer stored at that element in the inherited 'm_Polygons' array, and pass that pointer directly into the new leaf's 'AddPolygon' method. This will proceed to take that pointer and update the leaf's internal polygon list to store the specified polygon.

```
        // Store bounding box details in the new leaf
        pNewLeaf->SetBoundingBox( vecMin, vecMax );

        // Read the face indices
        for ( j = 0; j < PolygonCount; ++j )
        {
            // Read the index into the polygon array
            pFile->Read( &PolygonIndex, sizeof(long) );
            if ( PolygonIndex < 0 ) continue;

            // Add the specified polygon to the leaf
            pNewLeaf->AddPolygon( pLoader->m_Polygons[ PolygonIndex ] );

        } // Next Leaf
```

Once this loop has completed the required number of iterations, we should have loaded each of the polygon indices contained in the file for this leaf, and added the physical polygon pointers to the new leaf object that we are building. With this operation completed, we can now move on to process the remaining items stored in the file.

Due to the fact that we are not interested in any exported portal index information in this application, the final thing we must do is to skip over any such information that *may* be contained in the file. Although the pre-processing tool developed in lab project 16.2 does not export these leaf portal indices, it is advisable that we do this regardless in case the source IWF file was not exported by that version of the compiler. Notice below that we also seek over the actual reserved data area. The size of this area is determined by the value read and stored in the local 'ReservedCount' variable which describes the number of DWORD sized chunks (32 bits / 4 bytes) of reserved data that is stored here. Again, no reserved data is written to file in lab project 16.2 and the 'ReservedCount' variable should contain a value of 0. However, as with the portal indices, we seek over any data that may have been indicated.

Now that we have read all of the data for this leaf, we can add it to the tree. However, we do not yet have access to the full spatial hierarchy and are unable to attach this leaf to any node that might reference it. As a result, we simply pass the new leaf into a call to the tree class' 'AddLeaf' method – inherited from the 'CBaseTree' class – that will proceed to store the leaf in the main centralized array. We can later retrieve this pointer when we reconstruct the tree hierarchy in the 'BuildTree' function.

```
        // Skip the reserved data areas
        pFile->Seek( PortalCount * sizeof(long) );
        pFile->Seek( ReservedCount * sizeof(long) );

        // Add this leaf to our leaf array
        pLoader->AddLeaf( pNewLeaf );

    } // Next Leaf
}
```

At this stage, the file should be positioned at the start of the *next* leaf ready to be loaded in the next iteration of this loop. We continue this entire process until all of the indicated leaves have been loaded and stored in the tree's centralized leaf array.

Once this loop has read and stored the leaves contained within the file and, assuming that the node and plane data has already been loaded at this stage, we now have all the information we need to be able to reconstruct the tree. Let us now take a look at how this is achieved.

CBSPTreeLoader::BuildTree

There have been several references to the reconstruction of the BSP tree throughout our coverage of the lab project 16.3 implementation. In previous applications, we developed a private 'BuildTree' function which served as the main recursive procedure in which the tree construction was undertaken. In lab project 16.3, this function has a similar role in that it must recursively build the spatial hierarchy. However, this time it is solely responsible for taking any information that has been previously loaded by the 'Build' function and piece it together such that it now exists in the appropriate format for use by our run-time rendering application.

This function accepts two parameters. The first of these indicated by the 'pFileNode' parameter is the current interim file node that will be used as the source for building a 'CBSPTreeNode' that will be used in the final spatial hierarchy for this tree object. The second 'pNode' parameter is the destination 'CBSPTreeNode' object that is to be populated with any relevant information. Recall from the earlier discussion of the 'Build' function that the first time that this 'BuildTree' method is called, a value of NULL is passed to the 'pNode' parameter. This is used to indicate that we are constructing the root node of our final spatial hierarchy. As a result, the first task undertaken by this function is to allocate a new root node and store the resulting pointer in the tree's 'm_pRootNode' member variable. Of course, this will only happen the first time that this method is invoked due to each subsequent call being passed an already instantiated destination node object.

After creating the root node, or simply using the destination node that was passed, we begin populating this node with the simple bounding box and plane information indicated by the interim 'iwfNode' structure passed to this iteration of the recursive procedure. The first of these is the separating plane on which the node lies. Recall that we imported the combined plane array from the file and stored these in a temporary 'm_pFilePlanes' member array. Due to the fact that the final 'CBSPTreeNode' class stores a physical plane item, the plane indicated by the file node must be extracted from this array and stored directly into the destination node object. The final two values we update in the initial stages of this

function are the ‘BoundsMin’ and ‘BoundsMax’ values which are taken directly from the imported node structure.

```
bool CBSPTreeLoader::BuildTree( iwfNode * pFileNode,
                                CBSPTreeNode * pNode /* = NULL */ )
{
    D3DXVECTOR3 vecMin, vecMax;

    // First time in?
    if ( !pNode )
    {
        // Allocate a root node
        if ( !(pNode = new CBSPTreeNode) ) return false;
        m_pRootNode = pNode;

    } // End if no node specified

    // Build node data from that loaded from file
    pNode->Plane     = m_pFilePlanes[ pFileNode->PlaneIndex ];
    pNode->BoundsMin = pFileNode->BoundsMin;
    pNode->BoundsMax = pFileNode->BoundsMax;
```

With these simple properties updated, this function now proceeds to process and create the child node and leaf items where necessary. The first case we come to is the creation of any applicable front child. Because we are always guaranteed to have a front child whenever we are dealing with a node that does **not** store a leaf, we first allocate a new ‘CBSPTreeNode’ item which will represent the child in front of the current node. The pointer to this new node item is then stored into the ‘Front’ member of the node we are currently processing. Once we have allocated this new front node item, this function then tests to determine whether the interim file node indicates that a child *node* or child *leaf* is attached to the front side of the node at this level. The first case we come to is one in which a child *node* has been indicated by the ‘FrontIndex’ member of the imported node structure, in which we would find a positive index value. If this turns out to be the case, then there is nothing further for us to do with the current node and we simply recurse into the new front child node by making a further call to the ‘BuildTree’ function. At this stage we pass in as the first of two parameters the imported node that was specified by the ‘FrontIndex’ value of the current ‘iwfNode’, as well the node destination node we allocated a moment ago. Should we enter this initial ‘if’ statement, then this process would begin again such that the entire subtree of the current node is built and attached to the front side of the current destination ‘CBSPTreeNode’ object.

```
    // Allocate new node in front
    pNode->Front = new CBSPTreeNode;
    if ( !pNode->Front ) return false;

    // Node or leaf in front?
    if ( pFileNode->FrontIndex >= 0 )
    {
        // Build this new front node
        if ( !BuildTree( &m_pFileNodes[ pFileNode->FrontIndex ], pNode->Front ) )
            return false;

    } // End if node in front
```

The alternate case that we have to deal with is one in which there is a child *leaf* attached to the front side of the current node. This is indicated by the 'FrontIndex' value of the imported node having a **negative** value. Because the initial 'if' statement simply test for any positive value including zero, we can ensure that we are dealing with a leaf simply by using the 'else' keyword. If we drop into this 'else' case we must of course attach a 'CBSPTreeLeaf' item to the front of this node. However, recall that our run-time spatial hierarchy design requires that a leaf-node always be inserted above any given leaf in the tree. Due to the fact that we always explicitly allocated a front node earlier in this function, this is taken care of automatically. By simply attaching the indicated leaf to the **font child** rather than the current node, we can always ensure that this parent leaf-node exists. Notice that we first retrieve the pointer to the correct leaf from the tree's existing leaf array using the leaf indexing logic we discussed in lab project 16.2. Recall that because the value for any indices available for describing a leaf in the file's front or back index members is in the range of -1 and below we must add 1 to the 'FrontIndex' member here before flipping its sign. By doing so this value is converted back into a valid array index in the range of 0 and above.

```
    else
    {
        // Build a leaf
        CBSPTreeLeaf * pLeaf =
                       (CBSPTreeLeaf*)m_Leaves[ abs(pFileNode->FrontIndex + 1) ];
        if ( !pLeaf ) return false;

        // Store pointer to leaf in the node
        pNode->Front->Leaf = pLeaf;

        // Store the leaf's bounding box in the node
        pLeaf->GetBoundingBox( vecMin, vecMax );
        pNode->Front->BoundsMin = vecMin;
        pNode->Front->BoundsMax = vecMax;

    } // End if leaf in front
```

With the front side of this node and the entire front subtree fully reconstructed, this function now turns its attention to the back. We perform the initial steps in an identical fashion to that of the front simply substituting each of the relvant front indices and pointer variables with those specifying the information attached to the back of each node. In the same way as before, we first allocated a new back child 'CBSPTreeNode' object for the current node and then recurse into the back subtree should the value of the 'BackIndex' member of the imported node indicate that a child *node* should be attached here.

```
    // Allocate new node behind
    pNode->Back = new CBSPTreeNode;
    if ( !pNode->Back ) return false;

    // Node or leaf behind?
    if ( pFileNode->BackIndex >= 0 )
    {
        // Build this new back node
        if ( !BuildTree( &m_pFileNodes[ pFileNode->BackIndex ], pNode->Back ) )
            return false;
```

```
    } // End if node in front
```

Once again, the alternate case is one in which an attached child *leaf* is indicated by the imported node data. In this case, we perform exactly the same steps as discussed previously. However, there is an additional consideration that must be taken with this type of compiled BSP tree information when processing the information for the back side of any given node. This is of course when the back halfspace of that node is describing an area of solid space.

If we think back to the development of the BSP leaf tree compilation process, solid leaves were not physically created or inserted into the tree and instead a value equal to that of the 'BSP_SOLID_LEAF' defined constant was stored in the 'BackIndex' member of the node. To this end, the code within this else clause first tests to see whether the current file node's 'BackIndex' member contains this value. If it does then of course we must also signify this 'solid' area within our current spatial hierarchy framework. We achieve this by simply storing a value of 'NULL' in the back child of the current destination node after releasing the child node that we allocated earlier. We could alternately create a back leaf-node that simply stores a value of 'NULL' in its 'Leaf' pointer member. However, the former method that we have chosen to employ in this lab project is slightly more efficient in both processing and memory overhead and has no significant drawbacks.

If the space behind the node is not describing a solid area of space, then we simply attach the leaf indicated by the imported node in the same manner as with any front child leaf.

```
    else
    {
        // Solid leaf?
        if ( pFileNode->BackIndex == BSP_SOLID_LEAF )
        {
            delete pNode->Back;
            pNode->Back = NULL;

        } // End if solid leaf
        else
        {
            // Retrieve the leaf specified
            CBSPTreeLeaf * pLeaf =
                          (CBSPTreeLeaf*)m_Leaves[ abs(pFileNode->BackIndex + 1) ];
            if ( !pLeaf ) return false;

            // Store pointer to leaf in the node
            pNode->Back->Leaf = pLeaf;

            // Store the leaf's bounding box in the node
            pLeaf->GetBoundingBox( vecMin, vecMax );
            pNode->Back->BoundsMin = vecMin;
            pNode->Back->BoundsMax = vecMax;

        } // End if empty back leaf

    } // End if leaf behind

    // Success!
    return true;
```

```
}
```

At this stage, from the point of view of the first level of recursion, both the front and back subtrees will now have been fully reconstructed and attached to the front and back member pointers of the root node. Hopefully it should be clear that no physical compilation has really been undertaken here, we have simply taken the information stored in the file and converted it into the applicable format ready for our application to use.

CBSPTreeLoader::ReleaseFileData

Recall that the 'ReleaseFileData' method is called by the 'Build' function after the tree data has been loaded and reconstructed. Due to the fact that this information is only required during import – and would simply consume memory unnecessarily – each of these file data arrays should be released once the hierarchy has been built. This function is responsible for clearing these temporary file data arrays and resetting any appropriate values for the possibility of later use.

```
void CBSPTreeLoader::ReleaseFileData()
{
    // Destroy arrays
    if ( m_pFileNodes  ) delete []m_pFileNodes;
    if ( m_pFilePlanes ) delete []m_pFilePlanes;

    // Clear Variables
    m_pFileNodes      = NULL;
    m_pFilePlanes     = NULL;
    m_nFileNodeCount  = 0;
    m_nFilePlaneCount = 0;

}
```

CBSPTreeLoader::ProcessVisibility

In this method we begin to see the visibility call counting scheme from the point of view of the tree class. The 'ProcessVisibility' function is almost identical to those we have implemented in each of our spatial hierarchy classes so far. The only addition here is that we increment the 'm_nVisCounter' member of the *tree* class before we begin the recursive 'UpdateTreeVisibility' process. It is important that we do this first, because we need to ensure that each of those leaves subsequently found to be visible are updated with a value that will remain constant until the *next* call to this function. If this value was to be incremented after the update process, then the visibility counter value stored in each leaf will become out of date the moment we stepped out of the 'UpdateTreeVisibility' call.

```
void CBSPTreeLoader::ProcessVisibility( CCamera & Camera )
{
    CBaseTree::ProcessVisibility( Camera );

    // Increment the visibility counter for this loop
    m_nVisCounter++;

    // Start the traversal.
```

```
    UpdateTreeVisibility( m_pRootNode, Camera );
}
```

CBSPTreeLoader::UpdateTreeVisibility

Once again, the 'UpdateTreeVisibility' method defined by this new tree class is almost identical to those we have already encountered. However, there is one minor alteration to this function that has a significant impact from an execution point of view.

As we can see, with the exception of substituting the type of the 'pNode' parameter to that of our new node class, and including this method in the new 'CBSPTreeLoader' namespace, the initial part of this function remains unchanged. Each of the parameters are declared and used in the same manner as before, and the frustum culling result code is retrieved in the same way. Once we have retrieved this frustum value, we then come to the conditional 'switch' statement that is also part of each of the previous implementations.

```
void CBSPTreeLoader::UpdateTreeVisibility( CBSPTreeNode * pNode, CCamera & Camera,
                                           UCHAR FrustumBits /* = 0x0 */ )
{
    CCamera::FRUSTUM_COLLIDE Result =
                             Camera.BoundsInFrustum( pNode->BoundsMin,
                                                     pNode->BoundsMax, NULL,
                                                     &FrustumBits,
                                                     &pNode->LastFrustumPlane );

    // Test result of frustum collide
    switch ( Result )
    {
```

The first case we come to when determining if the current node's bounding box is fully within the frustum is that of the 'FRUSTUM_OUTSIDE' case. The only difference in this function can be found in here. Recall that this result is returned whenever that bounding box is *completely* outside of all of the camera's frustum planes and as a result cannot possibly seen. In addition we know that none of its children can possibly be seen either because of the fact that a node's bounding box will be large enough to contain every child node beneath it in that branch of the tree.

If you recall the earlier implementations of this function, we previously called the node's 'SetVisible' method, passing in a value of 'false' in this *outside* case. This function would then traverse this node's subtree simply in order to visit every node and leaf that existed as a child of the current node, marking each leaf encountered as invisible. With our new visibility call counter mechanism, this process of updating each leaf's visibility status when it is *not* visible is no longer required. As a result, this case now simply returns from the function without taking any additional action.

As we move forward and add concepts such as the 'Potential Visibility Set' – covered in the next lesson – this adjustment could save us a significant amount of additional processing in a highly occluded scene. However, even in the case of simple frustum culling, this technique can be employed in order for us to remove a large portion of the traversal operation we were previously required to perform during the 'ProcessVisibility' pass.

```
        case CCamera::FRUSTUM_OUTSIDE:
            // Node (and all its children) are not visible
            return;
```

The remaining cases in this switch statement remain unaltered from our previous implementations. In the ‘FRUSTUM_INSIDE’ case we must continue to recurse through the subtree of the current node in order to set each child leaf as visible. In the ‘FRUSTUM_INTERSECT’ case we must continue to perform the frustum tests for any child node until we find a node that is either contained within or is completely outside of the frustum. This is of course unless this is a leaf node, in which case the leaf must be set to a visible state to ensure that the visibility status information and rendering buffers are updated correctly for that leaf.

```
        case CCamera::FRUSTUM_INSIDE:
            // Node is totally visible
            pNode->SetVisible( true );
            return;

        case CCamera::FRUSTUM_INTERSECT:
            // We need to resolve this further, unless this is a leaf
            if ( pNode->Leaf )
            {
                pNode->SetVisible( true );
                return;
            } // End if leaf
            break;

    } // End Switch
```

As before, the final block of code is only ever executed if the bounding box of the current node was found to be intersecting the frustum planes. If this was the case then further consideration needs to be taken and as a result we must traverse down the front and back of this node.

```
    // The remaining case (FRUSTUM_INTERSECT) means we need to test further
    if ( pNode->Front ) UpdateTreeVisibility( pNode->Front, Camera, FrustumBits );
    if ( pNode->Back  ) UpdateTreeVisibility( pNode->Back, Camera, FrustumBits );
}
```

Additional CBSPTreeLoader Routines

There are several tree related support routines that we have developed in the past that allow the application to perform operations such as the collection of a list of leaves that are intersected by either an axis aligned bounding box or a ray, and the drawing of debug information. Due to the large similarities between the basic principals of both the BSP tree and the kD-tree, the ‘CBSPTreeLoader’ class duplicates several of these functions taken directly from the ‘CKDTree’ class. Because we have covered the kD-tree support methods in earlier lessons, we will not spend any time covering them again here.

The list below outlines those functions which are direct copies from the ‘CKDTree’ class that have simply been altered to be declared within the ‘CBSPTreeLoader’ namespace and also to make use of the new ‘CBSPTreeNode’ class.

```
bool CollectLeavesAABB    ( LeafList & List, const D3DXVECTOR3 & Min,
                            const D3DXVECTOR3 & Max );
bool CollectAABBRecurse   ( CBSPTreeNode * pNode, LeafList & List,
                            const D3DXVECTOR3 & Min, const D3DXVECTOR3 & Max,
                            bool bAutoCollect = false );
bool CollectLeavesRay     ( LeafList & List, const D3DXVECTOR3 & RayOrigin,
                            const D3DXVECTOR3 & Velocity );
bool CollectRayRecurse    ( CBSPTreeNode * pNode, LeafList & List,
                            const D3DXVECTOR3 & RayOrigin,
                            const D3DXVECTOR3 & Velocity );
void DebugDraw            ( CCamera & Camera );
bool DebugDrawRecurse     ( CBSPTreeNode * pNode, CCamera & Camera,
                            bool bRenderInLeaf );
bool GetSceneBounds       ( D3DXVECTOR3 & Min, D3DXVECTOR3 & Max );
```

Scene Class Modifications

With the new BSP tree loading class fully implemented, the only task that remains is to make any modifications to the application code such that this new spatial hierarchy class is utilized. Because of the way that the ‘ISpatialTree’ concept has been developed, switching to other types of tree within the application is trivial. We have observed on several occasions how we can alternate between an oct-tree, quad-tree and kD-tree simply by altering a single line in the ‘CScene’ class such that the relevant type of object is instantiated before the scene is loaded. The new ‘CBSPTreeLoader’ class is integrated into the application in exactly the same way. With this in mind let us look at the minor modification that we must make in the scene class’ ‘LoadSceneFromIWF’ function in order to make use of the compiled solid leaf BSP tree.

CScene::LoadSceneFromIWF

The following code block shows a small portion of the ‘LoadSceneFromIWF’ method that we should already be extremely familiar with. The only line of code that has changed here is marked in **bold**. We can see that when instantiating the spatial partitioning tree object we have simply created an object of the type ‘CBSPTreeLoader’, storing the returned pointer in the scene’s ‘m_pSpatialTree’ member variable. Recall that this member is of the type ‘ISpatialTree’ which allows the application to access the tree functionality without necessarily having to be aware of the specifics of the selected tree class itself.

When instantiating this type of spatial partitioning tree we pass in the common parameters required by all types of tree that we have developed. These are the Direct3D device that was registered with the

scene during application startup, along with the Boolean flag describing whether hardware transformation and lighting is being used. These two parameters are used by the underlying 'CBaseTree' class to create and populate the vertex and index buffers used in the rendering of the geometry registered with the tree. The third and final parameter is the one that is specific to the 'CBSPTreeLoader' class. Here we simply pass in the filename that was also passed to the 'LoadSceneFromIWF' method by the application. This means that both the scene geometry and the custom tree information will be loaded from the same file. Whilst this is convenient it is not a requirement. Due to the fact that the BSP tree loader class opens and processes the file independently of the scene class, it would be possible to have the scene geometry and BSP tree information stored in separate files. In this case we would simply pass in an alternate filename to the loader class constructor.

```
    ...
    ...

    // File loading may throw an exception
    try
    {
        // Allocate our spatial partitioning tree of the required type
        m_pSpatialTree = new CBSPTreeLoader( m_pD3DDevice, m_bHardwareTnL,
                                             strFileName );

        m_pAlphaTree   = new CBSPNodeTree( m_pD3DDevice, m_bHardwareTnL );

        // Add our scene callback to the player.
        GetGameApp()->GetPlayer()->AddPlayerCallback( CScene::UpdatePlayer, this );

        // Attempt to load the file
        File.Load( strFileName );

        ...
        ...
```

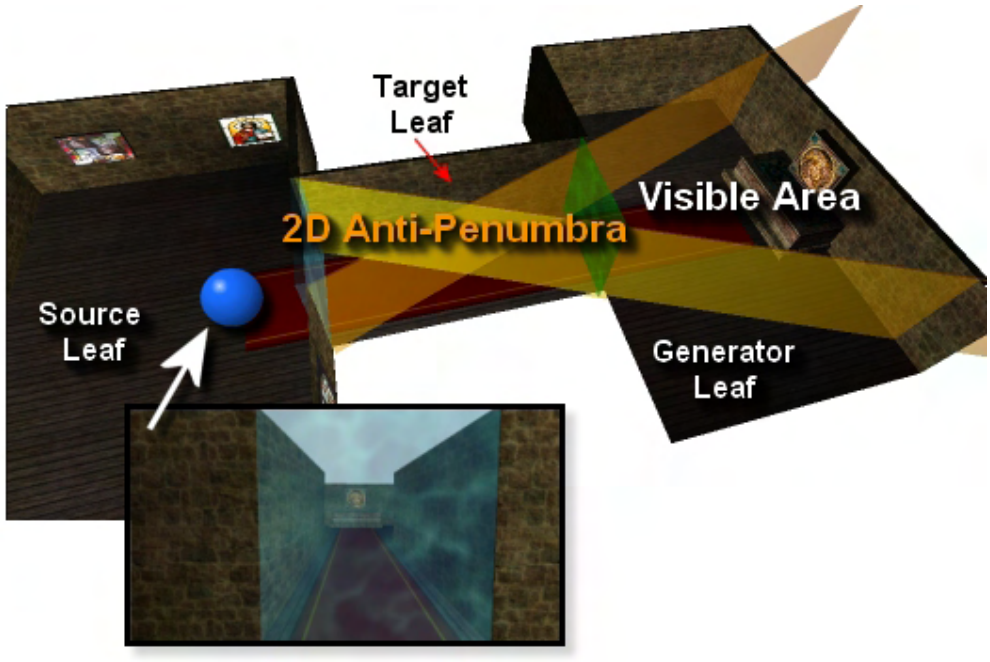
This line is all that needs to be altered in order for our application to begin using the compiled BSP tree information generated and exported by the pre-processing tool developed in lab project 16.2. It is still also entirely possible for the application to select an alternate spatial partitioning tree class at any point, using the same compiled IWF file. The polygon data that is loaded by the scene will simply be compiled as has always been the case in earlier lab projects.

Lab Project Conclusion

This concludes our coverage of the first BSP tree rendering application. In the next lesson we will enhance both the compiler tool and the BSP tree loader class to make use of accurate visibility information. This will be used to cull away any level geometry that cannot possibly be seen due to any other geometry that might be occluding the player's view of other parts of the scene. This should greatly enhance both the performance of our rendering application, but will also open up many opportunities for improving the efficiency of many tasks that we must undertake in the future when developing additional game technologies.

Chapter Seventeen

Spatial Partitioning IV



Introduction

In the previous lesson we discussed and implemented the BSP leaf tree which demonstrated yet another form of spatial partitioning. While one of the key use cases for the BSP node tree was made clear in Chapter 16, when we implemented a perfect alpha sorter, the ideal usage of the BSP leaf tree may still be a little unclear at this point. The BSP leaf tree certainly had some interesting characteristics. Like the node tree, it divided the level into arbitrarily shaped convex areas due to the fact that the split planes at each node were taken from the level geometry itself. Although useful, it might be hard to imagine at this time why this would somehow be preferable to our previously discussed bounding volume based spatial tree types. After all, the leaf tree generates many more nodes and leaves in the typical case and the bounding volumes assigned to each leaf are not tightly fitting like the quad-tree, oct-tree or kD-tree. This means that the BSP leaf tree would theoretically be slower to traverse and frustum cull in the typical case. The frustum culling applied to the leaves would also not be as precise as the other tree types due to the fact that the AABB we store in each leaf exhibited quite a loose fit. The result is that even axis aligned leaves that are outside the frustum might still get rendered because the loose fitting box intersects the frustum even though the geometry in that leaf does not. When viewed in this light, one might wonder in what situation the application of a BSP leaf tree would be a wise choice.

The key to understanding the usefulness of the BSP leaf tree is found in the properties it exhibits when fed geometry that follows the solid/empty guidelines. You will recall in the previous lesson that if we feed our BSP compiler geometry that has no hidden surfaces (i.e., the front of one polygon can never see the back of another), the tree provides us with the ability to distinguish between which areas of the level are assumed to define solid matter (such as the space behind a wall for example) and which areas are assumed to define empty space (the empty space between our polygons in which the player and NPCs are allowed to freely navigate). Providing geometry in a solid/empty form to the BSP tree compiler does mean that the game artist has to be especially vigilant when building the scene, although as we also learned that using CSG techniques to perform hidden surface removal as a pre-process before the compile step can remove hidden surfaces in the typical case. We saw in Lab Project 16.2 that we can run union operations on the individual brushes/meshes comprising the scene so that any faces of objects which are touching or intersecting each other are removed. This provides our BSP leaf compiler with a level that obeys the rules for what is considered *legal geometry* by a solid/empty leaf tree compiler. Even if the level was not created by the artist in a solid/empty format, as long as the individual meshes in the scene do not contain any faces that touch or intersect themselves, we can union these meshes into a single mesh (pre-compile) and remove any offending surfaces in the process. If the level we are given is a polygon soup (i.e., essentially a single mesh) however, or is comprised of meshes that individually contain illegal geometry, there is nothing we can do to resolve this situation and the compilation of a solid/empty leaf tree will not be possible.

Illegal geometry places a burden on the project artist to be extra careful during the level creation process, and it is for this reason that many artists use world editors (such as GILES™ or WorldCraft™) to build assets for use in a solid/empty environment. These editors allow the artist to build up a scene using a variety of primitives that can be carved, unioned or intersected with each other using CSG techniques to build more complex shapes that remain geometrically legal in the BSP leaf tree sense. For example, in GILES™ you can perform hidden surface removal on your final level before saving it out to disk by selecting all objects in the scene and then pressing the Union button. This action will perform a

union test between each brush with every other brush in the scene and discard any polygons that exist in solid space (such as those contained inside another brush). This will prepare the geometry for solid/empty BSP tree compilation.

Although the solid/empty property of the BSP leaf tree was an interesting one to discover, and certainly useful in the sense that it made our CSG routines possible, we will learn in this chapter that this information is actually going to be critical during the next stage of our engine development process. We will use it during the implementation of a new major module in our BSP leaf compiler tool -- the ability to calculate a Potential Visibility Set (PVS).

In this lesson we are going to learn how to leverage the power of BSP leaf trees to significantly reduce the number of polygons that have to be rendered each frame, allowing our applications to run much, much faster. Our new design will enable us to quickly reject unseen geometry, thereby separating the concept of frame rate from the size of the overall level. Using a BSP tree in combination with our Potential Visibility Set, we can reject nearly all geometry that is not currently visible with almost no processor or GPU overhead. This is because, like the leaf BSP tree in Lab Project 16.2, the Potential Visibility Set is pre-calculated at development time and saved out to disk along with the leaf tree data. Our renderer will no longer need to test each polygon or each leaf to see if it should be drawn. Instead, only polygons that can be seen from the current location within the scene are processed in any way.

Unlike our previous spatial tree demonstrations, the BSP leaf tree demonstration provided in the previous lesson was divided across two lab projects in order to separate out the compile process from that of the runtime renderer. The compiler itself was essentially implemented as a development tool that would compile the BSP tree and then save the data in its compiled format out to file. All the BSP tree information was included (the nodes, planes, leaves, polygons, etc.) so that all the renderer had to do was load in that data and use it to reconstruct the tree. This is obviously much quicker than waiting for the BSP tree to compile every time the application is run, especially on complex levels. Ideally we want our player to progress from one level to the next without long wait times in between. Of course, this is a good idea with any spatial tree partitioning scheme, so you could certainly use the previous lab project as a template for how you might save your oct-trees, quad-trees or kD-trees out to file. In each case, if the tree is static (not expected to change its form throughout the life of the application/level) it is generally better to pre-calculate this information at development time and package the level assets in their compiled form.

Although having to wait for an oct-tree compile (for example) can be an annoyance, the potential visibility set (PVS) calculator we add to our BSP leaf tree compiler is going to require much more time than a simple oct-tree compile. The calculation of PVS data is actually a very time consuming process. It can take anywhere from 5 minutes to several hours to complete, depending on the complexity and size of the scene data. Obviously this is not a process that we can perform in the final distribution of our game; it must be calculated at development time. Therefore, by separating out the leaf compiler into its own application in the previous lesson, we were actually laying the groundwork for a development tool that we will complete in this lesson. Lab Project 17.1 will be a BSP Leaf Tree Compiler and PVS Calculator that can be used at development time to compile our data and save it out to file. Lab Project 17.2 will demonstrate how to load and render the scene using the compiled BSP leaf tree and PVS data just generated. This highlights the actual rendering engine code which is shipped to the end user. Thus, at the end of this lesson we will have a tool to generate geometry files that are stored in BSP/PVS form and an application that demonstrates how a game engine can load and render this data.

17.1 Introducing Potential Visibility Sets

It is perhaps not overstating the point to say that the technology we will learn about and develop in this lesson is the most exciting we have learned thus far with respect to geometry management. It is even fair to say that this is the technology that we have been building up to over many of the previous lessons. The PVS calculator we develop in this chapter will open doors for us that were previously closed. It will allow us to render levels of such a size and complexity at frame rates that our engine, up to this point, could not possibly achieve. So what is a potential visibility set?

A Potential Visibility Set (PVS) is a set of visibility information stored for each leaf (generally in an array) which tells us which other leaves are considered visible from that particular leaf. We will look at how to generate and store PVS data a bit later when we cover the implementation of a PVS calculator, but for now, let us just understand the theory.

When covering the previous spatial tree types we discussed a visibility system that employed hierarchical frustum culling for efficient rejection of geometry outside the frustum. Yet, this is hardly what one might refer to a robust visibility system. In theory, a visibility system should tell you what is currently visible. Of course, our previous spatial trees did not exactly do this with much accuracy. They were quite good at telling us what was *not* in the view frustum (and thus not visible), but that did not lead to the conclusion that the geometry that was within the camera's view frustum was actually visible. Consider a camera located in a small room where, regardless of the size of the frustum, the only visible elements are the polygons comprising the floor, walls, and ceiling of that room. If we had a way of knowing that this was the case it would prevent us from having to render the possibly thousands of polygons located behind the polygons in the current room that are well within the FOV and far plane range of the frustum.

Because our previous visibility system did not take occlusion into account, in such a scenario, every polygon inside the frustum would be rendered, even if the camera was facing a wall and could see only that single polygon. Although the player would correctly see only that one polygon, the thousands that may be behind it still get drawn to the frame buffer during the render pass only to be eventually overwritten by the single polygon we can see. Even if the polygon we can see was, by luck, rendered to the frame buffer first, thus preventing any of the other polygons behind it from being rendered, those polygons would still need to be transformed, lit, and clipped by the pipeline only to be rejected at the per-pixel level during the depth test. This situation is what is commonly referred to as overdraw, and without implementing some form of occlusion culling in our engine, we might have a situation where, by the time we have rendered the final image into the frame buffer at the end of each frame, each pixel in the frame buffer may have been rendered and then replaced tens, if not hundreds, of times. This can be a serious problem when you consider that many of today's game players expect to play in very high pixel resolutions (e.g., up to 1600x1200). Even in a case where there is no overdraw whatsoever, the graphics hardware is going to have to paint 1,920,000 pixels every update (in a fraction of a second). If we imagine a scenario where each pixel has an average overdraw count of 25, that means the graphics hardware now has to paint 48,000,000 pixels to fill the same frame buffer. Even this one factor can lead to the difference between the game running smoothly and the game running at unacceptably low frame rates.

When one examines the origin of the overdraw problem, we naturally arrive at the conclusion that it is in highly occluded game environments where it is at its worst. A level of small passageways and rooms is one where we can imagine that thousands of polygons that lay behind the walls of the current hallway in which you reside are going to be rendered. A classic example is a game like Doom3™ or the original Quake™ series of games (or most other first person shooters) where the player is navigating through building interiors where the view is generally limited by surrounding geometry. The PVS calculator we develop in this lesson is tailored to take advantage of scenes like this that exhibit a high level of occlusion, and it will generate the visibility for each leaf taking that occlusion into account. For example, if two leaves were in very close proximity, but there was no line of site between these two leaves, they would both be omitted from each others visibility set.

> **Note:** The PVS system we will develop in this lesson does not work well with environments that have very little occlusion. A level comprised of a vast sprawling terrain for example is not a good candidate for this kind of PVS calculation. It is not that the PVS calculator will fail to work; simply that terrain occlusion requires a different (although not terribly dissimilar) approach. There are methods that can be implemented to calculate PVS for terrains, and you can find some good discussions of these techniques in the Game Programming Gems series by Charles River Media. Once you understand the basic PVS system that we develop in this chapter, you should have little trouble moving on to extend these ideas to other scenarios should you so choose.

Although we will discuss the implementation of a PVS calculator (with implementation specifics in the accompanying workbook) shortly, it should prove beneficial to start by discussing the data that will be produced by the PVS calculator and see how it will be used by our rendering application. This will give us a better idea of the data our rendering code will be working with to determine leaf visibility, along with a basic feel for the system as a whole. It will also identify the expected output of the PVS calculator.

The PVS calculator has a seemingly simple task. For each leaf in the BSP leaf tree, it will calculate a visibility set describing which other leaves should be rendered when the camera is in that leaf. We refer to the visibility information from all leaves as being the potential visibility set. That is, it contains potential visibility information for each leaf in the level, which taken together forms a set of potential visibility data for the whole scene. After this data has been saved out to file, the rendering application can load in that data and will have instant access, from any leaf, to the leaves it can see. As such, it knows immediately that the polygons in those leaves that should be rendered

For simplicity, let us just assume that each leaf in the tree maintains an array of bytes whose number of entries equals the total number of leaves in the tree. Imagine now that we are examining the PVS array for one of those leaves (call it “current leaf”). Each byte in this array is set to either 1 or 0 for every other leaf in the tree (assume that the leaves also have their pointers stored in a linear array or STL vector). This value basically tells us whether that leaf is visible from the current leaf. Byte 0 represents Leaf 0, byte 1 represents Leaf 1, and so on. For this example, assume that we are in Leaf 10. We loop through Leaf 10's PVS data and check byte 0. If this byte is set to 1 then Leaf 0 is visible from Leaf 10 and thus its polygon data should be collected into leaf bins and rendered; otherwise it should be skipped. You should see where this strategy is starting to lead us. By pre-calculating a PVS for each leaf ahead of time, not only can we avoid rendering unseen polygons, we will not have to process them at all. There will be no costly tests to see if polygons are within the view frustum because if they are not in that leaf’s PVS, then the leaf is simply skipped. The polygons in that leaf are never transformed, lit, culled or processed in any way. This also means that the only tree traversal we have to do is with the camera’s

location. We send it down the tree until it pops out in a leaf, fetch this leaf's PVS data array, and collect/render any polygons contained in leaves which have their PVS byte set to 1 in the current leaf's array.

In the next section we will examine what exactly the word 'potential' means with respect to a potential visibility set and talk about the amount of occlusion culling we can expect to get from such a system.

17.2 Potential Visibility

Figure 17.1 shows some example geometry that might be used in the calculation of a potential visibility set. We are looking at the level after the BSP tree has been compiled into eight leaves. For the purpose of explanation, we are assuming that each room in the level comprises a leaf, even though we have no guarantee that the level would be partitioned in such a way. It does not matter for this example because we know that each leaf in our BSP leaf tree will represent a convex region and, as such, the potential visibility set is actually calculating the visibility of each leaf. However, for the sake of demonstrating the basic premise, pretending that each room is a leaf makes it easier to identify the problem our PVS calculator will have to solve. Note that it is also assumed that a ceiling would exist over this level, but has been removed so that we can see inside.

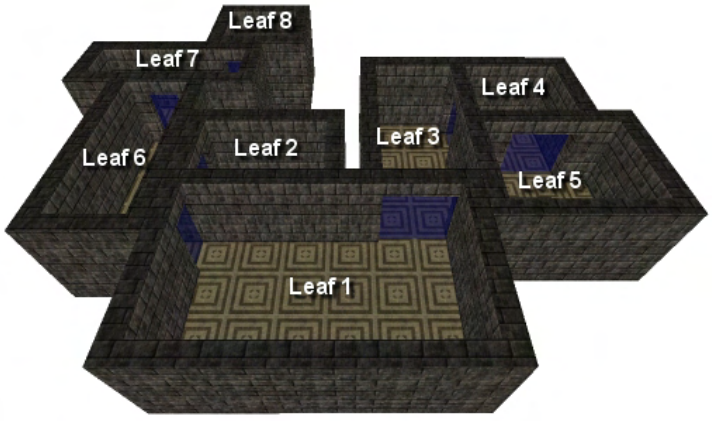


Figure 17.1

When this BSP tree is passed to the PVS calculator, the calculator has the task of determining every leaf that can potentially be seen from every other leaf. As this level consists of eight leaves, this means that eight visibility sets will be generated (one per leaf). Furthermore, the size of each of these arrays would also be 8 so that there is a byte element for each leaf. The eight bytes in leaf 1's visibility set would represent which of the eight leaves are potentially visible and should be rendered when the camera is located in leaf 1. Forgetting about the fact that arrays are zero indexed, byte 1 would always be set to 1 in the first leaf's visibility set since this is the byte which identified itself as being visible (i.e., every leaf will always be visible with respect to itself). Byte 2 would be set to 1 in leaf 1's visibility set if leaf 2 was potentially visible from leaf one. We can clearly see in Figure 17.1 however that this is not the case as there is no doorway (gap) leading from leaf 1 into leaf 2. As such, no line of sight between these two leaves is possible. This means that byte 1 in leaf 2's visibility set would also be set to 0 because, if leaf 1 cannot see leaf 2, leaf 2 cannot see leaf one either. We can see that byte 3 in leaf 1's visibility set would be set to 1 by the PVS calculator because there is an open doorway leading from leaf 1 directly into leaf 3. Consequently, leaf 3 would also have the first byte of its visibility array set to 1 as it can also see leaf 1. So, we have determined that after the PVS calculator has compiled the PVS, each leaf would have an array of leaf visibility information equal in size to the total number of leaves in the level. During the rendering of our level, any leaves that have their bytes set to 1 in the visibility set for the current leaf we are in should be rendered.

The reason that this data structure is called a 'potential' visibility set instead of an 'actual' or 'exact' visibility set is a result of the fact that it is calculated at development time and the resulting data is essentially static. In order to get the exact visibility set at the camera's current location in the game world, we would have to also factor in the camera orientation and the FOV. The PVS calculator is a tool that analyzes the geometry at development time and as such has no such concept as a camera (or similar runtime components). The camera is something that exists in the game world only after the game is running and is something that is dynamically changing as the player moves about the scene. As mentioned, the calculation of a PVS on a complex level can take many minutes or even hours, so we certainly cannot calculate it every time the player moves. Even if it were possible to calculate it in a respectable time, the whole idea of the PVS is that it removes any such runtime burden from the CPU. Therefore, the PVS for a given leaf will not describe what is currently visible from the player's location within the game world, but will instead describe everything that could possibly be visible from that given leaf.

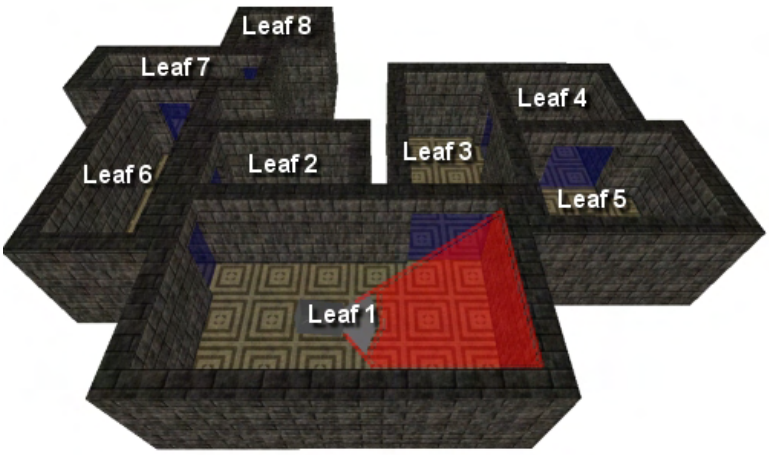

Figure 17.2

To understand the differences between the two situations, take a look at Figure 17.2 which shows the same level geometry. We also see where the camera might be located and oriented during a given frame update. We note that the camera is in leaf 1 and is oriented to the right. The only geometry that can actually be seen would be sections of the east and south wall of that leaf. The red tinted area describes the FOV given by the view frustum. As you can see, if we could pre-calculate this information, it would mean only a very small number of polygons would have to be drawn in a given update when compared to the total polygon count of the level as a whole. However, since this would involve factoring in the camera's position and orientation, which can change from frame to frame, this is something we cannot pre-calculate at compile time.

Although we cannot pre-calculate the exact visibility information for the camera at every given location in the scene using this type of PVS system, we can do the next best thing. For each leaf, we can calculate everything that can possibly been seen through all its exits. To do this, we will borrow ideas from the theory of light transport. That is, we will essentially fill the leaf with light and let it flood out through each of its exits. Any other leaves in the level that are touched by this light are added to the visibility set of the current leaf being processed. By filling leaf 1 with light for example and finding all the leaves in the level that get touched by that light, we essentially compute everything that could possibly be seen from any location within leaf 1. This completely covers the full range of orientations that the camera could be maneuvered to within that leaf to get the maximum view angle through one its doorways.

The process of shining this light out of the leaf though its exits is done for each exit in that leaf in turn. After we have done it for each of the exits in the leaf currently being processed, we will have successfully identified all the leaves that have the potential to be seen (i.e., the potential visibility set for

that leaf). This process is performed for each leaf in the level, resulting in potential visibility information being generated for each leaf. Collectively, we refer to this as the PVS for the game level.

To bring some clarity to the above explanation, take a look at Figure 17.3 which depicts a situation part way through generating the visibility set for leaf 1. The green tinted area filling leaf 3 and partially filling leaf 4 shows how the light would flow out of the north east exit of leaf 1 were we to fill it with light. This tells us that both leaves 3 and 4 can be potentially seen from leaf 1 were the camera to be looking through that exit during the game. The square inset in Figure 17.3 demonstrates this fact by showing a render of what the camera could actually see through that exit were it to be located directly in front of it. Therefore, we know that if the camera is ever found to be in leaf 1 during the game, leaves 3 and 4 would need to be rendered as they have the potential to be visible. Whether or not they are *actually* visible depends on where the camera is located in the leaf at run time and which direction it is facing. Were it to be in the same location as shown in Figure 17.3 but facing southwards, obviously neither of those leaves could be seen. However, calculating what has the potential to be seen in an occluded level narrows down the number of leaves that have to be processed. In the end, we will only have to work with a few of them in the typical case.

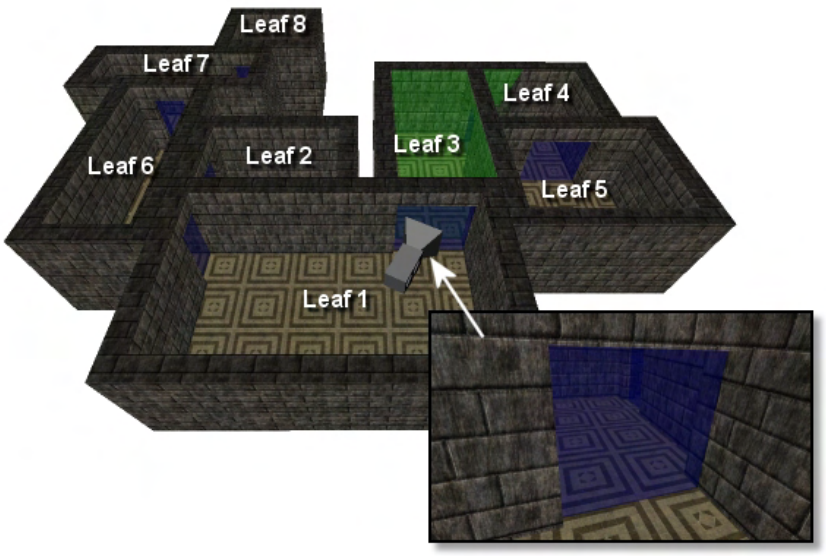

Figure 17.3

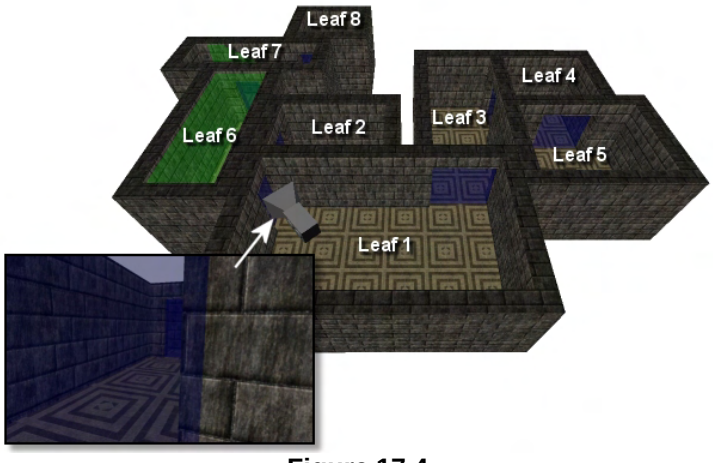

Figure 17.4

So, we can see above that after the PVS calculator has calculated the visibility for the first exit in leaf 1, it will set the bytes that correspond to leaves 3 and 4 in its visibility array to 1 (indicating potential visibility).

As leaf 1 actually has two exits, the PVS calculator would then have to perform the same step for the northwest exit. Once again, we model the phenomenon of light flooding out from the northwest exit and find that the light touches leaves 6 and 7. We can see that the light only partially touches leaf 7 through leaf 6's north exit, but that is all we need to know. Can any part of leaf 7 ever been seen when the camera is in leaf 1? In this case the answer is yes, and as such, when the camera is located in leaf 1, leaf 7 should also be rendered. The square inset in Figure 17.4 demonstrates that this is

the case by showing a render of what the camera might see if it was located in leaf 1 and looking through the northwest exit.

Figure 17.5 shows the visibility set that would be constructed by our PVS calculator for leaf 1. It contains itself (naturally) and the four leaves that light flooded into. In this small and simple example, this means that 5 of the 8 leaves would need to be rendered when the camera is located in leaf 1. While this does not seem like much to be excited about, we can easily imagine the savings that would be introduced when working with a proper game level of vast size and complexity. For example, imagine if leaf 8 had a doorway that led into a network of 100 other leaves, and leaf 5 also had an eastern exit that led to a network of an additional 250 leaves. Although the level would now be 358 leaves in size and would be much slower to render using brute force, with a PVS, only those same 5 leaves would ever need to be rendered as leaf 1 cannot see leaves 8 or 5 and thus, any of the leaves they might lead to.

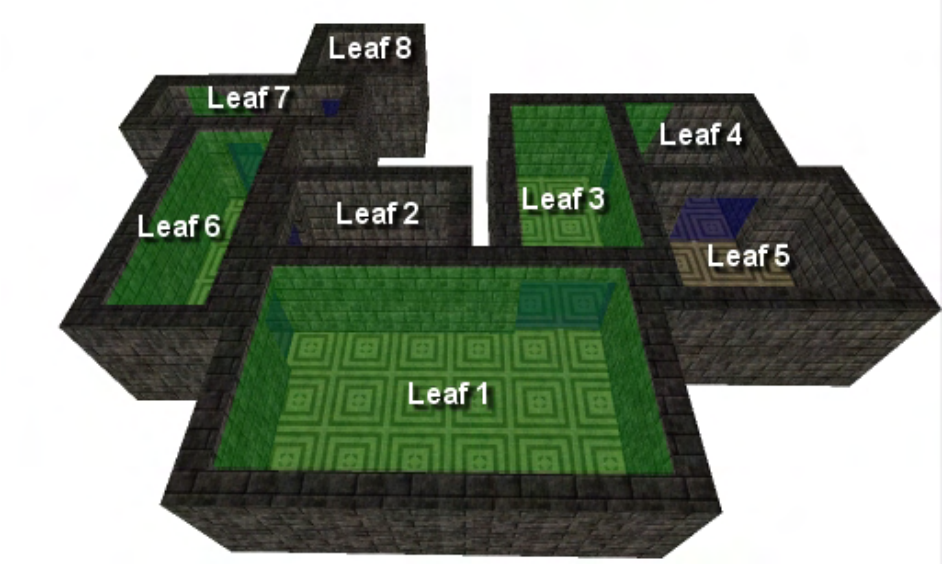

Figure 17.5

So the visibility set for a given leaf will provide us with all the leaves that could possibly be seen through the exits in that leaf. We can see in Figure 17.5 that this is always an over-approximation since we have to cover all bases and calculate everything that could be seen from every position/orientation that the camera might assume within that leaf. We can imagine that if the camera were located in the south region of leaf 1 in Figure 17.5 and was facing in a southerly direction, leaves 7, 6, 4, and 3 would not actually be visible since they would be behind the camera (and therefore, not contained in the frustum). Nevertheless, the visibility set for the leaf would still contain them.

> **Note:** Although we discussed the process of computing the visibility set as one of shining light out through the exits of each leaf, this was really just an analogy with respect to the process that will be performed. No lighting calculations of any kind are performed and no lights are ever placed into the scene during the process. We essentially simulate the same effect of light flooding using clip planes and portals as we will discuss later in the lesson.

Finally, before finishing up this initial review of how PVS data is calculated and what it represents, it is worth noting that it can be further refined using frustum culling at run time. This can often produce something that is much closer to an actual visibility set. In the previous example we said that if the camera was in leaf 1 and facing south, we would still have to render leaves 7, 6, 4, and 3 even though

they would be outside the frustum. Of course, once we have the leaves that are potentially visible from the current leaf, instead of just blindly rendering them, we can frustum cull their bounding boxes if we wish. In this case, 4 of the 5 leaves in leaf 1's visibility set would be culled away, leaving us to render only the one leaf. So, the PVS is a conservative pre-calculated visibility set for each leaf which can be fetched at run time for the current leaf the camera is in. After the visible leaves described by the PVS have been retrieved, we can further reject leaves from the visibility set by performing a frustum cull on those leaves. As we already know, frustum culling will factor in the camera's position and orientation, so we can reject any leaves in the PVS for the current leaf that are situated outside the frustum.

17.3 Rendering a BSP Leaf Tree with PVS

It might seem strange that we would discuss the technique for rendering a BSP leaf tree using a PVS when we have not yet discussed how to calculate that PVS data. However, the rendering process that uses the PVS data is completely separate from the development of the tool that is used to generate it (the PVS calculator). The rendering of the PVS equipped level data will be performed by the game itself and is actually extremely simple once we now how the data will be stored and loaded from file. Examining how our BSP leaf tree will draw itself using the PVS data will also help us understand the PVS calculator that we will need to write in order to build that data. Therefore, the topic discussed in this section is applicable to the application that ultimately ends up rendering the PVS data (the game's 3D rendering engine) and not the PVS calculator tool itself.

Rendering the PVS is delightfully simple. The general rendering algorithm works as follows on a per-frame basis:

- Traverse the BSP tree with the camera's position vector to determine which leaf the camera currently resides in. This is very fast because we are only be traversing a small fraction of the entire tree (thanks to the hierarchical nature of BSP trees). This phase returns 'Camera Leaf'; the leaf in which the camera currently resides.

- Each leaf has a PVS defined for it describing which leaves are visible. The size of this array for each leaf would be the total number of leaves in the tree. Loop through that camera leaf's PVS data. Any bytes in the array that are set to 1 indicate that we need to render the leaf (i.e. the polygons in that leaf). If Byte 23 is set to 1, then we render all of the polygons in Leaf 23 for example.

These two steps are all that is involved once the data has been stored in memory. Each leaf in the tree would have its own visibility array and therefore, all we have to do is find the leaf the camera is in and then iterate through that leaf's set rendering any visible leaves.

We will now look at some code demonstrating this process. Although the actual implementation will be discussed in the accompanying workbook, the code and pseudo-code in this textbook will stay close to the system we will be using. For example, in this next section of code it is assumed that the CBSPLeafTree class is derived from CBaseTree and as such, it is in the ProcessVisibility method of the derived class that the camera's leaf is located and its PVS iterated through. The function first issues a

call to CBaseTree::ProcessVisibility so that the leaf bins get emptied and then it issues a call to the CBSPLeafTree method called FindLeaf. This method is passed a (camera) position and returns the index of a leaf in the tree's leaf array. This index is then used to fetch a pointer to the leaf. This first section is shown below.

```
void CBSPLeafTree::ProcessVisibility (CCamera &Camera)
{
    CBSPLeaf *pCurrentLeaf=NULL, *pVisibleLeaf=NULL;
    UINT     CurrentLeafIndex;

    // Call base class to empty leaf bins
    CBaseTree::ProcessVisibility( Camera );

    // Get pointer to current leaf the camera is in
    CurrentLeafIndex = FindLeaf ( CCamera.Position );
    pCurrentLeaf = m_Leaves[CurrentLeafIndex];
```

Now that we have the leaf the camera is currently in we will walk through its PVS array. In this example each leaf is assumed to have a BYTE array called 'PVS' which has an entry for every leaf in the level which can be set to either 1 (visible) or 0 (invisible). In the final section of this function we loop through each element in this array and test to see if it is non-zero. If it is then it means that leaf is visible and should be rendered. The loop variable 'i' describes the current byte/leaf in the array we are testing visibility for. It is used to fetch a pointer to the leaf that needs to be rendered. We pass this leaf's bounding box into the CCamera::BoundsInFrustum method and if the leaf is inside the frustum we set its visible status to true.

```
    // Loop through PVS for this leaf
    for (int i = 0; i < m_nNumberOfLeaves; i++)
    {
        // Is leaf 'I' visible to potentially visible from current leaf?
        if (pLeaf->PVS[i])
        {
           //Fetch pointer to potentially visible leaf
           pVisibleLeaf = m_Leaves[i];

           // Is it actually visible (inside the frustum)
           if (CCamera.BoundsInFrustum(   pVisibleLeaf->BoundsMin,
                                          pVisibleLeaf->BoundsMax) ;
              pVisibleLeaf->SetVisible( true );
        }
    }
}
```

Remember that the CBaseLeaf::SetVisible call is the method that adds all the data in that leaf to the relevant leaf bins so that it is ready to be output to the frame buffer batched by subset when the application finally calls CBaseTree::DrawSubset. As you can see, the PVS idea fits in very nicely with our CBaseTree rendering system.

An important thing to remember is that the PVS array for each leaf is *view independent*. When we calculate the PVS it will contain all of the leaves that are visible from anywhere inside the current leaf. This does not mean that during our game the camera can necessarily see into all of those leaves at the

current moment in time. As mentioned, the nature of PVS it that it represents an *overestimate* of visible geometry and as such, frustum culling has been employed to further reduce the number of leaves that have to be rendered (to a mere few in the typical case of a highly occluded environment). This means that even if the game level contained 10,000 leaves, we would still only have to process and render a handful of them. As a result, the frame rate is essentially decoupled from tree size, as it was with the node compiler.

17.4 Zero Run Length Encoding

The problem with the code snippet discussed in the last section is scalability. If our game level had 5000 leaves then the total memory needed for just the PVS data alone would be:

5000x5000 bytes = 25,000,000 bytes = 25 MB (approx)

For most game programmers, that is simply too much memory to dedicate to this task, important though it may be. Remember that this does not account for the memory consumed by textures, polygons, or even the BSP tree itself. There is at least one fairly obvious thing we can do to reduce the memory requirements for PVS. For starters, because a leaf is in going to be in only one of two states (visible or invisible), we do not need a full byte per leaf to store that state. Instead we can store a single bit per leaf in the PVS. This reduces the PVS memory footprint by a factor of 8 (down to about 3 MB in this example) since each byte now stores visibility information for eight leaves instead of one. But even this is still a bit on the large side.

Imagine that you are located in a large installation of some kind (your game level) with the roof removed. Let us say that this installation has thousands of rooms, where each room is a leaf in our tree. In this case we know that most leaves will only be able to see a handful of other leaves (through doors, windows, etc.). We can deduce then that the PVS for any given leaf will contain mostly zeros, the exception being the leaves that are in close proximity which have direct line of sight with the source leaf.

Let us say that our example level has 1000 rooms and that we are in room (leaf) 0. Further, let us say that from leaf 0 we can only see into rooms 1, 2, 3, 20, and 35. Again, the PVS data for this leaf has to be large enough to hold one bit for every leaf in the tree. So our requirements will be (1000 + 7) >> 3 = 126 bytes. Do not worry if this number caught you off guard, we will explain how we arrived at this figure next.

We add 7 and then divide by 8 to deal with the truncation that happens when using a long integer. For example, if we had 9 leaves, we know that we need two bytes to hold this information. Byte 1 would hold the first 8 bits and byte 2 would hold bit 9. It is a common mistake to assume that to calculate the space needed we can simply do: 9 / 8 = 1. This would only give us 1 byte, which we know is not sufficient memory to store all of the information we need to in this example (9 bits). However, if we add 7 and then divide by 8 we get: 9 + 7 = 16 / 8 = 2 bytes. Thus we can always be sure that we round up to the nearest whole number and not down.

It is certainly wasteful to use 126 bytes for leaf 0's PVS when it can only see into five rooms, especially when we only need one bit per leaf. In this case, the visibility information for leaves 1, 2, and 3 would all be in byte 0 of the PVS array. The in-memory PVS data for leaf 0 (without Zero Run Length Encoding) would look like the scenario depicted below.

> **Note:** The array in this example is assumed to continue on to the 126th byte to represent the visibility bits for each of the 1000 leaves we are using in this example. Everything past byte 4 would be zero however, leaving 121 bytes of zeroes.

	Byte 0	Byte 1	Byte 2	Byte 3	Byte 4	Byte 5	Byte 6	Byte 7	.....
Value	15	0	16	0	8	0	0	0	0
Leafs	0-7	8-15	16-23	24-31	32-39	40-47	48-55	56-63	.....

Zero Run Length Encoding

If you are comfortable with binary numbers (and you should be) you should have no difficulty understanding the situation above. In this example leaf 0 can see leaves 0 (itself), 1, 2, and 3 and this information is all contained in the first byte (Byte[0]). We set bits 1, 2, 3 and 4 to '1', which produces the decimal value 15. We cannot see any of the leaves ranging from 8-15 so all of the bits in Byte [1] are left at zero giving us a decimal value of 0. The next byte in the array (Byte[2]) represents leaves 16-23 and we can see one of these leaves (leaf 20). Leaf 20's visibility bit is bit 5 in Byte[2] (16 = bit 1, 17 = bit 2, 18 = bit 3, etc.) so we set the fifth bit in Byte[2] to 1 and get a resulting byte value of 16. The next byte in the array represents leaves 24-31 and since none of these are visible from the current leaf, we leave the byte set at 0. Byte[4] represents leaves 32-39 and we can see leaf 35. So the appropriate bit in Byte[4] is set (bit 4) giving us a decimal value of 8. From this point on, all of the other bytes in the PVS data array would be zero because no other leaves are visible from leaf 0. For a very large level, this proves to be a tremendous waste of memory, especially when we consider that these wasted (zero) bytes occur on a per leaf basis. It also adds unnecessary overhead at runtime if the renderer is required to test all of these bytes when we know beforehand that the rest of the array is set to zero.

Now look at the list of numbers just below and you will see the same example represented using Zero Run Length Encoding (ZRLE). You will note that even our simple data set has been compressed from 126 bytes down to 9 bytes. The savings would be even greater on larger levels. This is the compressed format which our PVS calculator will use when generating the data and saving it to file. Our runtime component will therefore need to know how to interpret this data when calculating visibility. That is, the PVS data for each leaf will now be stored in a compressed format even in memory and we will have to learn how to decode it when we are testing a leaf's visibility array. Using this compressed format will help us keep the PVS memory footprint down to a minimum. The implications for runtime performance are clear as well since we will now need to examine only 9 bytes at every leaf instead of 120 bytes. See if you can spot the pattern in the following numbers:

15, 0, 1, 16, 0, 1, 8, 0, 121

When a byte does not equal zero, it is simply stored in the array as it normally would be (uncompressed). You can see that byte 0 which was equal to 15 does not get compressed and is instead just written to the data array. The bits set in this byte have the same meaning as before; if a bit is set to 1

then the corresponding leaf that maps to that bit is visible. However, when a 0 is encountered, instead of just writing it to the array we will count how many zeros follow it. In our example, there is only one zero at byte 1, so we write in the zero byte followed by an additional byte which describes how many zeros are in "the run". While this does not seem all that significant, you can see the savings more clearly at the end where we would have had a run of 121 additional zero bytes. This has been reduced to only two bytes (0 and 121). On very large levels, you are sure to find many such "runs" throughout the data set. Note that the maximum single run of zeros can be at most 255 because that is the largest value that can be stored in a single byte.

Although the last code snippet demonstrated that each leaf structure had its own visibility array, our PVS calculator will actually store all the visibility information for every leaf in a single PVS data array that is owned by the tree. This means the PVS data for the entire block would be stored in a single continuous array. That is, leaf 1's visibility bits will be followed by leaf 2's visibility bits which will be followed by leaf 3's visibility bits, and so on. The leaf structures will store indices into this master PVS array describing the byte index where that leaf's visibility bits begin.

With all of this in mind, we will look at a revision of the previous function which has been adapted to index into the master PVS data array to fetch the visibility information for a given leaf. Once the start of that information has been located, we will iterate through it in its compressed form and flag any visible leaves as being so.

The first part of the function is the same and calls the base class ProcessVisibility method to empty the leaf bins. The CBSPLeafTree::FindLeaf method is then used to fetch the index of the leaf the camera is currently in. This index is then used to fetch a pointer to that leaf.

```
void CBSPLeafTree::ProcessVisibility( CCamera &Camera)
{
     CBSPLeaf *pCurrentLeaf=NULL, *pVisibleLeaf=NULL;
     UINT     CurrentLeafIndex;
     int i;

    // Call base class to empty leaf bins
    CBaseTree::ProcessVisibility( Camera );

    // Get pointer to current leaf the camera is in
    CurrentLeafIndex = FindLeaf ( CCamera.Position );
    pCurrentLeaf = m_Leaves[CurrentLeafIndex];
```

Next we get a pointer to the start of the tree's master PVS data array which, in this example, is assumed to be stored in a byte member array called m_nPVSData. The current leaf will store a PVS index member (which will be calculated by the PVS calculator tool) which will describe the location from the start of the master PVS array where the current leaf's visibility bytes begin in this array. This offset is fetched from the leaf and used to increment the PVS pointer so that the local variable PVSPointer now points to the start of the PVS data for the current leaf.

```
    // Get pointer to tree's master PVS array (compressed byte array)
    BYTE *PVSPointer = m_nPVSData;
```

```
    // Find where this leaf's PVS begins in master set
    long PVSOFFSET   = pCurrentLeaf.PVSIndex;
    PVSPointer += PVSOFFSET;
```

We can no longer just set up a loop to iterate through the number of leaves since there will no longer be a byte in this array for each leaf in the tree. In fact, because the visibility information for the current leaf has been zero run length encoded, we really do not know beforehand how many bytes this leaf's visibility information will span in the master array. So we will have to keep track of the current leaf we are testing in the local variable nCurrentLeaf. This will start off at zero and we will break from the loop when we have processed all the leaves in the current leaf's visibility set.

```
    // Search through all leaves starting at zero
    long nCurrentlLeaf = 0;

    while (nCurrentLeaf < m_nNumberOfLeaves)
    {
```

We will now test the current byte being pointed to by PVSPointer, which will be the first byte in the current leaf's visibility information in the master PVS array in the first iteration of the loop. If this byte is non-zero then it means that this byte does describe some visible leaves (i.e., it has some of its bits set to 1) and therefore is not a compressed zero length run. When this is the case, we set up a loop to iterate through the 8 bits.

```
      if (*PVSPointer != 0)
      {
          for (i=0;i<8;i++)
          {
              BYTE mask = 1 << i;
              BYTE pvs = *PVSPointer;
              if (pvs & mask)
              {
                  //Fetch pointer to potentially visible leaf
                  pVisibleLeaf = m_Leaves[nCurrentLeaf];

                  // Is it actually visible (inside the frustum)
                  if (CCamera.BoundsInFrustum(  pVisibleLeaf->BoundsMin,
                                                pVisibleLeaf->BoundsMax ) ;
                   pVisibleLeaf->SetVisible( true );

              }
              nCurrentLeaf++;
          }// end for i;

          // Advance pointer to next byte
          PVSPointer++;
       }
```

As the above section of code shows, in each iteration of the inner loop we build a byte mask. This is a mask that is all zeroes except for the bit we wish to test. When a bitwise AND with the current PVS byte we are testing has a non-zero result, it means this bit must be set to 1 in the PVS byte and therefore the leaf it corresponds to (nCurrentLeaf) might be visible. Thus it should be frustum tested and, depending

on the outcome, flagged as visible. As you can see, just inside the bottom of the inner loop we increment the nCurrentLeaf counter variable as we step through each bit in the byte. This is our way of keeping track of how many leaves we have processed and therefore, which leaf the current bit we are testing corresponds to.

Now we see the final section of the function which is executed when the current PVS byte is found to be zero. This means that this byte is the start of a 'zero run' and the next byte that follows it will tell us how many zero bytes were collapsed into this single byte. This is very important for us to know because if the byte following the zero is 10 for example, this means that the zero byte actually represents a zero for 10*8=80 leaves. As such, we should increment our nCurrentLeaf variable by this amount.

```
       else
       {  // we have hit a zero so read in the next byte
          // and see how long the run of zeros is
          PVSPointer++;
          BYTE RunLength = *PVSPointer;
          PVSPointer++;
          CurrentLeaf += RunLength * 8;
       }

     } // End while
}
```

As you can see, because we only enter this code block when the current PVSPointer points to a byte that is zero, we know that the next byte following it will be the run length. So we increment the pointer and fetch the run length value. As this represents a compressed run of zero bytes and each byte holds the visibility information for 8 leaves (8 bits) this means we have just avoided testing a potentially large number of leaves. For example, if the run length following the zero byte was 20, this means we have just avoided having to test 20*8=160 leaves and we have also avoided 160 loop iterations. Of course, we must increment our nCurrentLeaf counter by this amount so that we know how many leaves we have skipped and what leaf the first bit in the next byte maps to.

> **Note:** The above code is for demonstration purposes only and will differ from the actual code explained in the accompanying workbook. All code in this textbook should be considered only placeholder and is shown to clarify the processes being discussed.

You should take away four things from the code snippet above.

- Each leaf has a PVSIndex variable that describes how far into the master PVSData array its own PVS begins. Remember that each leaf has its own PVS, but that all of the leaves will store their PVS data together in one master array. It is this master array that is commonly known as the PVS and it describes the visibility of all leaves from any other leaf.

- If a non-zero byte is encountered, then we loop through all 8 bits in that byte, rendering the polygons in any leaf which has its bit set to 1. Remember that each bit in that byte represents a leaf, not a single polygon.

- If a zero byte is encountered in the PVSData array, we adjust the CurrentLeaf index variable to compensate for how many leaves *would have been* represented by the bits in the zero run. This shuttles us past all the zeros and speeds up the main rendering loop.

- The rendering loop exits once nCurrentLeaf > m_nNumberOfLeafs. This means we have processed the visibility bits for every leaf in the current leaf's visibility set.

We now have a good understanding of how the PVS data will be used by the runtime component to efficiently process only potentially visible geometry. Now might be a good time to run Lab Project 17.1 to see PVS in action. If you study the accompanying source code and workbook for this lab project you will also see that the additions to the leaf tree are extremely light. We have added a new member to our leaf structures so that they can now store an index into the master PVS data array describing where each leaf's visibility information begins, and we have also added code to read in the PVS data from file. Of course, this file is created by a development tool which we started to implement in the previous lesson. In this lesson we will now add a PVS calculator to our BSP leaf compiler. This will be the component of the compiler that will generate the PVS data for the compiled tree and save the zero run length master PVS data array out to file.

From this point on, all the processes discussed in this textbook will pertain to the compilation process of the PVS data in the compiler tool. That is, everything discussed from this point on will not be done at runtime, but will be part of our development cycle. The single goal of the PVS compiler is to create the PVS data array. While this is seemingly simple in theory, writing a PVS calculator is actually a non-trivial job. So consider yourself warned that creating a PVS is not an easy undertaking from the coding perspective. However, it is one of those tasks which is deceptively hard when you are struggling to understand it and then later seems so obvious and simple once you do. The rest of this chapter will make that clear.

17.5 The PVS Calculator

The process of calculating a PVS for BSP trees can be essentially broken down into two steps. These steps are performed after the leaf tree has been compiled. That is, our compiler will first build the BSP leaf tree and, instead of saving the data straight out to file as was the case in our previous lab project, the following two processes will now be performed.

- **Portal Generation**

- **Anti-Penumbra Clipping**

Since you may not be familiar with either of these terms, we will start with step one, 'Portal Generation'. In the coming discussions we will begin to see how these two concepts work together to create the PVS we are aiming for.

17.5.1 Portals Overview

In order to determine which leaves in the tree can see each other, we need to know about the gaps (exits/spaces) that exist between those leaves. For example, if we have two rooms with a doorway between them, we need to know how much of Room 2 can be seen through the doorway while standing in Room 1. The problem is that this is not information that we have automatic access to in our 3D world dataset. In fact, our polygon set tells us the opposite – where the gaps are *not*, instead of where they actually are.

To solve this problem, we are going to create temporary polygons called **portals** that are going to fill these gaps (they will be the same size and dimensions of all the gaps) between all of the leaves in the tree. In the two rooms with a doorway example, we somehow need to create a polygon that would fit into the doorway -- to "plug it up" so to speak. These portals will not be rendered or optionally not even kept around after the PVS has been calculated. The important role they serve is that by getting the dimensions of the portal which plugs up the doorway, we wind up getting the dimensions of the doorway itself, which is exactly what we need.

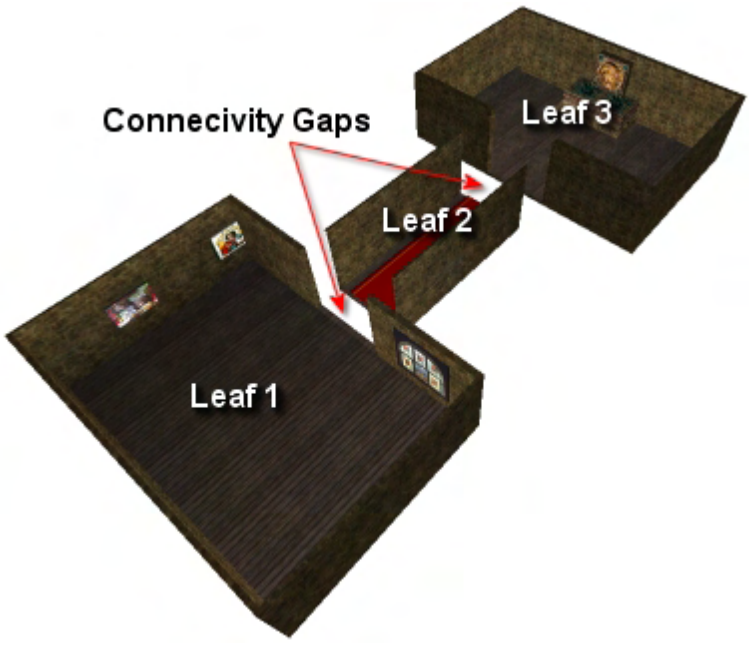

Figure 17.6

Although the BSP tree compiles the level into convex areas, the empty space regions are not typically closed hulls as Figure 17.6 demonstrates. We can see for example that leaf 1 represents a convex area of empty space and the polygons contained in leaf 1 lay on the bounds of that convex region. However, we can also see (note that we have deliberately pulled the construct apart into 3 distinct pieces for clarity) that there is a hole in the polygon data surrounding leaf 1's empty space. This is the hole/gap that leads into leaf 2 and thus describes the possible visibility from leaf 1. What we need to do is find a way to build temporary polygons to plug these gaps (a little like using them as doors). Of course, while this example assumes that each leaf is a separate room, this need not be the case depending on how the tree was built. All we know is that a leaf is a convex region of empty space that is partially bounded by polygon data. Anywhere there is a gap in this bounding data, the leaf has visibility out into a neighbouring leaf and it is this information we need to know. Thus we need to build portals for every single gap between all the leaves so that we have exact information about which leaves connect to which other leaves.

Once these portals are created, we then enter the second phase: anti-penumbra clipping. Without going into detail at this present time, let us just say for now that the edges of these portals are going to be used to build frustum-like shapes so we can determine exactly what a leaf can see through each of its portals. This is a somewhat fast and loose description, but will suffice at this time.

As you can probably imagine, creating portal polygons to fit into all of the gaps in our level results in a very high portal count. If a room has 5 doorways, we will create a portal in each doorway. This is going to be true for every leaf, so we expect to see many portals created along the way.

One might also imagine that we can create these portals given the information at our disposal in the BSP tree. In fact, the BSP tree tells us everything we need to know. In the previous lesson we discussed how the split planes of the BSP tree will, by their very nature, divide a non-convex region into a series of convex ones. This is because the planes are created from the actual polygon data and thus any non-convex object will have one or more polygons whose planes cut through the geometry.

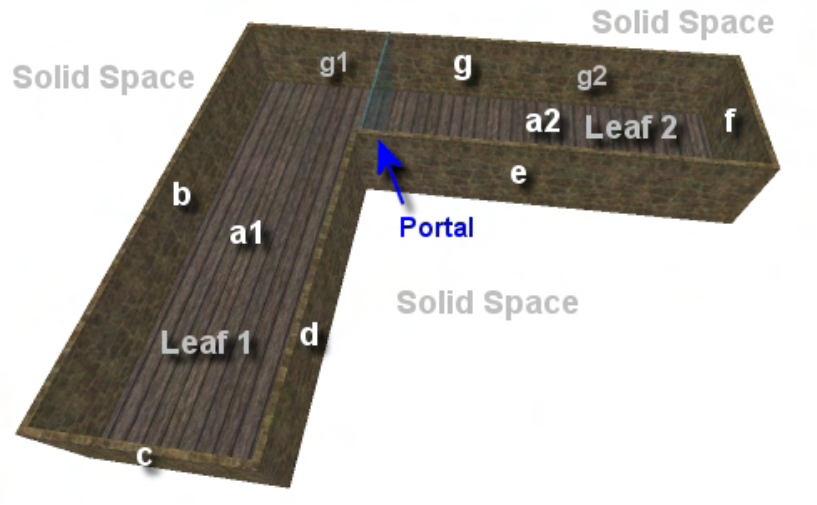

Figure 17.7

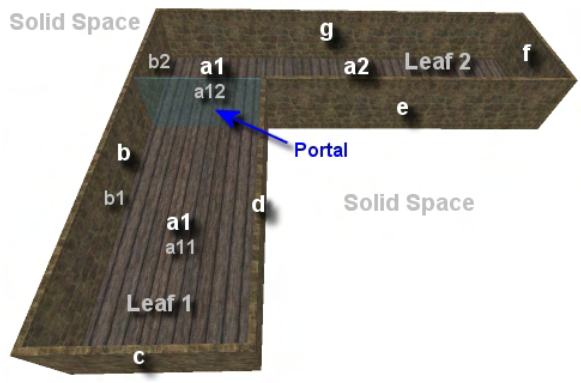
To demonstrate this fact, Figure 17.7 shows a simple non-convex mesh (roof removed). The labels given to each wall identify the polygons and the order in which they were chosen (alphabetical) as node planes during the BSP compiler. For example, polygons a1 and a2 represent two polygons that lay on the same plane -- plane A, used as the root node of the tree. Assuming that the split planes were chosen in alphabetical order, we can see that only when we get around to choosing polygon d as the split plane does the geometry get subdivided by this plane. We see that this cuts the polygon g into two g1 and g2 and splits the non-convex object into two convex objects. Because this split is caused by node d in this example, which created a leaf on either side, we know that a portal will definitely exist on this plane (in this example). We do not know how big this portal should be yet and we will get to that in a moment. But we can see that since node d was the node that split the geometry into a leaf on either side, this node must be where the portal exists between those two leaves. The portal we would ultimately need to generate in this example is shown in the diagram. Of course, the exact same construct could be compiled using a different plane selection order which would generate a completely different tree. That is, the splits would happen at different planes and the leaves formed would be of different dimensions to those shown in figure 17.7. This also means the portal that bridges those leaves would be in a different location.

> **Note:** Although all of the following diagrams are shown with back face culling disabled, all polygon normals are assumed to be facing inwards towards the center of the leaves in which they belong.

As one example, imagine that the above geometry was compiled into a tree such that polygon e was selected prior to polygon d. This means the split into two convex leaves would happen along plane e instead of along d. Consequently, the portal would be along this plane instead, as shown in the top-most image in Figure 17.8. In fact, to make sure we definitely understand this relationship, let us build the BSP tree in that section so that polygon e is selected prior to d. Although we have discussed building solid leaf trees in the previous lesson, we will still show step by step how this particular tree is constructed so that we can analyze the tree properties and recognize where portals can exist.



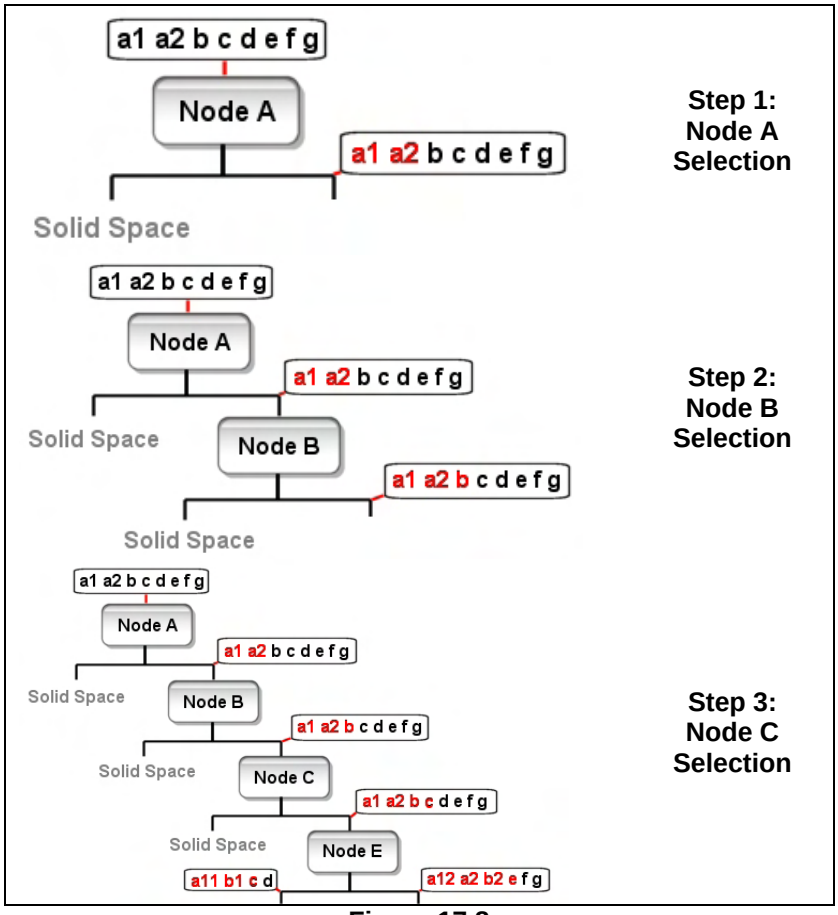


Figure 17.8

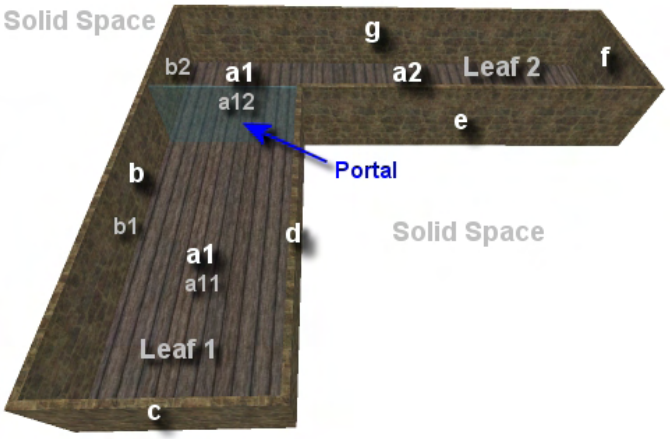
The BSP tree compiler is passed a list of polygons (a1,a2,b,c,d,e,f,g). At the moment, this is a single non-convex mesh. At the root node in this example polygon a1 is selected and its plane (labeled A) is stored in the root. Polygon a1 is then marked as a splitter so that it is not selected as a split plane again further down the tree. It is then added to the front list. The rest of the polygons in the list are also classified against plane A and are all determined to belong in the front list. We can see that in the diagram all the polygon data is either on or above the floor plane. During the classification test polygon a2 is found to be on the same plane as A, so it too is marked as having been used as a splitter so that it is not selected again. We can see in step one that all the polygons are passed into the front list and polygons a1 and a2 are highlighted red so that they are not used as a split plane again. Because no polygons exist in node A's back list, its back pointer is set to null and we know that this means it is solid space. This makes sense when looking at the diagram as this would represent the region of space underneath the floor.

In step 2, polygon b is chosen as the splitter and is marked as such before being added to the front list. All the polygons in the list are either on plane (with matching normals) or in front of plane B, so they all get added to the front list. The space behind polygon b (node B) is identified as being solid space.

In step 3, polygon c is chosen and the same process is repeated; all of the polygons are added to the front list and the halfspace behind node C is identified as being solid. The front list is passed down to the front child where, in this example, polygon e is chosen as the next splitter, creating node E. If you refer back to the geometry diagram, you will see that this node carves its input polygon set into a front and back lists, splitting polygon b into two child polygons labeled b1 and b2 and splitting polygon a1 into

polygons a11 and a12. Polygons a11, b1, c, and d are assigned to the back list as they are clearly situated behind polygon e and polygons a12, a2, b2, e, f, and g are passed into the front list.

For the sake of simplicity let us process the back list first. As we step into the back child we find that only polygon d has not yet been selected as a splitter, so it is selected, creating node D. At this point, polygons a11, b1, c, and d have all been used as splitters. We classify them against node D and find that they all belong in the front list. This identifies the back of node D as being solid space. As there are no polygons in the front list which have not been used as splitters, this means we have reached a terminal node and a leaf is created. In the diagram, this is referred to as leaf 1 and as we can see, it contains the polygons that made it into that leaf (a11, b1, c, and d).



At this point we return from node D (having created a leaf there) and find ourselves back up at node E. Node E's back tree has been built, but we have not yet recurred into its front child. In the diagram we can see that polygons a12, a2, b2, e, f, and g are passed into the front child with only polygons f and g remaining as potential splitters. In this example polygon f is chosen as the splitter and the polygon list is classified against the node. All polygons are found to exist in the front space which creates an empty back list, thus identify the backspace of node F as being solid space.

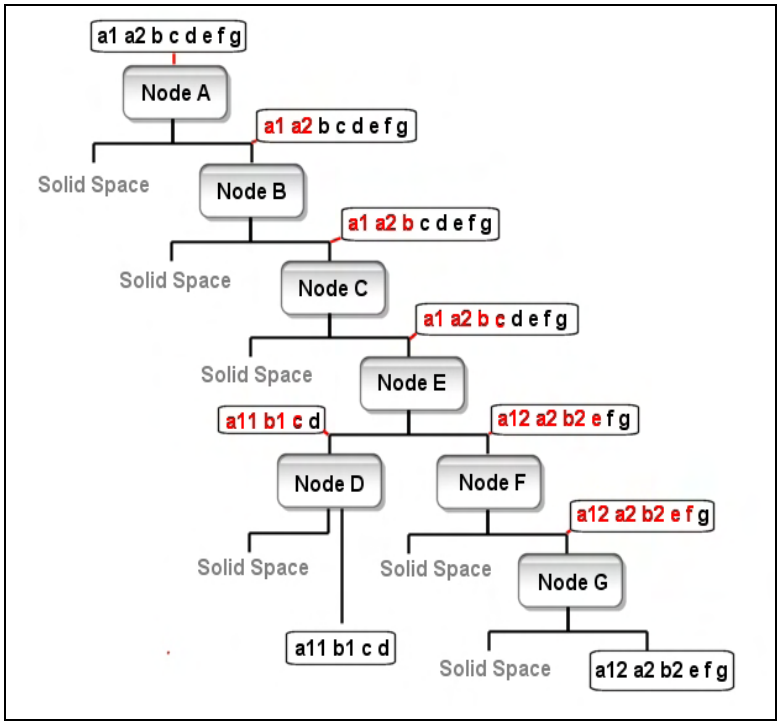


Figure 17.9

The front list is passed down into a final child where the only polygon not yet selected as a splitter (polygon g) is selected, creating terminal node G. Classifying the input list of polygons against node G reveals an empty back list and thus solid space exists at node G's back halfspace. All the polygons end up in the front list, but because they have all been chosen as splitters, this must be a terminal node and a leaf is created here and the polygons are added to it. The final tree is shown in Figure 17.9.

When analyzing this tree, something starts to become very clear. A portal is a polygon that bridges the gaps between two leaves and therefore, is a polygon that, if fed into the tree, should end up existing in both of those leaves. Therefore, the only nodes in the tree that could possibly create valid portals are the

nodes which have front *and* back children. A node that has only one child could not possibly create a valid portal because a portal by its very nature must have a leaf both in front and behind it. These are the leaves for which the portal describes connectivity. Therefore, we can see by looking at our tree that the only node plane on which a portal could possibly exist in this example is node plane E. All other nodes have solid space behind them. Thus, any portal created on that node plane would have a leaf on one side and solid space on the other.

Since a portal must have a leaf (empty space) on either side, our first step in the portal generation process will be to identify which nodes in the tree have both front and back children. These are the only nodes where portals can exist and are the only nodes that we will consider in the portal generation process. This typically rejects somewhere in the region of about 50% of nodes having to pass through the portal generation process. Imagine for example that we created a polygon that lay on the plane of node E and was the size of the portal depicted in the diagram. If we were to pass this polygon through the tree (performing portal/plane classifications at each node) the polygon would make its way into node E. At node E it will obviously be found to be on plane and could be sent down both the front and back trees of that node. This portal polygon would eventually end up popping out in both of the leaves on either side of node E and thus is a valid portal (i.e., a portal that exists in two leaves).

It is important to note that this does not mean that every node plane that splits the geometry into two lists will always create a valid portal. For example, imagine compiling the geometry shown in Figure 17.10 into a BSP leaf tree. In this example we can see that at some point during the BSP compilation process the long wall polygon of the closest inward facing cube would be selected as a splitter. This plane clearly has polygons both behind it and in front and as such, would be a node that has two children. However, we can also see that no portal should be created on this wall as it clearly does not connect the two leaves (cubes). Admittedly, this is an extreme case since in this particular scenario there is no way for the player to navigate from one region into the other, but it does highlight the fact that not every plane that has front and back children will create a valid portal. However, we do know now that nodes that have only a single child cannot possibly create portals. Therefore, we should not even try to do so for these nodes. Only the nodes in the tree that have two children are candidates for portal generation, although we now recognize that only some of them will actually create valid portals.

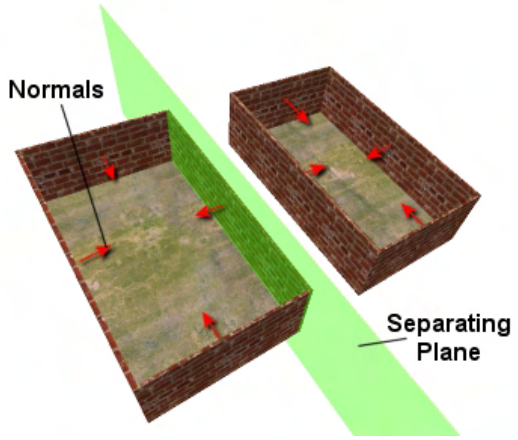

Figure 17.10

Although we still have no idea how to create a portal at this point, we have discovered some very important facts necessary to understanding the portal generation process:

- A portal is a polygon that ‘plugs’ the gap between two leaves.
- If a valid portal polygon was fed into the tree and sent down both sides of a node when it was determined to be on plane with that node, the portal would exist in two leaves.
- All portals throughout the entire level will exist on one of the tree’s node planes.
- Portals will never exist on the planes of nodes that have only a single child.

- We only need to create portals at nodes that have two children, although not all portals generated will necessarily be valid.

17.5.2 Portal Generation Overview

In this section we will discuss the steps involved in the generation of portals. Since this can seem to be a very complex topic at first, we will use a lot of diagrams to help you visualize the process.

At a high level, creating a complete set of portals for our Solid Leaf BSP Tree involves the following steps:

1. Visit each node in tree (node[i])

2. If node[i] does not have front and back children, skip this node

3. Generate a huge polygon (i.e., portal) on the plane of node[i]. This polygon should be large enough so that it encompasses all of the polygons in the level along that plane. How large it is does not matter just as long as it is large enough so that it spans the entire level along that node plane. This polygon represents an initial portal that we will later send through the tree and clip down to the appropriate size. A portal structure will be used to contain the information for a portal. This will be identical to a polygon structure except that it will have a few extra members so that it can store the two indices of the leaves it ends up in (if does turn out to be a valid portal). It will also store a 'next' pointer so that multiple portals fragments can be linked together and returned from the portal clipping function.

4. Once we have created the initial large portal for node[i], we send it down the BSP tree starting at the root node. Because a solid leaf tree is divided into solid/empty areas, clipping the portal against other nodes is easy. Any portal fragments that end up in solid space can be removed (because a portal cannot exist in the middle of a wall). As the portal gets recursively split, any fragments that end up in solid space are deleted and we are left with the shape and size of the portal as it should be to fit the gap between the two leaves the portal is being generated for. The actual clipping of the portal to the tree can seem a little complex. We will discuss it in some detail here and in greater detail later when we examine some code. Clipping involves traversing each node in the tree and testing the portal against the node plane to see whether it is to the front, back, spanning, or on the plane. Because the initial portal may get split into many valid portals as it is clipped to the tree, the portal clipping function will accept an initial portal as input and will return (potentially) a linked list of valid fragments that survived. Each fragment is a valid portal that ended up in two leaves. Of course, the function may return null if no portion of the initial portal survived. This means that there exist no valid portals on node[i].

   The portal clipping function will make extensive use of many of many of the skills we have already learned (e.g., polygon/plane classification and polygon splitting). The portal will be passed into the root node and will be classified against each node plane as it passed down the tree. Again, the portal can be either in front, behind, spanning, or on plane with the current node being visited. Here is an overview of what we do in each case:

- **In Front**

  If the portal passed into the current node being visited is found to be contained in the node's frontspace, the following two conditionals are executed:

  - If this is a terminal node then it means that the portal has ended up in empty space (a leaf). The index of the leaf in which it has landed is recorded in the portal's leaf index array. There will only ever be two elements in this array as a portal can never exist in more than two leaves.

  - If the front child of the current node is not a leaf, then the portal is passed into the front child recursively. As the clipper function will return a portal pointer (or a linked list of portals), the function then returns the portal pointer returned from its front child back to its parent. The portal that was passed into the front child may have been recursively split and clipped from the front branch of the current node's tree, so the pointer it gets back from its children may be a list of surviving fragments from the original portal that the current node passed into the child.

- **Behind**

  If the portal is found to exist in the backspace of the current node being visited, the following two conditionals are performed.

  - If no back child exists, then it means that the portal that has been passed into this node by the parent (or the application in the case of the root node) has ended up in the solid space behind the current node. The portal is deleted from memory and NULL is returned from the parent. This result is propagated up the tree through its chain of parents.

  - If the back child of the current node exists, then the portal is not in solid space and is passed into the back child node recursively. Any of the fragments that survive the portal being clipped to the back tree of the current node will be returned via a linked list or portal fragments which is then passed back to the parent.

- **Spanning**

  This is an interesting case as it is only this case which is responsible for the initial portal being split into multiple fragments. As those fragments are then passed down the front and back trees respectively, where they themselves may get split when found to be spanning other planes in the tree, we have a cascade effect where a single initial portal may get split into dozens of valid portals during the recursive clipping process.

  When the portal is spanning the node, the portal is split by the node plane. This returns two new child split portals and the original portal is deleted. What is ***very***

important however is that the child portals inherit the leaf array from their parent. That is, if the parent being split was found to have existed in leaf 5, both child portal fragments will also have this leaf index stored in them as well. This way, should the child portals end up in leaves of their own, we know the two leaves each fragment ended up in. What happens to both the front and back split portals is discussed below.

- The Front Split
    - If the current node is a terminal node then it means the front split has made it into a leaf. The leaf index is determined and stored in the portal. This may be a valid portal if it ends up in another leaf later in the process.
    - If the current node has a front child then the front split portal is passed into the front child and the portal fragments that survive that branch of the tree are returned (in a linked list).
- The Back Split
    - If the current node has no back child then it means solid space exists behind this node and therefore the back split portal ended up in that solid space. When this is the case, the back fragment is deleted.
    - If the current node has a front child then the back split portal is passed into the front child and the portal fragments that survive that branch of the tree are returned (in a linked list).

After the front and back splits have been processed, we may have two linked lists of fragments (returned from the front and back sub-trees at the node). When this is the case, the two lists are stitched together and returned to the parent. If only a front list or a back list was returned, then just that single list is returned.

- **On Plane**

The on plane case is perhaps the most complex to deal with. Essentially we have to send the portal down both the front and back children (if they exist). However, the portal must be passed down the front first, which will return a list of any portal fragments that survived the front of the tree. If any portals fragments were returned from the front traversal, then each one in turn is sent down the back of the tree. What we are essentially saying in such a scenario is “first find out if any part of this portal ends up in a leaf in the front tree, and if so, find out if any of those fragments also end up in leaves in the back tree”. If so, then this plane is the plane that created a split between leaves and these portal fragments exist in those leaves. Of course, the node plane being tested may have solid space behind it, or it may have a leaf in front of it, so the basic process performed in the on plane case is as follows:

- If the node has a front child then the portal is passed into the front child and we get back a list of portal fragments that survived the front of the tree.

- If the node has no front child then the portal has ended up in a leaf and the leaf index is stored in that portal.

- If no portal fragments survived the front tree (and if the portal did not end up in a leaf at this node) we return NULL from the function as nothing survived down the front tree (i.e., it ended up in solid space).

- If there is a list of portals that survived the front tree, then loop through each portal in the list and pass it down the back tree. The portal fragments returned (if any) from each fragment being passed down the back are all collected such that, we have a list of all fragments that survived both the front and back sub-trees at the current node.

5. When the portal clipper function has returned all surviving portal fragments for node[i] (the current node having a portal generated for it), any portal fragments that survived will contain the index of two leaves in which that fragment belongs. Each portal in the list is then added to the tree's main portal array since they are valid portals.

6. Finally we return to step one and do the same thing for each node that has two children. At the end of this loop we will have created all the portals that plug the gaps in the entire level between leaves and our portal generation process will be complete. We will now have the means with which to calculate the PVS.

The above list of steps provided only a high level view of what has to be done, but do not worry, since we will not leave it at that. Next we will step through some examples of the portal generation process with diagrams to clarify the process. We will follow a portal as it makes its way through the portal clipping process and see exactly why the rules we have set out above generate the correct results. Before getting deep into the processes involved, let us have a look what the top level portal generation process might look like with some placeholder code. The function that we have called ProcessPortals in this next example is passed a CBSPLeafTree pointer to a compiled tree that contains the level data we wish to generate portals for. A PVS compiler tool would issue a call to this function after the leaf tree has been compiled.

In the following code CPortal is a specialized polygon class that has the following members, in addition to an array of vertices and a face normal.

```
CPortal        *NextPortal;
unsigned char   LeafCount;
unsigned long   OwnerNode;
unsigned long   LeafOwner[2];
```

Next Portal
This is a mechanism which allows us to stitch multiple CPortal structures together in a linked list during the recursive clipping process.

LeafCount
This will contain the number of leaves the portal was found to exist in. For a valid portal, this will be exactly 2. Any portal that does not end up in two leaves will be removed.

OwnerNode
This contains the index of the node that was used to create this portal. We will see why this is necessary during the clipping process. What is meant by OwnerNode is the node that the initial portal was created on prior to being clipped to the tree.

LeafOwner[2]
After the compile process, this will contain the indices of the two leaves whose gap is plugged by the portal.

> **Note:** It is assumed throughout the code snippets in this chapter that the nodes of the tree are also stored in a linear array along with the node planes and leaves. This is similar to how we implemented our BSP leaf tree compiler in the previous lab projects.

Let us now look at what a top level function in a portal processor might look like.

```
HRESULT ProcessPortals( CBSPLeafTree * pTree )
{
    HRESULT      ErrCode;
    CBounds      PortalBounds;
    CPortal    * InitialPortal = NULL;
    CBSPNode   * CurrentNode   = NULL;
    CBSPNode   * RootNode      = NULL;
    CPlane     * NodePlane     = NULL;
    CPortal    * PortalList    = NULL;

        // Store required values ready for use.
        RootNode = m_pTree->GetNode(0);
```

As can be seen above, the first thing we do is get a pointer to the root node of the tree, which will always be stored in element zero of the tree's node array.

In the next section we see the start of the main loop that will iterate through all the nodes in the tree's node array and generate initial portals on the node planes that have both front and back children. Inside the loop you can see that we use the loop index to fetch the current node being examined and then use the node's plane index to fetch the node plane itself. If the current node does not have a back child (or leaf) then it means that this node cannot possibly be a portal generator because it does not have leaves in both its halfspaces. You will recall from the previous lesson's workbook that a back node that has solid space behind it is assigned the value BSP_SOLID_LEAF, which is defined as the smallest negative floating point number we can assign.

> **Note:** BSP_SOLID_LEAF is defined as hex value 0x80000000. We make this the smallest possible negative number so that it does not conflict with other negative numbers we store in a node's back child index. Remember, this represents the index for a leaf in the tree's leaf array that exists behind that node.

```
        // Create a portal for each node
        for (unsigned long i = 0; i < pTree->GetNodeCount(); i++)
        {
            // Store required values ready for use.
            CurrentNode = m_pTree->GetNode(i);
            NodePlane   = m_pTree->GetPlane(CurrentNode->Plane);

            // Skip any that have solid space behind them
            if ( CurrentNode->Back == BSP_SOLID_LEAF ) continue;
```

In the next section we are now going to create a new portal on the current node plane that is large enough to fill (on that plane) the bounding box of the root node (the entire scene). As you can see in the following code, we fetch the bounding box of the root node and pass it (along with the node plane) into the portal's GenerateFromPlane method, which we will discuss in a moment. This will build the vertices for the portal such that the initial portal is a single polygon that fills the entire root node.

```
            // Allocate a new initial portal for clipping
            InitialPortal = new CPortal;

            // Should we build a full portal or not
            PortalBounds = RootNode->Bounds;

            // Generate the portal polygon for the current node
            InitialPortal->GenerateFromPlane( *NodePlane, PortalBounds );
            InitialPortal->OwnerNode = i;
```

When the function returns, the portal will be ready for clipping to the tree. Before we do that however, the portal is assigned the index of the node whose plane was used to create it. We will see later that this will be useful information to have during the clipping process.

At this point we are ready to send the portal into the tree at the root node. In this code we pass the initial portal and the root node index (node 0) into the ClipPortal method.

```
            // Clip the portal and obtain a list of all fragments
            PortalList = ClipPortal(0, InitialPortal );
```

This method is assumed to clip the initial portal to the entire tree and return a list of portal fragments that survived the process and ended up in two leaves (PortalList). At this point we can set the InitialPortal local pointer to NULL as we have another pointer to the list of fragments. We can now add these fragments to the master list of portals being compiled. In this example we do this using the AddPortals function. This function is assumed to take a linked list of portals and add each one to the master portal list.

```
            // Clear the initial portal value, we no longer own this
            InitialPortal = NULL;

            // Add any valid fragments to the final portal list
            if (PortalList)
            {
                AddPortals( PortalList );
```

```
            } // End If PortalList

          } // Next Node
    return BC_OK;
}
```

And that is essentially the top level process. As you can see, this is done for every node that has more than one child. By the time this function returns, a master list of portals will have been compiled and is ready for the PVS calculator to use.

Admittedly the above code snippet still leaves a number of important questions unanswered -- how do we create the initial portal on the plane to begin with? How do we perform that complex procedure of clipping portals to the tree? These topics will be explained in the next two sections.

17.5.3 Creating the Initial Portal

As we saw in the code in the previous section, if a node has both a front and a back child it has the potential to be a portal generator. When this is the case, we must create a huge initial portal on the node plane and then clip it to the tree. In the previous code this was assumed to take place in a function called CPortal::GeneratePortalFromPlane, so we will carry that example over into this section. The function took two parameters -- the plane on which to construct the portal and the bounding box describing the area that the portal must completely fill. The polygon generated may be larger than the box, but the function will always generate a polygon that at least fills it along that plane. The root node's bounding box was passed as this parameter, which means we always create an initial portal at a node that is large enough to span the entire level. This is important since the plane may have split geometry into two leaves right on the outer edges of the geometry set. If the portal is not big enough to begin with, it will never make it into the two leaves it is supposed to. This would mean that we would risk not generating enough portals and would lead to the calculation of incorrect PVS data.

So given a bounding volume and a plane, how do we create a polygon on that plane that is large enough to at least fill the volume? We first retrieve the center position of the box and classify it against the plane. The box center is shown as 'CB' in Figure 17.11. By classifying this point against the plane, we get the distance to that plane from CB along the plane normal. We can then add the negated plane normal multiplied by this distance to CB, thus moving CB along the normal until it rests on the plane. This is the projection of the box center onto the plane and is shown as CP in Figure 17.11. This will be the center of our portal. Out next task is to generate two tangent vectors for the plane which we can use to position the portal vertices on the plane. Because we have the plane normal, we can cross this with any vector that is not identical to generate vector U in the diagram. We can think of this as the right

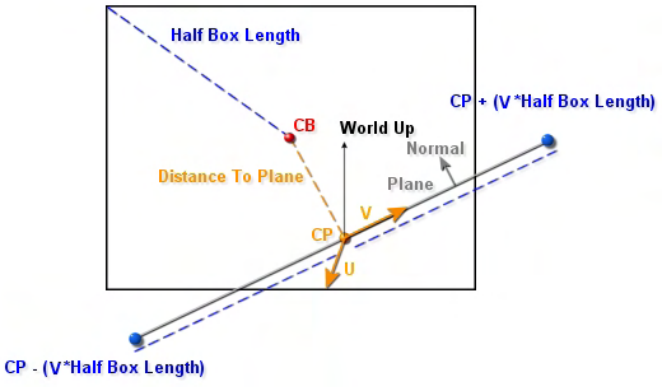

Figure 17.11

vector of the portal. In Figure 17.11 we can see that the normal was crossed with the world Y axis vector to generate vector U, which is perpendicular to both. We can then cross vector U with the plane normal vector to generate the second tangent vector (the V vector). These two vectors will be unit length at this point, but will describe the direction we would need to traversal from the portal center to reach the right and top edges of the portal quad we wish to build.

All we need to do now is find out how big we wish to make these vectors so that the top and right edges are defined as being as far (or further) than the box extents. This step is quite easy as we can simply use half the diagonal length vector of the box, shown in Figure 17.11 as the blue dashed line extended from the box center to one of the box corner. The half diagonal box vector describes the furthest you can possibly travel from the center point before piercing the extents of the box. If we multiply our U and V vectors by this amount we will describe the right and top edges of the portal as being at least far enough away such that they extend outside the box (the typical case) or on the box boundary. Either way, these vectors can now be combined and used to describe the position of the four corner vertices of the portal quad. As Figure 17.12 shows, because the U and V vectors are tangent vectors, they describe the top and right edges of the vertices on the plane. Therefore, we can combine them to find the positions of the four portal vertices.

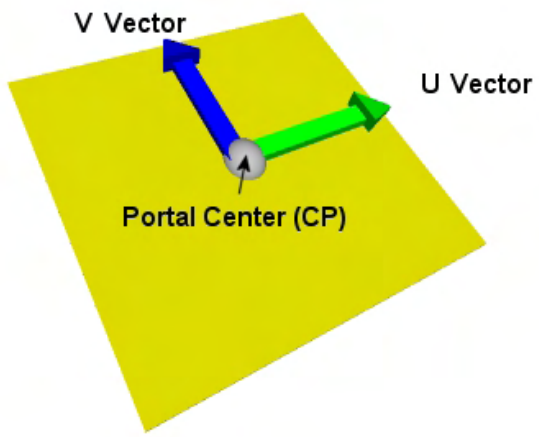

Figure 17.12

As CP is the center point of the polygon on the plane and U and V describe the half width and half height of the portal and are also tangent to the plane, we can generate the four vertex positions of the portal quad as shown below:

Bottom Right = CP + U - V;
Top Right = CP + U + V;
Top Left = CP - U + V;
Bottom Left = CP - U - V;

With this in mind, we now have everything we need to write a function that generates the initial portal. The first section is shown below. We calculate the center of the bounding box (CB) and then calculate the distance from this point to the plane. We then move CB along the plane normal by the negative of this distance to place the point on the plane. We store this in CP (short for Center of Portal).

```
bool CPolygon::GenerateFromPlane( const CPlane3& Plane, const CBounds& Bounds )
{
      CVector3 CB, CP, U, V, A;

      // Calculate BBOX Centre Point
      CB = (Bounds.Max + Bounds.Min) / 2;

      // Calculate the Distance from the centre of the bounding box to the plane
      float DistanceToPlane = DotProduct( Plane.Normal, CB) + Plane.Distance;
```

```
      // Calculate Centre of Plane
      CP = CB + (Plane.Normal * -DistanceToPlane );
```

Now that we have the portal center we need to create the U and V vectors. We first generate U by crossing the plane normal with an arbitrary vector which is non-identical. We choose this arbitrary vector from one of the world axes. Essentially, we choose a normal vector (A) which is least aligned with the normal of the plane, so that we get a cross product with plenty of resolution. That is, vector A will either be (1,0,0), (0,1,0) or (0,0,1) and we want the one that is least like the plane normal, just to be safe. As we know, if the two vectors fed into the cross product are identical (with tolerance), the cross product result will be undefined and we will not get back a vector that is perpendicular to the two input vectors (thus tangent to the plane).

```
      // Calculate Major Axis Vector
      A = CVector3(0.0f,0.0f,0.0f);

      if( fabs(Plane.Normal.y) > fabs(Plane.Normal.z) )
      {
            if( fabs(Plane.Normal.z)  < fabs(Plane.Normal.x) )
                A.z = 1;
            else
                A.x = 1;
      }
      else
      {
            if (fabs(Plane.Normal.y) <= fabs(Plane.Normal.x) )
                A.y = 1;
            else
                A.x = 1;
      } // End if
```

With vector A chosen, we cross it with the normal vector for the plane to generate the first tangent vector U. We then cross V with the plane normal to generate the second tangent vector V. Now we can normalize these vectors to make sure they are at all unit length.

```
      // Generate U and V vectors
    U = A.Cross(Plane.Normal);
    V = U.Cross(Plane.Normal);
    U.Normalize(); V.Normalize();
```

Finally, we subtract the center position of the box from maximum extents vector of the passed bounding box which gives us the diagonal half length vector of the box. We then fetch the length of this vector and use it to scale the lengths of the two tangent vectors. We then allocate an array of four vertices which will be used to store the four vertex positions of the quad and use U and V to calculate their positions as described above.

```
      float Length = GetVectorLength(Bounds.Max - CB);

      // Scale the UV Vectors up by half the BBOX Length
      U *= Length; V *= Length;
```

```
      CVector3 P[4];
      P[0] = CP + U - V; // Bottom Right
      P[1] = CP + U + V; // Top Right
      P[2] = CP - U + V; // Top Left
      P[3] = CP - U - V; // Bottom Left
```

We now have the four vertex positions, so we will increase the vertex array of the current portal being generated (remember that this function is assumed to be a method of the portal class in this example) and then copy the four vertex positions we have just calculated into those vertices.

```
    // Allocate new vertices
    if (AddVertices( 4 ) < 0) return false;

      // Place vertices in poly
      for ( int i = 0; i < 4; i++)
    {
        Vertices[i] = CVertex(P[i]);

    } // Next vertex

    // Success!
    return true;
}
```

So we have now seen the function that generates the initial portal for each node that has two children during the portal generation process. Once the initial portal has been generated for the current node being processed for portal candidacy, this initial portal is then sent into the ClipPortal function. This is the function that clips the portal to the tree and returns a list of surviving fragments which can be added to the master portal list.

17.5.4 Clipping the Initial Portal to the Tree

In this section we will spend a good amount of time covering the portal clipping process as this is where all of the hard work is done. Although it is essentially a CSG routine that clips a portal to a solid/empty tree, there are a lot of things to consider in all of the classification cases at each node.

Before we even begin to look at the code to such a function, we will look at some images that show the portal clipping process a step at a time. This will allow us to more easily digest all of the rules we discussed earlier for classifying the portal against each node in the tree.

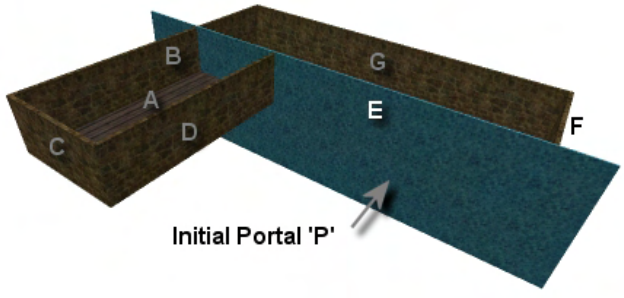

Figure 17.13

In this section we will use the geometry (and tree) that we showed being built in an earlier section (see Figure 17.9). When we examined the tree we saw that only node E had both front and back children and therefore, was the only node that could possibly generate a portal for our two leaf

level. This means that we would need to generate an initial portal on that plane that was large enough to span all the geometry. This initial portal (created by the function discussed in the previous section) is shown as the blue slab in Figure 17.13. In this image we have labeled the polygons themselves with the labels of the nodes that were created from those polygons.

We will now feed this initial portal ‘P’ into our BSP tree and do a dry run through the process that our ClipPortal function will need to perform on it. At the end of this section, you should have a much better understanding of why the portal traversal logic we discussed earlier works and generates correctly sized portals.

The large initial portal ‘P’ is passed into the root node and is classified against node plane A. This plane is shown in Figure 17.14 and is the floor plane of our level. The initial portal on plane E is spanning this plane so it is split into two child portals. The original portal is discarded and replaced with the two child portal fragments P1 and P2. P2 lies behind the plane, so is supposed to be passed down into the back child of node A. But as you can see, because there is no back child, it means that P2 must have ended up in solid space and thus we delete it. This makes sense since we can see in the image that portal P2 is clearly underneath the floor plane and thus would be situated in solid space.

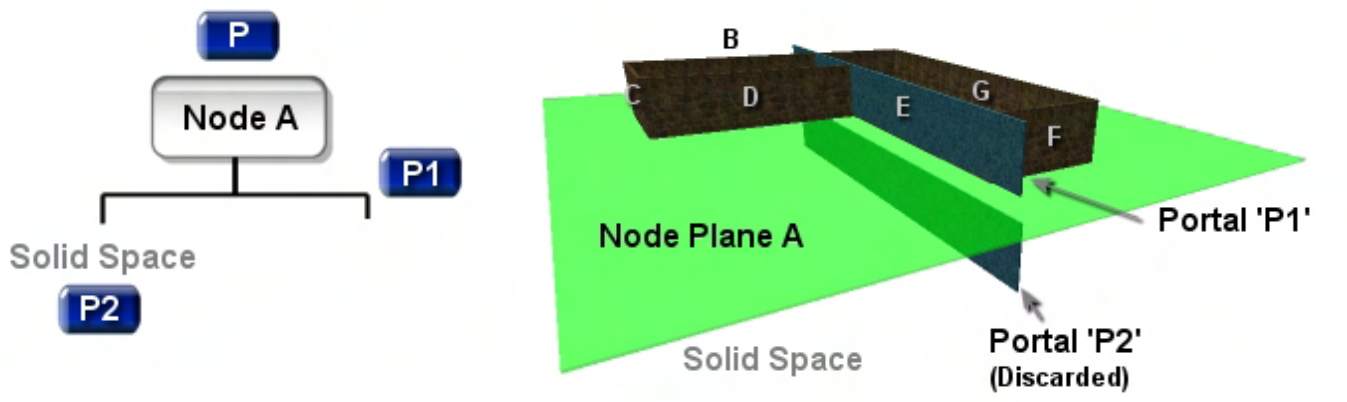

Figure 17.14

We have just performed our first split and the back split has been discarded. This is because we needed to pass it into the back child, but no back child exists. Again, we know that in a solid/empty tree this means it represents a solid area.

Our next task is to send the portal fragment P1 into the front child of node A because this portal fragment was the section that exists in the node’s frontspace. You are once again reminded that in all of these diagrams, the plane normals are assumed to face into the leaf. Therefore, in the case of the floor plane A, the normal is assumed to be pointing vertically up so that ‘in front’ equates to ‘above’, and ‘behind’ equates to ‘below’.

Node A does have a front child (node B) as shown in Figure 17.15. When portal P1 enters node B, it is found to be spanning the plane and is once again split into two child portals. The original portal P1 is deleted and is replaced with the two child split portals labeled P3 and P4 in Figure 17.15.

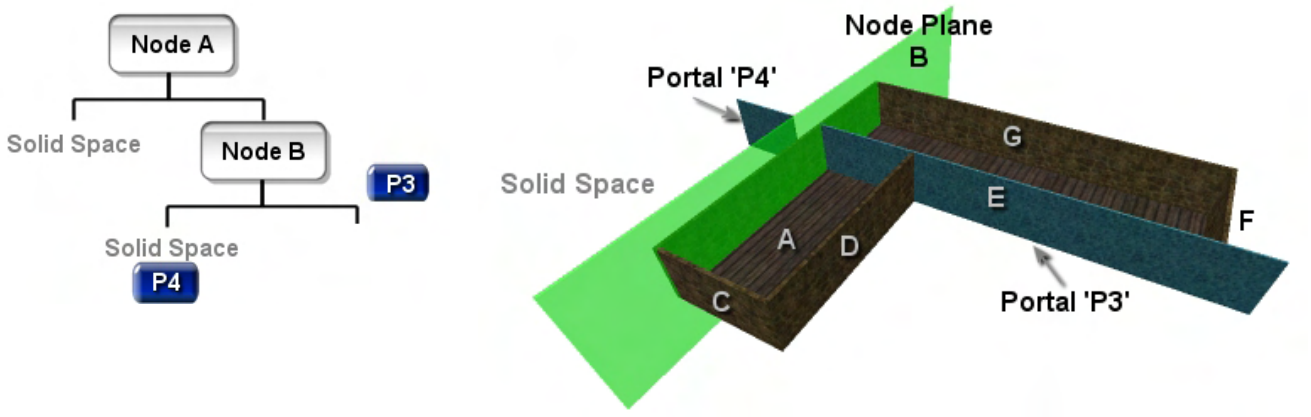

Figure 17.15

In Figure 17.15 we can see the section of the original portal (P1) that was split by node plane B into portal P4. Portal P4 is behind node B and as such would normally be sent into the back child. But since node B has no back child, it means portal P4 has ended up in solid space and should be deleted. Portal P3 however is contained in the frontspace of node B and as such should be passed into the front child. The front child of node B is node C. Therefore, portal fragment P3 becomes the input to node C.

When P3 is passed into node C is it found to exist in the frontspace of node C, as can be seen in Figure 17.16. This means it is passed into the front child of node C.

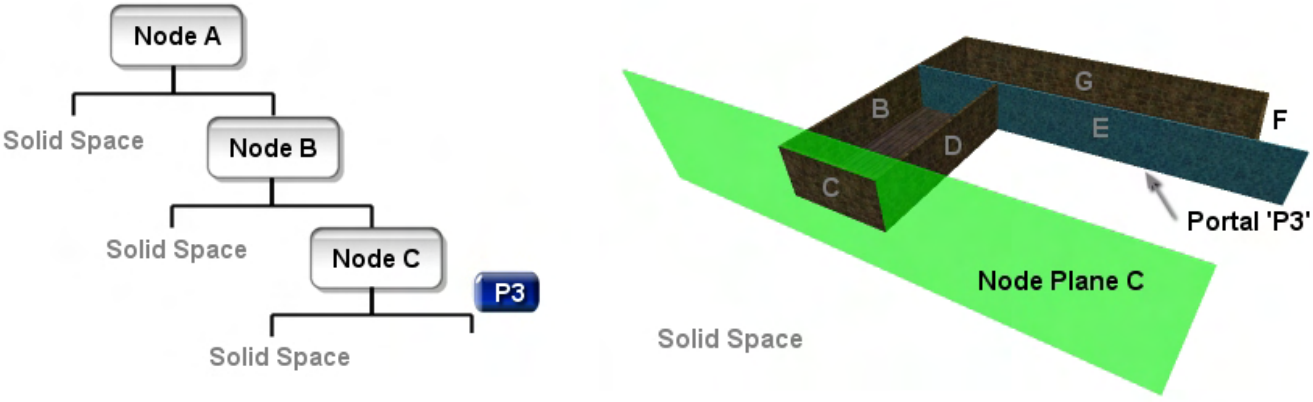

Figure 17.16

When we built this tree earlier you will hopefully recall that node E was selected next (instead of node D). Therefore, portal P3 becomes the input for node E and, since this portal was initially created on node E, it will obviously be found to be on plane.

As we discussed earlier, when the portal is found to lie on the node plane, we send the portal down into the front child first. If any fragments of the portal survive the front tree, they will be returned and passed down into the back child separately. Figure 17.17 shows the portal being classified against node E and it should be clear that the portal is located on the plane. This means that we must send portal P3 down E's front list first.

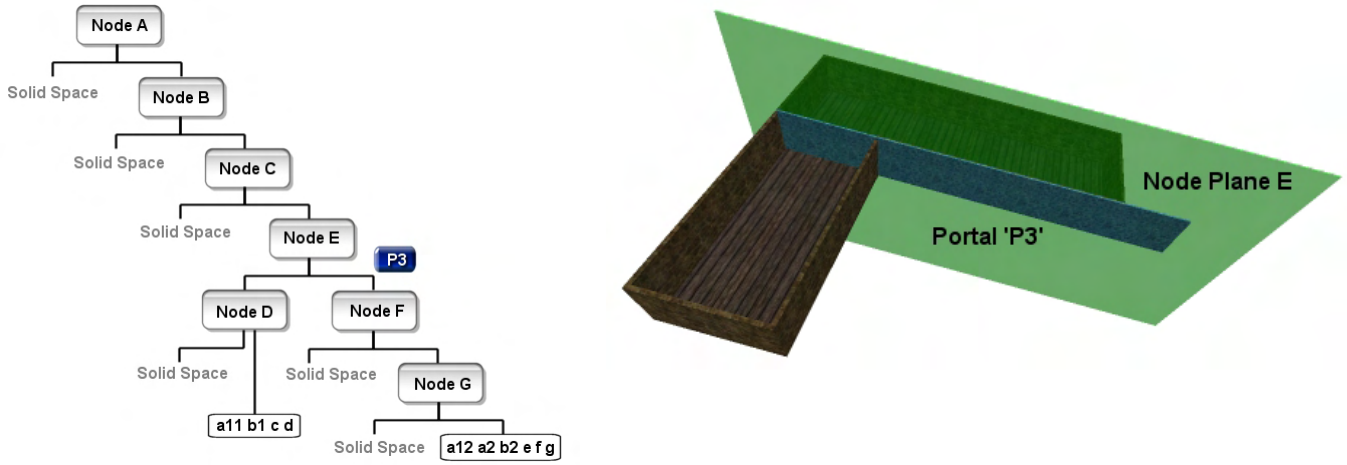

Figure 17.17

Let us now track portal P3 as it makes its way down the front sub-tree of node E. The normal at node plane of E is assumed to point into the top region of the geometry and thus is facing away from us in this image. This means that as we pass P3 down into the front child of node E, it enters node F. In Figure 17.18 we will show its path down the remaining branch of the node E's front tree.

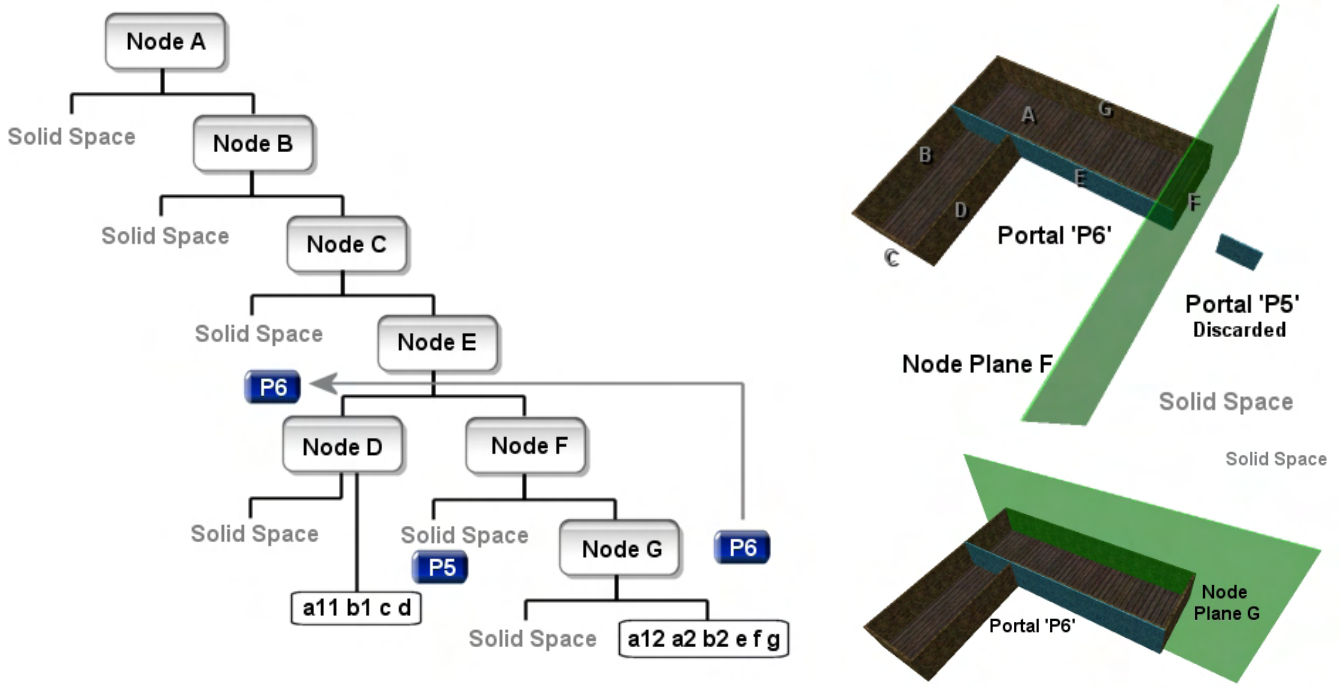

Figure 17.18

As we can see in the diagram, as P3 enters node F it is classified against the plane. It is found to be spanning plane F and is therefore split. The original portal P3 is deleted and replaced with the two child splits P5 and P6. P5 is situated in node F's backspace and enters solid space behind that node. This means portal P5 is deleted. Portal P6 is in node F's frontspace so is passed into the front child where it enters node G. Portal P6 is found to lay in the frontspace of node G as well, so it is passed down the

front child where it enters a leaf. The index of the leaf it has entered is retrieved from the tree (more on this later) and stored in the portal. Portal P6 is then returned back up through all the parent nodes until it is finally returned back to the on plane case at node E.

You will recall that because the portal was on plane with node E, it had to be sent down the front tree first and then any surviving fragments will be sent down the back tree. Portal P6 is the only surviving fragment from node E's front tree and has the index of the leaf it ended up in stored within its structure. Node E, having been returned portal P6 from its front list, must now send this portal down its back tree.

When we pass the portal P6 into the back child of node E, it enters node D. As can be seen in Figure 17.19, the portal P6 is found to be spanning node D and so it is split to the node plane. P6 is deleted to be replaced by the two split fragments P7 and P8. What is vitally important to note is that when this portal is split, the two child portals inherit the parent portal's leaf list. This means, if the leaf that portal P6 ended up in down the front tree of node E was leaf 64, both portals P7 and P8 would also have a leaf index of 64 stored in them also. This makes sense as these fragments were part of the parent portal when they landed in this leaf so they too exist in the leaf the parent did.

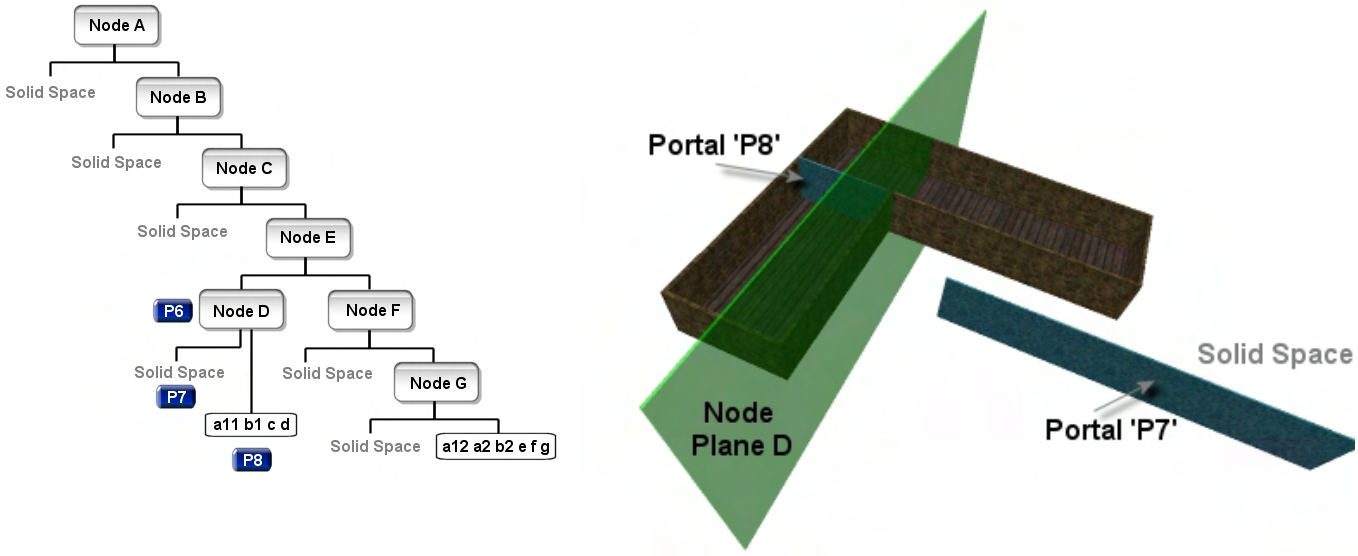

Figure 17.19

Portal P7 is found to lie behind node D and as such we identify it as existing in solid space. Portal P8 is found to lie in front of node D and is passed into the front child. However, node D is a terminal node which means anything that is passed down the front of it enters a leaf. The index of the leaf that portal P8 enters is added to its leaf list so that portal P8 now stores the indices of both the leaves it ended up in. Portal P8 is the only surviving fragment of the initial portal P that was fed into the root node. This portal is propagated up to the root node as the stack unwinds and is returned from the ClipPortal function to the parent process. The parent process is the ProcessPortals function we saw earlier which created the initial portal P on node E and sent it into the tree to be clipped. Portal P8 is returned from the ClipPortal function where it is added to the master portal list as a valid portal. Figure 17.20 shows the final shape of portal P8 and the two leaves it was found to exist in. As you can see, this portal exactly plugs up the gap in the geometry between leaf 1 and 2 and is therefore, the portal that leads from leaf 1 *into* leaf 2 and vice versa.

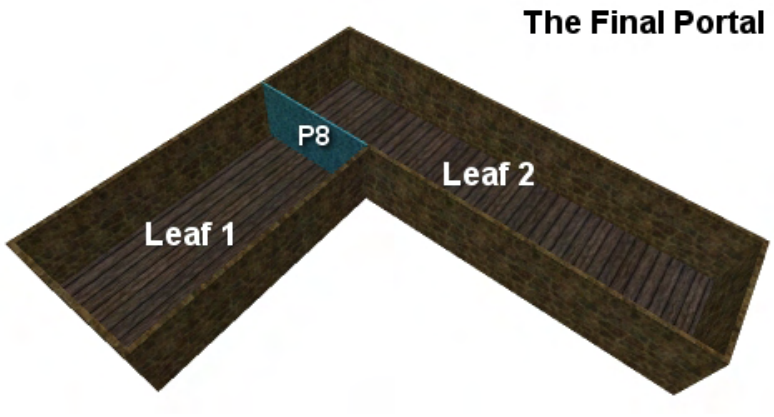

Figure 17.20

As we have now discovered, it is the solid/empty arrangement of geometry that makes this portal generation possible, as was the case with meshes used in CSG operations. If the geometry fed into the BSP compiler is not defined such that solid space is always bounded, we will no longer be able to tell which areas are solid and which are empty. This will obviously produce incorrect portals since the solid space tells us when a portal fragment needs to be discarded.

The above example that generated a portal on node E was a somewhat simple case in as much as it returned only a single portal. As we discussed earlier when reviewing the portal clipping process, a single initial portal may be clipped into many smaller valid portals and a linked list of these portal fragments may be returned from the clipper. Although this may sound a bit strange, it is actually quite obvious that this is the case when we consider that a node plane splits all the geometry in its space. Think of the root node as a perfect example. If the root node passed through the center of the scene for example, many rooms, passageways, etc. would by split into two pieces by this plane and thus, portals would be developed on those planes to bridge the split.

In the next example we will use slightly more complex geometry and a node plane that will create two portals. We will not build or show the BSP tree that has been compiled as it is not really necessary to get the idea of what we are trying to demonstrate.

Figure 17.21 shows a level comprised of two detached mesh constructs which we will now use to demonstrate a situation where a single initial portal can be clipped to the tree resulting in two valid portals being returned from the process.

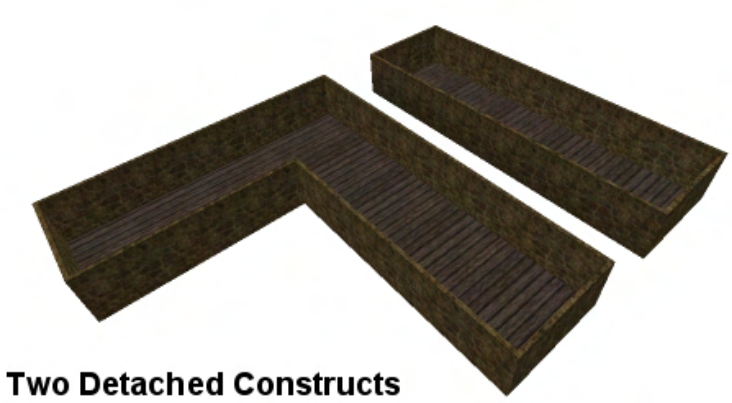

Figure 17.21

In Figure 17.22 we see the level again with the walls labeled alphabetically, describing the order in which the planes were placed in the tree. The initial portal we will create will be on node D which, in

this example, was responsible for splitting the two mesh constructs into two leaves when the BSP tree was compiled.

It should be noted that I and B are co-planar so would both be marked as having been used as a splitter when B is selected as the second node. Likewise, polygons F and K would only create one node (F) as they too are co-planar. The ProcessPortals function that we looked at earlier is assumed to have looped through each node in the tree and determined that node D was a node that had both front and back children and therefore, an initial portal would be created on that plane and clipped to the tree. It is this clipping, and the generation of the portals on that plane which we will walk through now.

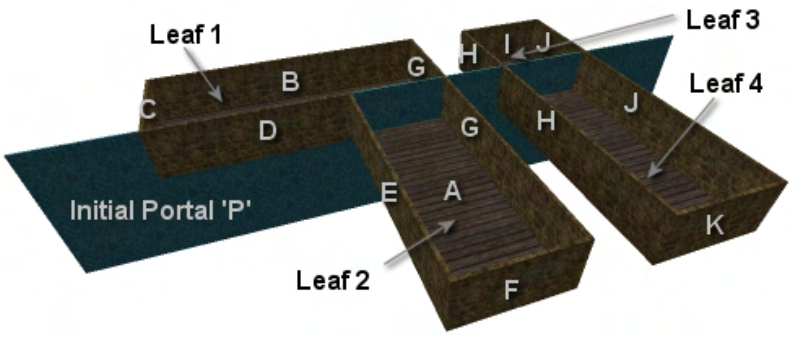

Figure 17.22

In Figure 17.22 we see the initial portal created on node plane D, which we have labeled portal P. Notice that it spans the entire geometry set of the level along that plane as all initial portals should do.

Portal P is first passed into the tree where it is classified against the plane of node A (Figure 17.23). In this example, node A is the floor plane and portal P is clearly spanning that plane, so it is split into portals P1 and P2. Portal P2 is sent down the back of A where it ends up in solid space and portal P1 is passed down the front tree where it enters the second node in the tree, node B.

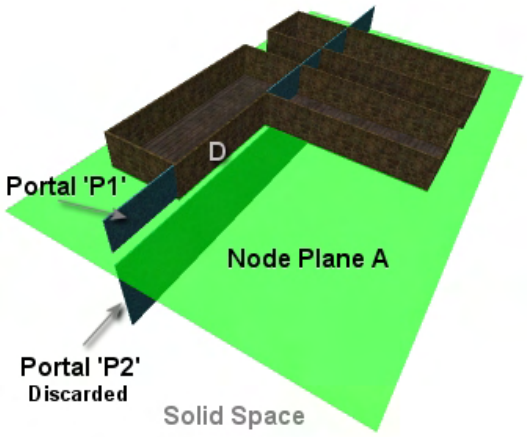

Figure 17.23

Figure 17.24 shows what happens when the surviving fragment portal P1 is passed into the front child of node A, which is node B. This is the plane of the polygons on the far walls of the construct and we can clearly see that portal P1 is in front of the node plane. This means portal P1 is passed into the front child of node B which, in this example, will be node C. Node C's plane is shown in figure 17.25.

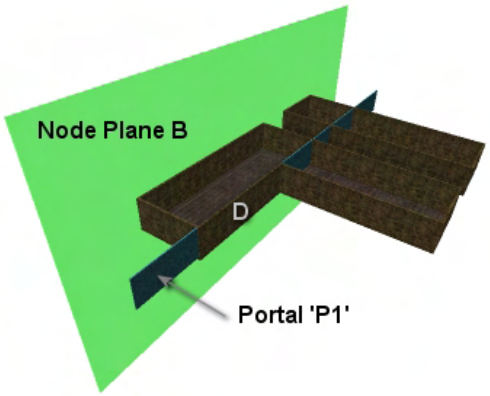

Figure 17.24

When portal P1 enters node C it is classified again the plane at that node. As we can see in Figure 17.25, it is found to be spanning the plane and is therefore split into two child portals (P2 and P3) and deleted from memory.

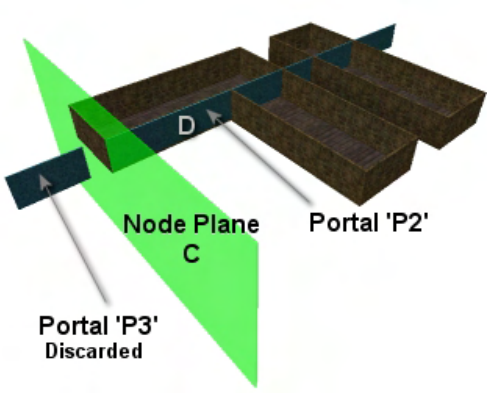

Figure 17.25

P3 is in the plane's backspace and is therefore passed down the back of node C where it is identified as being in solid space. Because of this, portal P3 is deleted as it could not possibly be a valid portal. Portal P2 however is contained in node C's frontspace and is passed down the front list of C where it arrives at node D. This is where things begin to get interesting, because node D is the node on which the initial portal was created. In this case, the portal is obviously going to be found to be co-planar.

As we know, when a portal is found to be situated on the current node plane, we must first send the portal down the front tree of the node. If any portal fragments survive the front tree they are each individually sent down the back tree.

Looking at Figure 17.26 we can see that node plane D was also the node that was responsible during the compilation process for dividing the one non-convex construct and the convex construct into four convex constructs. Remembering that the normals all face inwards, we can see in the diagram that the front child of D would be node G (a split plane which actually exists down both sides of D). Therefore when the portal P2 is passed down the front of D, it arrives at node G.

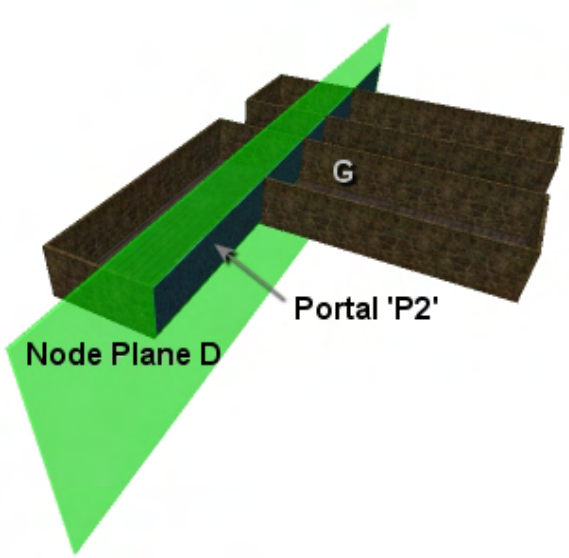

Figure 17.26

Notice where wall G is in the above diagram, because for the next image we will rotate the camera to a different view point so that we can see the portal clipping that is happening on the far side of the level. Also remember that when we are processing the planes down the front of D, any portal fragments that survive down that branch of the tree will be returned to node D and each will be passed down the back tree as well.

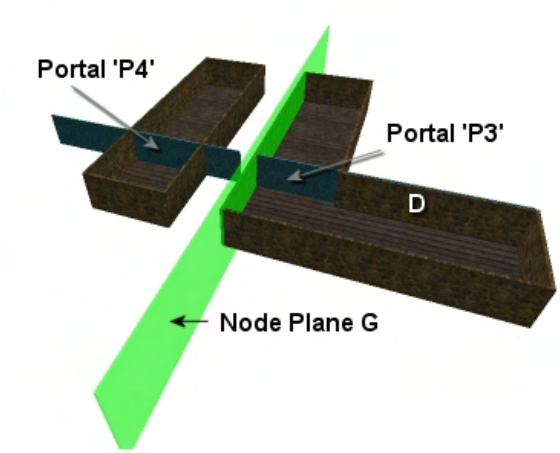

Figure 17.27

In Figure 17.27 you can see that down the front of node D the portal is then tested against node plane G where it is found to be spanning. Portal P2 is deleted and replaced by the front and back child splits P3 and P4, respectively.

P3 is in node G's front halfspace, so is passed into the front of the node where it ends up in a leaf. We can see this is the case as it ends up in the region bounding by all the planes we have already tested surrounding this area. The index of the leaf it has ended up in is recorded in portal P3 (which has so far ended up in one leaf).

Portal P4 is found to be located in node G's backspace, so is passed down the back where it is tested against node H. Portal P4 is found to be spanning node H, so is split into portal fragments P5 and P6 as shown in figure 17.28.

At this point we now have three portal fragments in existence. However, portal P5 is found to lay behind node H, which means it is in solid space. This describes it as existing in the space between the two constructs as shown in Figure 17.28. Because of this, portal fragment P5 is deleted.

Portal fragment P6 however is found to exist in the frontspace of node H and as such is passed into the front child where it moves into node J, as shown in figure 17.29.

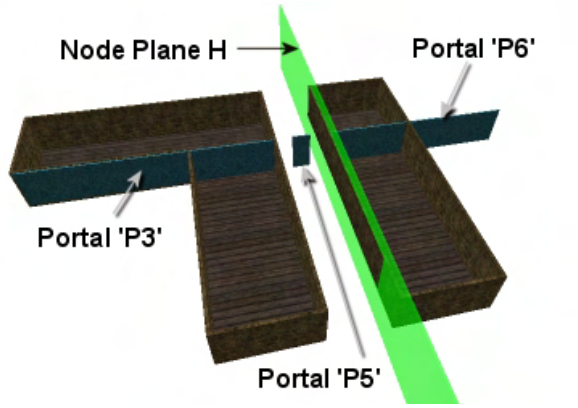

Figure 17.28

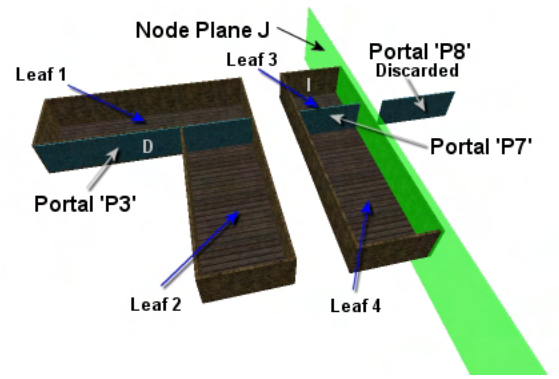

Figure 17.29

At node J, the portal P6 is spanning the plane and is split into portals P7 and P8. Portal P8 is in the back space of this node and is deleted because it ends up in solid space. Portal P7 is passed down the front, but as this is a terminal node, we know that this means it has entered a leaf (Leaf 3 in this example). The index of the leaf is stored in portal P7 and we have reached the end of the road down this branch of the tree.

Portal P7 is returned and the stack unwinds back up to plane G where the portal was originally split (see Figure 17.30).

Figure 17.30 depicts the situation after we have returned to node D, where the original portal was split and sent down the front and back branches of the tree. As discussed a little earlier, the front split was sent down the front where it ended up in Leaf 1 and the back split was send down the back where it got clipped a few more times before the fragment P7 eventually ended up in Leaf 3. This means that at node G, portal P3 would have been returned from the front tree and portal P7 would have been returned from the back tree. As discussed earlier, in the spanning case, the returned fragments from both of the nodes are joined together in a linked list and returned to the parent node. So when node G returns flow back to its parent node D, it returns two portal fragments from node D's front list.

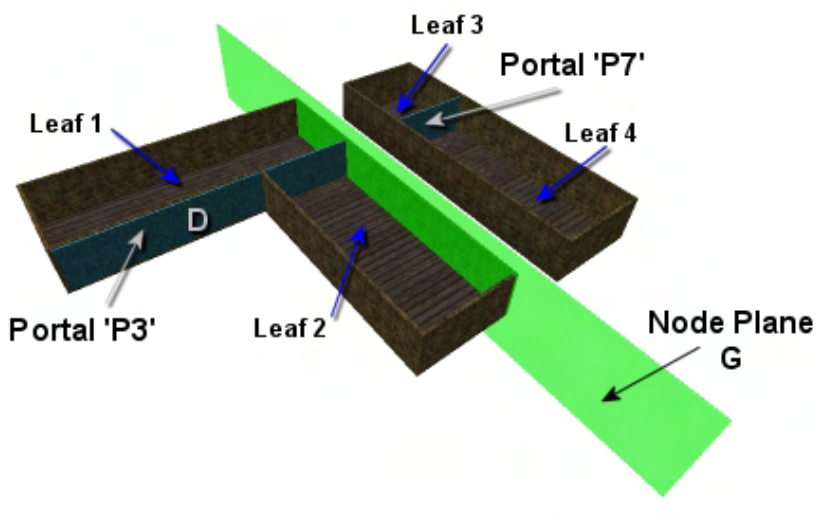

Figure 17.30

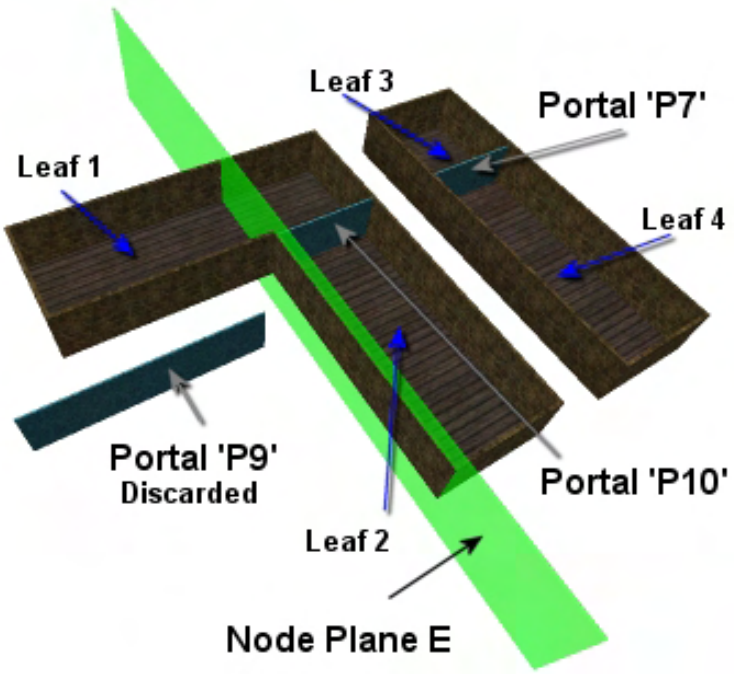

Figure 17.31

Node D was the plane on which the initial portal was created and therefore this was the plane on which the portal was found to be 'on plane'. We know that in the on plane case, the portal is first clipped to the front tree and any returned fragments sent down the back tree. We have now processed the front tree of node D and we have gotten back portals P3 and P7 which have been found to exist in leaves 1 and 3, respectively.

When portals P3 and P7 are returned to node D from its front list, each of these must now be clipped to the back tree as well. Although this is done one at a time in code we will show this happening simultaneously in the diagrams.

As Figure 17.31 shows, when P3 and P7 are passed down the back of node D they enter node E where they are classified against its plane. Portal P7 is completely contained in node E's frontspace, so is sent down the front tree as we would expect. Portal P3 however is found to be spanning node E so is split at the plane. Portal P3 is deleted and replaced by the child portals P9 and P10. Portal fragment P9 is passed down the back of E where it is found to exist in solid space and is therefore deleted. Portal P10 is

contained into the frontspace of node E and, like portal P7, is sent into the front tree. This means both portals P7 and P9 enter node F, as shown in Figure 17.32.

When portals P9 and P7 enter node F they are classified against the node plane and found to both be in front of that plane. Notice in the diagram how we also draw attention to the fact that this node plane is the plane that both polygons F and K lay on, and therefore a node would not have been created for both (K would have been marked as a splitter when node F was first selected). We can already see at this point that portals P9 and P7 are the final portal shapes we are looking for, but let us continue the process a little further just to make sure they both end up in two leaves down the back of D. Fragments P9 and P7 are both passed down the front of node F where they enter node G (see Figure 17.33).

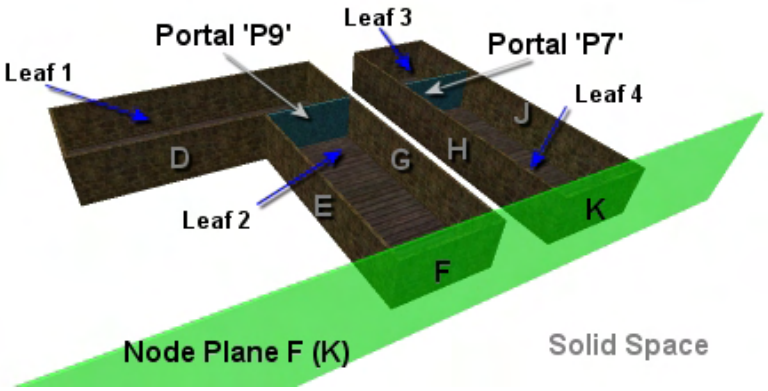

Figure 17.32

Notice that we are using some artistic license here when we refer to this node as node G. We already processed a node G down the front tree of plane D, and this is obviously not the same node. However, because polygon G would have been split during the build process by node plane D which was selected before it, its child splits of polygon G would have been passed down their relevant sides of the tree and used as splitters later. This means the split plane that we are referring to as G would in fact have been chosen as a node plane both in the front and back trees of node D.

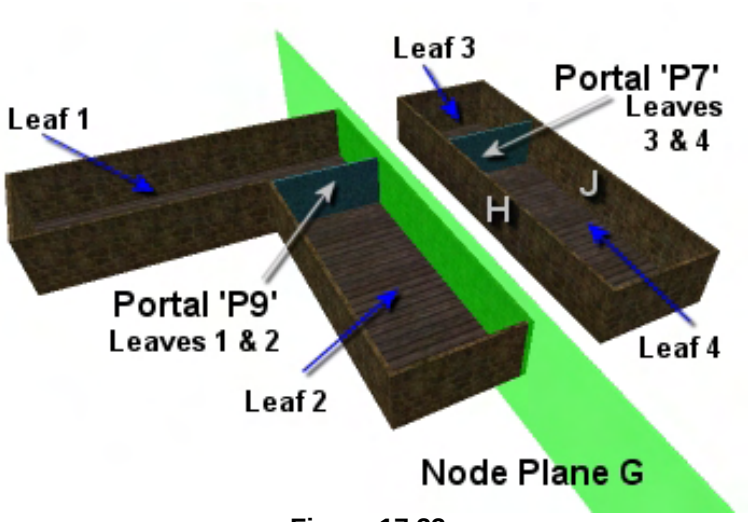

Figure 17.33

At node G, portal P9 is found to exist in the frontspace, so is passed into the front tree. However, Leaf 2 is attached to the front of node G and therefore portal fragment P9 has just entered its second leaf, indicating that it is a valid portal. The index of portal P2 is also added to the portals leaf owner array so that on function return this two element array will contain the two leaf indices in which the portal resides. This portal now exists in leaves 1 and 2 as can be seen in Figure 17.33. We will quickly describe the remaining path for portal P7, which is also nearly over.

Portal P7 is found to be in the backspace of G, which means it would be passed into the back tree where it would enter node H. When classified against node H it would be found to be in that node's front space and would be passed into its front tree where it enters the final node down that branch of the tree, node J.

When classified against node J it is found to exist in its front space and should be passed down the front, where it enters Leaf 4. This is also the second leaf that this portal has entered, and thus it is a valid portal. The index of the leaf is also added to the portal's leaf array which will then contain the leaf indices 3 and 4 in this example. At this point, the stack unwinds all the way back up to node D where it has had returned portals P7 and P9 from its back tree. These are stitched together into a linked list and returned from the node and the stack will unwind all the way back up to the root. These two portal fragments are exactly what will be returned from the ClipPortal method for the initial portal created on node D. They are ultimately the two portals that would be added to the master portal list, ready to be used by the PVS calculator.

Recursive Portal Splitting

As you might imagine, the portal clipping process utilizes a highly recursive algorithm. Although the code to the ClipPortal function in the lab project might look a little intimidating, much of this is the linked list management that must happen in the split case. Figure 17.25 shows an example of a split case and how the lists are maintained.

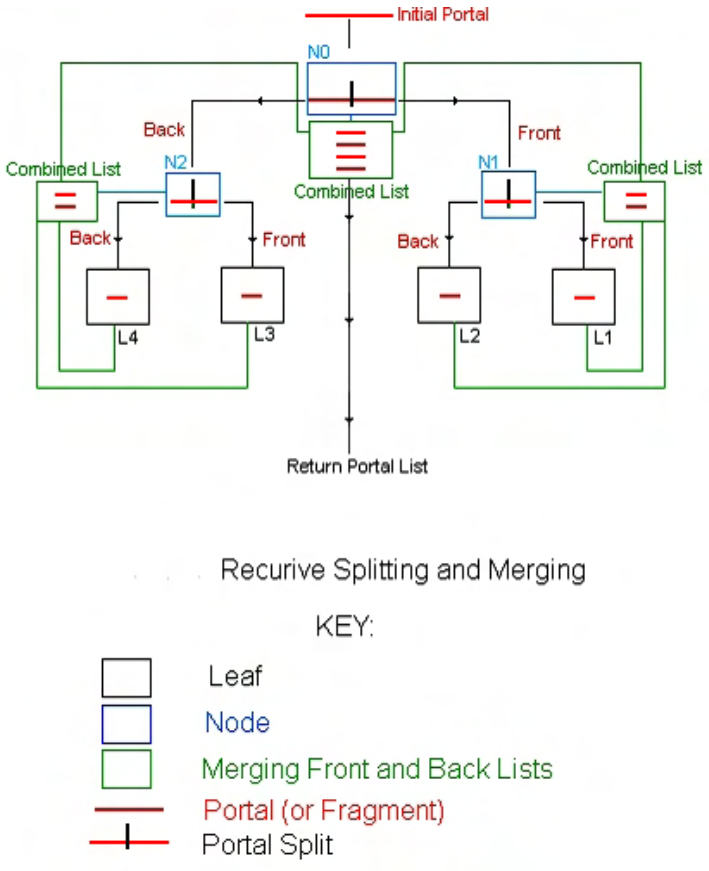

Figure 17.34

In this example, the initial portal is fed into the root node (N0) and is found to be spanning. It is split into two and the front fragment sent down the front into node (N1). At N1 this fragment is also found to be spanning so is split into two further fragments and sent down the front and back of N1 where it enters two leaf nodes (for the sake of this demonstration we are assuming back leaves as well). The portal fragments that made it into leaves L1 and L2 are returned to N1 from the front and back trees, respectively. They are then stitched together into a linked list at that node so that the two portal fragments can be returned to the parent node, N0. We can now see that node N0 has had a linked list of two portals returned from its front tree. However, we are still to process the back fragment that was split at node N0. This fragment is sent down the back tree where it enters node N2 and is further split. These two splits end up in leaves L3 and L4 down the front and back of this node. That is, N2 will have portal fragments returned from both its front and back trees, which are then stitched together and returned to the root node. At the root node N0 we can now see that it has two portals returned from its front tree and another two returned from its back tree, making four valid portal

fragments in total. These two lists are then stitched together into a single linked list of four fragments which is then returned from the function back to the calling process.

Leaf Classification

When a portal enters a leaf we will store the index of that leaf in the portal's two element leaf array. As we now know, if the portal is a valid portal then it will eventually have this array filled with the two leaf indices in which it was located. However, you will see later that we do not just need to know in which leaves the portal is contained; we also need to know which leaf is behind the portal and which leaf is in front of the portal (with respect to the portal's normal). This will be important later when we calculate the PVS so that we know the direction in which the visibility calculations should flow from one leaf to the next. The determination will be done during the clip portal process at the time the portal enters the leaf. That is, we will classify the leaf against the portal and if the leaf the portal has just landed in is in front of the portal (i.e., the portal's normal is facing into that leaf) we will store its index in element zero of the portal's leaf array. If the leaf is found to be behind the portal, then the leaf index is stored in element one of the portal's leaf array. To make this easier to remember, we will set three defines in our code which we can use as the indices when we wish to fetch the leaf indices at the portal.

```
#define FRONT_OWNER          0
#define BACK_OWNER           1
#define NO_OWNER             2
```

As you can see these defines just describe the location in the portal's leaf array where the indices of front and back leaves should be stored. The NO_OWNER define will be explained in a moment.

One might imagine that classifying the leaf against the portal could be done by simply taking the center of the leaf's bounding box and classifying this point against the portal. However, this will not suffice as it is entirely possible that the leaf will contain a single polygon. It is quite possible due to some split planes chosen further up the tree that a portal might be created where the floor meets the wall within a room. Figure 17.35 shows an example of this. As you can see, all of the room except for the left wall is part of leaf, 1 but due do an odd split somewhere up the tree, the left wall polygon has fallen into leaf 2. Therefore, the portal that bridges these two leaves will actually exist on the node plane and worse still, because leaf 2 contains a single polygon, it will have a zero volume bounding box. Finding the center of leaf 2's box would therefore give us a point that is on the plane of the portal and

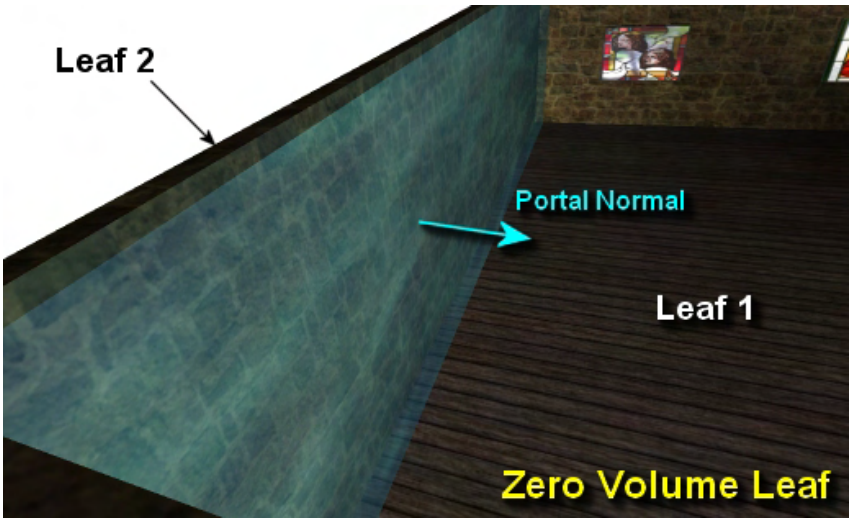

Figure 17.35

therefore we have no way of determining which side of the portal the leaf is on. Of course, the portal normal indicates that leaf 2 should exist behind the portal and leaf 1 in front.

In order to solve this problem and correctly identify on which side of a portal a leaf is located, when the portal enters that leaf, we will use a function called ClassifyLeaf to leverage the hierarchical nature of the BSP tree. Essentially it will locate which sub-tree of the node that was used to create the portal contains the leaf which the portal has just entered.

Some placeholder code for a ClassifyLeaf function is shown below. Is called from the portal clipper at the time a portal fragment enters a leaf. The function is passed the node on which the portal was created and the index of the leaf we are looking for (down either its front or back tree). We know that if this portal has ended up in a valid leaf, then it must be a portal that is either down the front or back tree of the node. After all, it is the node itself which split the geometry into two leaves and therefore, those leaves must exist below it in the tree. If the node is found down the owner node's front tree, then the function returns FRONT_OWNER which tells the portal clipper that the leaf is in front of the portal and should be stored in element 0 in the portal's leaf index array. If the leaf is found down the back tree, then it returns BACK_OWNER and the portal clipper function knows that it should store the leaf index in element 1 in the portal's leaf array.

> **Note:** In this version of the function it is assumed that if the front child index of a node is a negative number, then a leaf exists in front of the node and it is not just another internal node. The negative index has one added to it and is negated to get the index of the leaf in the leaf array that is stored there. This is in keeping with the way our data structures were arranged in the previous lab project when we first developed the leaf tree compiler.

The function is passed the index of the leaf the portal has ended up in and the index of the node (in the node array) that was used to create the portal. Now you know why we stored the index of the node that created the initial portal in the portal's OwnerNode member. When the portal lands in a leaf, we now have immediate access to this node and we can pass it into this function as the second parameter.

```
unsigned long ClassifyLeaf( unsigned long Leaf, unsigned long Node )
{
    CBSPNode * CurrentNode = NULL;

    // fetch the node pointer from the tree
    CurrentNode = pTree->GetNode( Node );
```

The function first uses the passed node index to fetch the node pointer from the tree's node array, as can be seen in the above code.

Our next task it to test to see if the node's front child index is negative. If it is, then the node has no front child node. Instead, the index stored in the node's Front member will be the negative index (minus 1) of the leaf that is attached to the front of that node. By taking the absolute value of the front index and adding one, we get the index of the leaf that is stored there. If this matches the leaf index that was passed into the function (i.e., the leaf we are trying to classify against the portal) then we have found it and we know the passed leaf is attached to the front of the node. In this case, we return FRONT_OWNER.

```
    // Check to see if the front is this leaf
    if ( CurrentNode->Front < 0 )
    {
        if ( abs(CurrentNode->Front + 1 == Leaf ) return FRONT_OWNER;
    }
```

If the front member of the node is not a negative number, then it stores the index of the front child node of the current node. This means we will need to recur down the front of the node and search for a matching leaf index down that branch of the tree. This is done via a function called FindLeaf, which we will cover in a moment.

```
    else
    {
        if (FindLeaf( Leaf, CurrentNode->Front )) return FRONT_OWNER;
    } // End If
```

As you can see in the above code, we pass this function the index of the leaf we are searching for and the node we wish to start searching from. This is the front child node of the portal's owner node. If this function returns true, it means that it located a matching leaf down the front branch of the node and therefore we know that the leaf exists to the front of the portal. Thus, we return FRONT_OWNER.

If we have not returned from the function at this point, then it means we did not locate the leaf down the front tree of the portal's owner node so we must now search to see if we can locate it down the back of the node. If the owner node has a back child then its Back index will be non-negative and will describe the index of the child node. Therefore, we pass this node index into the FindLeaf function, along with the leaf index we are searching for, to perform a search down the back tree. If the FindLeaf function returns true, it means that the leaf was located in the search and therefore, the leaf is situated behind the portal. Therefore, we return BACK_OWNER.

```
    if ( CurrentNode->Back >= 0 )
    {
        if (FindLeaf(Leaf, CurrentNode->Back )) return BACK_OWNER;
    } // End If

    return NO_OWNER;
}
```

Notice at the end of the function we return NO_OWNER if the portal leaf could not be found down either the front or the back tree of the portal's owner node.

At first, it would seem that this situation could never arise. After all, the reason we called this function is that the portal ended up in a leaf. So we can assume that leaf must exist somewhere underneath the portal's owner node, right? In fact, no. Returning NO_OWNER will inform the portal clipper that the portal has ended up in a leaf that it has no business being in and that the portal should be deleted. This may sound absurd, but we will soon examine how these rogue portal fragments can come into being. Just know for now that by returning NO_OWNER if the portal has not fallen into a leaf that exists beneath the owner, the portal clipper knows it has a rogue fragment that can be deleted. This completely removes the problem.

Before we examine rogue portals in more detail, let us take a look at the FindLeaf function called from the ClassifyLeaf function. It is a simple recursive procedure that walks the tree starting from the input node and searches for a matching leaf index. If one is found, it returns true.

```
bool CProcessPRT::FindLeaf( unsigned long Leaf, unsigned long Node )
{
    CBSPNode * CurrentNode = NULL;

    // Validate Requirements
    CurrentNode = m_pTree->GetNode( Node );

    // Check to see if the front is this leaf
    if ( CurrentNode->Front < 0 )
    {
        if ( abs(CurrentNode->Front + 1) == Leaf ) return true;
    }
    else
    {
        if (FindLeaf( Leaf, CurrentNode->Front )) return true;
    } // End If

    // Iterate down the back if it's a node
    if ( CurrentNode->Back >= 0 )
    {
        if (FindLeaf( Leaf, CurrentNode->Back )) return true;
    } // End If

    return false;
}
```

As you can see, the function recursively calls itself searching for leaf at the front of each node it visits. If a node is reached that has a negative front node index, then it means that this is actually the index of a leaf that is stored here. The index is transformed into a valid leaf index (by adding 1 and negating) and is compared against the leaf index passed into the function. If a match is found, it returns true. If a match is not found, it recursively calls itself to walk down the front or back of the current node if those children exist. The only time the end of the function is reached and false is returned is when the front and back trees of the node have been traversed and no matching leaf was found.

Rogue Portal Fragments

It may at first seem that if a portal ever ends up in a leaf, we would always want to keep it because it is in empty space. However, when we are trying to generate a portal on that node, remember that we are only interested in finding the two leaves that the node divides. As it so happens, there may be other nodes in the tree that share the same plane and as such would have initial portals built on the same plane. As all initial portals are fed into the root node of the tree, this means that if action was not taken as described above, some portal fragments from the node we are currently trying to generate portals for can end up in leaves that are not underneath that node in the tree.

To understand this scenario, take a look at Figure 17.36. In this example, we will imagine that the wall labeled Node A was chosen as the root node when the BSP tree was first compiled. We know that polygons G1 and G2 are on opposite sides of the plane and therefore would be passed down different sides of node A. We will also imagine that G1 was passed down the front tree of A where it was then selected as the split plane. Wall G2 is assumed to have been passed down the back of node A where it will be used as the next node plane down the back tree of A. We now have two nodes that have identical planes, but exist in different sub-trees of node A. This situation arises when a polygon is split and passed down into the front and back trees of the node *before* it has been selected as a splitter. Remember that each of those polygon fragments will later be used as a node plane.

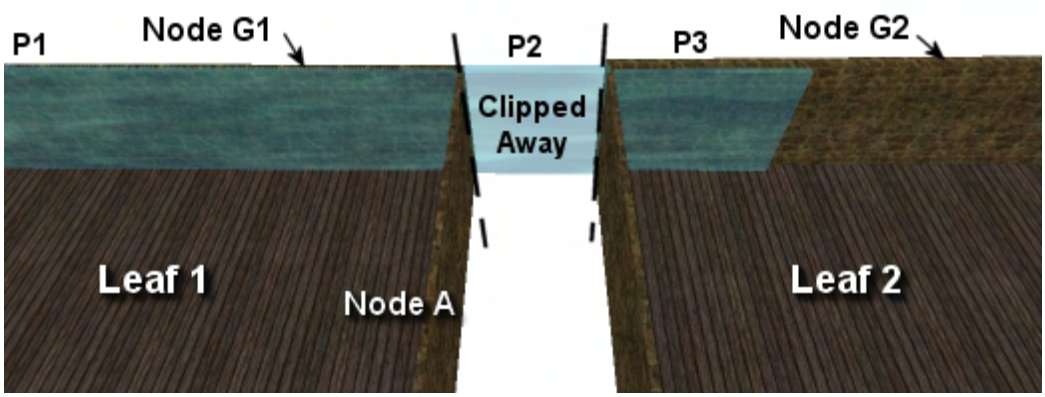

Figure 17.36

Now imagine that the tree is compiled and we are trying to find portal P. For this example we will say that the far walls of leaves 1 and 2 are not actually part of those leaves. Instead they exist in other leaves and as such, a portal will need to be created there. As we know, during the portal generation process we would determine that node G1 has two child nodes, so we should create an initial portal and send it down the tree. Of course, all we are interesting in finding is the fragment of the portal P1 which exists in leaf 2 and the leaf behind the portal. Initially, the portal P would be generated as a very large polygon and passed down the root node. Portal P is assumed to be the entire width of the blue portal shown in Figure 17.36. When this portal enters the root node, it is classified against node A and is split. The front fragment is sent down the front tree of node A where it ends up in leaf 1. This is the portal we were looking for, labeled P1 in the image. However, when the split occurred at node A there was also a significant portion of the portal that lay behind node A, and as such would be passed down the back list. Let us assume that it next enters a node where the split plane used is the left wall of the right construct. As we can see, this plane would split the fragment into portals P2 and P3. P2 would be sent down the back and deleted because it ended up in solid space. Portal P3 however is passed down the front where it ends up in leaf 2. So part of the portal that we were trying to generate for node 1 to plug the gap in leaf 1 has ended up in leaf 2. Furthermore, depending on the clipping process applied to that portal on its way to leaf 2, the portal fragment that actually lands there could be arbitrarily sized. Essentially, we want to get rid of this portal fragment (P3) since the portal that should be created here will ultimately occur when the initial portal is built on node G2. So how do we know if a portal ends up in a leaf that it is a rogue fragment that should be deleted?

Luckily, it is so simple that we have already taken care of it. The only way we can ever have two nodes sharing the same plane (such as G1 and G2 in the above diagram) is if they exist in different parts of the tree. This is due to the fact that the polygons used to create those nodes were separated into front and

back lists before either of them was used as a splitter. Therefore, the leaves we are looking for when generating a portal are always the leaves that exist below the portal's owner node in the tree. In Figure 17.36 for example, we can instantly tell that node G2 (and therefore leaf 2) would not exist underneath node G1 as one of its children. Therefore, when a portal enters a leaf, if we cannot find that leaf in either the front or back tree of the owner node, we know that we have a rogue fragment and that we can return NO_OWNER from our leaf classification function. The portal clipper can then delete this rogue fragment.

So as you can see, the classify leaf function solves two problems. First, it allow us to determine which portal halfspace the leaf in which that portal has just entered resides. Second, it also allows us to remove rogue portal fragments by testing whether the leaf that the portal has entered exists beneath the portal's owner node in the tree.

With a good deal of discussion, examples, and the examination of support functions under our belt, we are now ready to look at our first version of the portal clipper. It is a single recursive function that is called by the ProcessPortals function for each node that has an initial portal generated for it. Again, you are reminded that this is every node that has a front and a back child (or a back child and a front leaf).

The Portal Clipper

In this section we will examine the code to the recursive ClipPortal function, which is invoked to clip the initial portal generated at each applicable node (i.e., has two children). This code is only for demonstration and discussion and does not match up with all of the namespaces and types used in the actual lab project that accompanies this lesson (the actual source code will be discussed in the workbook). However, this version is very close to the true implementation and will provide a full understanding of the process we have been discussing thus far.

The ClipPortal function is called by the ProcessPortals function we looked at earlier. It is passed the root node and the initial portal that will need to be clipped to the tree. The passed portal will also store (in its OwnerNode member) the index of the node in the tree on which the initial portal was created. The function returns a pointer to a portal structure. Since this portal structure can be linked with other portal structures (via its Next member) the function may thus return a linked list of multiple portal fragments that survived being clipped to the tree.

The first thing the function does is use the passed node index to get a pointer to the node currently being visited by the function. This will be the root node the first time it is called from the parent process. When the node pointer is fetched from the tree's node array, its Plane member (which contains the index of the split plane stored at that node) is used to retrieve the relevant plane from the tree's plane array. The Portal is then classified against the plane. It is assumed in this code that the plane class has a ClassifyPoly method which classifies the portal polygon against the plane and returns a front, back, spanning, or on-plane result.

```
CPortal * ClipPortal( unsigned long Node, CPortal * pPortal )
{
```

```
    CPortal   * PortalList     = NULL, *FrontPortalList = NULL;
    CPortal   * BackPortalList = NULL, *Iterator        = NULL;
    CPortal   * FrontSplit     = NULL, *BackSplit       = NULL;
    CBSPNode    * CurrentNode    = NULL;
    CPlane      * CurrentPlane   = NULL;
    unsigned long  OwnerPos, LeafIndex;

    // Validate Requirements
    if (!pPortal || !m_pTree) throw BCERR_INVALIDPARAMS;

    // Store node for quick access
    CurrentNode  = m_pTree->GetNode( Node );
    CurrentPlane = m_pTree->GetPlane(CurrentNode->Plane);

    // Classify the portal against this nodes plane
      switch (CurrentPlane->ClassifyPoly(pPortal->Vertices,
                                         pPortal->VertexCount,
                                         sizeof(CVertex)))
    {
```

The CPlane::ClassifyPoly method parameters are a pointer to the polygon's vertices, the number of vertices in the buffer, and the size of each vertex structure. Our CPortal structure is a class that is derived from our CPolygon structure. Although it adds a few new members of its own, because it is a CPolygon, it can be passed to all functions that expect to work with polygon data. Notice in the above code that the result from the portal/plane classification is passed into a switch statement. The action taken on each result type will now be covered one at a time.

CP_FRONT

When the portal is found to be in front of the current node plane it means that we either have to send it down into the front child node if one exists, or if not, it means a leaf is attached to the front of the node and the portal has successfully made it into this leaf. We will cover the code that is executed if the portal has made it into a leaf first.

```
      case CP_FRONT:

            if (CurrentNode->Front < 0 )
            {
                // The front is a Leaf, determine which side of the node it fell
                LeafIndex   = abs(CurrentNode->Front + 1);
                OwnerPos    = ClassifyLeaf( LeafIndex, pPortal->OwnerNode );

                // Found the leaf below?
                if ( OwnerPos != NO_OWNER )
                {
                    // This is just returned straight away, it's in an empty leaf
                    pPortal->LeafOwner[OwnerPos] = LeafIndex;
                    pPortal->NextPortal          = NULL;
                    pPortal->LeafCount++;
                    return pPortal;
                } // End if leaf found
                else
                {
                    delete pPortal;
```

```
                    return NULL;

                } // End if leaf not found
            } // End if child leaf
```

In the IN_FRONT case we first test the value of the current node's front index. If it is negative then it means that it does not contain the index of a child node, but contains the index of a leaf structure that is attached to this node. As such, we know that the portal has made it into this leaf. The front index is negated and incremented so that it now represents the index of the leaf in the tree's leaf array, and then this index is passed into the ClassifyLeaf function that we covered in the previous section. The result of this function will be stored in the OwnerPos local variable and provided that it does not equal NO_OWNER, OwnerPos will be a value of either zero or one describing where in the portal's LeafOwner the index of the leaf should be stored. The portal's LeafCount member is also increased so that it correctly reflects how many (of the two possible) leaves have been added to this portal. For any valid portal that is returned from the function, this should be set to exactly 2. The portal's NextPortal member is also set to NULL since this is a single portal that is not yet attached to any linked list. This portal is then returned back to the parent node because it has survived clipping and made it into a valid leaf.

Notice in the above code however that if the ClassifyLeaf function returns NO_OWNER, it means that this leaf does not exist underneath the portal's owner node in the tree. Therefore, this is a rogue fragment and it should be deleted. After it is deleted, NULL is returned which indicates that the portal passed into this function did not survive the current node traversal.

The above section of code is executed when a leaf is in front of the current node being visited. However, if a leaf does not exist down the front of this node, then the node's Front index will contain the index of the child node. When this is the case, the function recursively calls itself, passing the portal down to the child.

```
            else
            {
                // Pass down the front
                PortalList = ClipPortal(CurrentNode->Front, pPortal);
                return PortalList;

            } // End If child node

            break;
```

Notice how the portal (or portal list) returned from the child is assigned to the PortalList variable and it is this list that is returned. Remember, although we are just passing the portal down the front of the tree, it may end up getting split into many valid fragments (or none, in which case NULL would be returned) down that section of the tree. The pointer returned to the child may point to the first portal in a linked list of many fragments that survived the front tree of the current node. It is this list that should be returned to the parent. That is the CP_FRONT case taken care of.

CP_BACK

If the portal is found to be behind the current plane then we first test the current node's Back child node index. If it is a positive number then it will describe the index of the back child node. If it is a negative number then it means that there is a leaf attached to the back of this node. However, if it is a negative number equal to BSP_SOLID_LEAF, it means that the portal, if passed down the back of this node would end up solid space. In this case, the portal is deleted and NULL is returned.

```
        case CP_BACK:

             // Test the contents of the back child
             if (CurrentNode->Back == BSP_SOLID_LEAF )
             {
                 // Destroy the portal
                 delete pPortal;
                 return NULL;

             } // End if solid leaf
```

The next section of code is executed if there is not solid space behind the node, but is instead a valid back leaf. This code should look very familiar. The Back child index is negated and incremented, transforming it into a valid leaf index (into the tree's leaf array). The leaf index and the portal's owner node are then passed into the ClassifyLeaf function and the result indicates whether the leaf is situated in front or behind the node. Provided the result was not NO_OWNER, the leaf index is stored in the relevant position in the portal's leaf index array and the portal's leaf count is incremented before the portal is finally returned from the function. If the result of ClassifyLeaf is NO_OWNER however, this means the leaf that the portal has made it into does not exist under the portal's owner node in the tree and as such, this is a rogue fragment that should be deleted.

```
             else if (CurrentNode->Back < 0 )
             {
                 // The back is a Leaf, determine which side of the node it fell
                 LeafIndex   = abs(CurrentNode->Back + 1);
                 OwnerPos    = ClassifyLeaf( LeafIndex, pPortal->OwnerNode );

                 // Found the leaf below?
                 if ( OwnerPos != NO_OWNER )
                 {
                     // This is just returned straight away, it's in an empty leaf
                     pPortal->LeafOwner[OwnerPos] = LeafIndex;
                     pPortal->NextPortal          = NULL;
                     pPortal->LeafCount++;
                     return pPortal;

                 } // End if leaf found
                 else
                 {
                     delete pPortal;
                     return NULL;

                 } // End if leaf not found

             } // End if child leaf
```

If the Back child index of the current node is non-negative, it signals that there is another child node attached to the back of this node and as such, we send the portal down the back tree.

```
            else
            {
                // Pass down the back
                PortalList = ClipPortal(CurrentNode->Back, pPortal);
                return PortalList;

            } // End If child node

            break;
```

The list of portal fragments returned (if any) from the back tree is then returned, as can be seen in the else conditional in the above code.

We have now covered the two simplest cases in the clipping procedure, the front and back cases.

CP_ONPLANE

The on plane case is quite a bit larger than the previous two but is not as complex as it first appears. The portal needs to be clipped to the front tree first and any surviving fragments then each need to be clipped to the back tree. The result is a list of fragments that have survived both the front and back trees of the node, which is then returned from the function. Of course, if a leaf exists to the immediate front or back of the current node, then the leaf index is simply recorded in the portal's leaf array as we have seen in the previous two cases.

In the first section of the code we test the front to see if it is the index of a leaf (i.e., it is negative). If it is, then the leaf index is passed into the ClassifyLeaf function as before and if found to be either behind or in front of the portal, it is added to the portal's leaf list. Notice in this case however that we do not simply return the portal when it is found to be in a leaf; it must also be passed down the back of the node. So instead, we cache the portal pointer in the FrontPortalList local variable.

```
          case CP_ONPLANE:

            if (CurrentNode->Front < 0 )
            {
                // The Front is a Leaf, determine which side of the node it fell
                LeafIndex   = abs(CurrentNode->Front + 1);
                OwnerPos    = ClassifyLeaf( LeafIndex, pPortal->OwnerNode );

                // Found the leaf below?
                if ( OwnerPos != NO_OWNER)
                {
                    // This portal is added straight to the front list
                    pPortal->LeafOwner[OwnerPos]= LeafIndex;
                    pPortal->NextPortal         = NULL;
                    FrontPortalList             = pPortal;
                    pPortal->LeafCount++;

                } // End if leaf found
```

```
                else
                {
                    delete pPortal;
                    return NULL;

                } // End If no leaf found

            } // End if child leaf
```

If the front child index is not a negative number then it means that a child node exists down the front of the current node. As such, the portal should be clipped to the front sub-tree and the address of the returned linked list of fragments should be stored in FrontPortalList .

```
            else
            {
                  FrontPortalList = ClipPortal(CurrentNode->Front, pPortal);

            } // End If child node
```

At this point FrontPortalList will either contain the portal that made it into the immediate child leaf down the front of this node or it will contain the linked list of fragments that survived the front tree. It might also be NULL if no fragments survived the front tree. If this is the case, we return NULL as shown below.

```
            // If nothing survived return here.
            if (FrontPortalList == NULL) return NULL;
```

We must return NULL if FrontPortalList equals NULL because if nothing survived down the front of the tree it cannot possibly be a valid portal (a valid portal is a portal that has a leaf on both sides of its plane). However, if the current node (with which the portal is on-plane) has solid space behind it, we just return the front portal fragments.

```
            // If the back is solid, just return the front list
            if ( CurrentNode->Back == BSP_SOLID_LEAF ) return FrontPortalList;
```

Now that we have a list of all the possible fragments that have survived the front tree (or the fragment that ended up in an immediate front list) stored in FrontPortalList, we will now loop through this linked list and send each portal fragment down the back tree one at a time (where they may also get split into multiple fragments). We collect the resulting fragments returned from clipping each front fragment to the back tree in a final linked list (called PortalList) which is returned from the function. This linked list will contain all the fragments of the original portal passed into the function that survived both the front and back trees of the current node.

The first thing we do is use the pPointer local variable to point at the head of the linked list. We then set up a while loop that will iterate this pointer though each portal in the list. The loop exits when we reach the end of the list and pPortal equals NULL.

```
            // Loop through each front list fragment and send it down the back
            pPortal = FrontPortalList;
```

```
            while ( pPortal != NULL )
            {
               CPortal * NextPortal = pPortal->NextPortal;
               BackPortalList       = NULL;
```

Each time through the loop, we store the next portal in FrontPortalList in NextPortal because the current portal will be getting sent down the back tree and possibly deleted. We certainly do not want to lose a pointer to the following portal in the list which was only linked to (and accessible via) the portal that got deleted. We send the current fragment (pointed to by pPortal) down the back tree, and store a pointer to the list of fragments that have survived in BackPortalList. BackPortalList will be NULL if no fragments of the current front list fragment being processed survive the back tree.

If some portals do survive, then we get the last fragment in the list and attach it to our master PortalList. Remember that BackPortalList will contain fragments that have survived for the current fragment that was in the front list. Any portals returned in BackPortalList are added to PortalList at the end of each loop. This means that when the loop exits, PortalList will contain a linked list of all fragments that survived both the front and back trees for each loop.

The next thing we do inside the code is test to see if the back child is a leaf or a node. If it is a leaf then the current fragment from the front list (pPortal) has made it into a back leaf, so we determine whether the leaf is in front or behind the portal and store the leaf index in the correct location in the portal's leaf array. If ClassifyLeaf returns NULL, then this is a rogue fragment and is deleted. If the portal does make it into a leaf, then we assign its address to BackPortalList since this will be the pointer that is linked to the master portal list at the end of the loop. If another node (not a leaf) exists down the back child, then we clip the fragment to the back tree and store any surviving fragments in BackPortalList . This is all shown in the following code snippet.

```
               // Empty leaf behind?
               if ( CurrentNode->Back < 0 )
               {
                   // The back is a Leaf, determine which side of the node it fell
                   LeafIndex   = abs(CurrentNode->Back + 1);
                   OwnerPos    = ClassifyLeaf( LeafIndex, pPortal->OwnerNode );

                   // Found the leaf below?
                   if ( OwnerPos != NO_OWNER )
                   {
                       // Attach it to the back list
                       pPortal->LeafOwner[OwnerPos] = LeafIndex;
                       pPortal->NextPortal          = BackPortalList;
                       BackPortalList               = pPortal;
                       pPortal->LeafCount++;

                   } // End if leaf found
                   else
                   {
                       // Delete the portal, but continue to the next fragment
                       delete pPortal;
                       continue;

                   } // End If no leaf found
```

```
                } // End if child leaf
                else
                {
                    // Send the Portal Down the back
                    BackPortalList  = ClipPortal(CurrentNode->Back, pPortal);

                } // End If child node
```

Remembering that we are still in the while loop for the current front list fragment we are processing, if BackPortalList does not equal NULL, then it means that we have a fragment (or potentially a list of fragments) that have survived both the node's front and back trees. If this is the case, we use a temporary portal pointer (Iterator) to seek to the end of the linked list (pointed to by BackPortalList). Once the end of the portal list has been reached, we assign the last portal in the list to point to the first portal in the master portal list (PortalList) so that any fragments we have collected in previous iterations (in Portal List) and the fragments we have just collected (in BackPortalList) are joined into a single list. PortalList is then reassigned to BackPortalList so that it points at the head of this merged list.

```
                // Anything in the back list?
                if (BackPortalList != NULL)
                {
                    // Iterate to the end to get the last item in the back list
                    Iterator = BackPortalList;
                    while ( Iterator->NextPortal != NULL)
                            Iterator = Iterator->NextPortal;

                    // Attach the last fragment to the first fragment
                    // from the previous iteration.
                    Iterator->NextPortal = PortalList;

                   // Portal List now points at the current complete list of
                   // fragments collected so far
                   PortalList = BackPortalList;

                  } // End if BackPortalList is not empty
```

At this point, the previous contents in PortalList and the contents in BackPortalList (generated from the current fragment being processed) have been joined into a single list, and PortalList points to the head.

With the current front list fragment processed and any fragments of it that survived the back tree added to PortalList, we now move on to the next fragment in the list. We do this by assigning pPortal to NextPortal. Remember that NextPortal was assigned to point at the next portal that needed to be processed at the head of this list.

```
                  // Move on to next portal
                  pPortal = NextPortal;

             } // End While

            // Return the full list
```

```
            return PortalList;
```

Finally, after the while loop exits, PortalList will contain any fragments that survived both the front and back trees of the current node, so we return it. That is the (rather tricky) on plane case taken care of.

CP_SPANNING

The final case is the spanning case which occurs when the passed portal is spanning the current node being visited. When this is the case, the portal is split into two child portals. Each child portal is clipped to the front and back tree respectively and the resulting fragments retuned from each sub-tree are linked into a single list and returned.

The first thing the function does is allocate the two new child portals that will be the by-product of the split. The current plane and these portal pointers are then passed into the current portal's Split function. This is just a standard polygon splitting function which we have seen before. When the function returns, FrontSplit and BackSplit will contain the two child portals and the original portal can be deleted.

```
      case CP_SPANNING:

            // Allocate new front fragment
            FrontSplit = new CPortal;
            BackSplit  = new CPortal;

            // Portal fragment is spanning the plane, so it must be split
            if (FAILED( pPortal->Split(*CurrentPlane, FrontSplit, BackSplit)))
            {
                delete FrontSplit; delete BackSplit;
                throw BCERR_OUTOFMEMORY;
            } // End If

            // Delete the ORIGINAL portal fragment
            delete pPortal;
            pPortal = NULL;
```

Now it is time to send each of these child portals down their respective sides of the tree, starting with the front split. If the current node has a leaf immediately in front of it, then we classify the leaf and store its index in the portal. We also assign the FrontPortalList pointer to point at this portal instead of just returning (we will see this being used in a moment). If NO_OWNER is returned from the leaf search, then this is a rogue fragments and is deleted. Alternatively, if a front child node exists down the front tree, we clip the front split portal to the front tree and store the surviving fragments in the FrontPortalList pointer.

```
            // There is another Front NODE ?
            if (CurrentNode->Front < 0 )
            {
                // The front is a Leaf, determine which side of the node it fell
                LeafIndex   = abs(CurrentNode->Front + 1);
                OwnerPos    = ClassifyLeaf(LeafIndex, FrontSplit->OwnerNode );

                // Found the leaf?
```

```
                if ( OwnerPos != NO_OWNER)
                {
                    FrontSplit->LeafOwner[OwnerPos] = LeafIndex;
                    FrontSplit->NextPortal          = NULL;
                    FrontPortalList                 = FrontSplit;
                    FrontSplit->LeafCount++;

                } // End if leaf found
                else
                {
                    delete FrontSplit;

                } // End If no leaf found

            } // End if child leaf
            else
            {
               FrontPortalList = ClipPortal(CurrentNode->Front, FrontSplit);
            } // End If child node
```

At this point, FrontPortalList will either point to the portal that made it into the immediate front child leaf, the list of fragments that survived when the front split was clipped to the front tree of the current node, or NULL if no fragments survived the front tree clipping process. Either way, we have a list that describes what fragments of the front split portal (if any) survived.

Now we will do the same for the back split. If the current node has solid space behind it then the back split is immediately deleted. If the node has an actual leaf behind it, the leaf is classified against the portal and its index is stored in the portal's leaf array. If the NO_OWNER result was returned from the leaf classification, then the portal is a rogue and can be deleted. If however a child node exists behind the current node, we will clip the back split portal to the back tree and store a pointer to the linked list of any surviving fragments in the BackPortalList local variable.

```
            // There is another back NODE ?
            if ( CurrentNode->Back == BSP_SOLID_LEAF )
            {
                // We ended up in solid space
                delete BackSplit;

            } // End if solid leaf
            else if (CurrentNode->Back < 0 )
            {
                // The back is a Leaf, determine which side of the node it fell
                LeafIndex   = abs(CurrentNode->Back + 1);
                OwnerPos    = ClassifyLeaf(LeafIndex, BackSplit->OwnerNode );

                // Found the leaf?
                if ( OwnerPos != NO_OWNER)
                {
                    BackSplit->LeafOwner[OwnerPos] = LeafIndex;
                    BackSplit->NextPortal          = NULL;
                    BackPortalList                 = BackSplit;
                    BackSplit->LeafCount++;
```

```
                } // End if leaf found
                else
                {
                    delete BackSplit;

                } // End If no leaf found

            } // End if child leaf

            else
            {
                BackPortalList = ClipPortal(CurrentNode->Back, BackSplit);

            } // End If child node
```

At this point we potentially have two fragment lists containing portals fragments that survived the front *or* back of the tree. We now need to merge FrontPortalList and BackPortalList into a single list so that we can return a pointer to this new merged fragment list.

In the first step, if FrontPortalList does not equal NULL, we iterate to the end of the list so that Iterator points to the final portal in the list. We then set the NextPortal member of this final pointer in the front list to point at the first pointer in the back list. This will connect the two lists and we can then return the FrontPortalList (which now points to the start of the combined list).

```
            // Find the End of the front list and attach it to Back List
            if (FrontPortalList != NULL)
            {
                        // There is something in the front list
                        Iterator = FrontPortalList;
                        while (Iterator->NextPortal != NULL)
                              Iterator = Iterator->NextPortal;

                        if (BackPortalList != NULL)
                            Iterator->NextPortal = BackPortalList;

                return FrontPortalList;

            } // End if front list
```

If there are no fragments in FrontPortalList, then we return just BackPortalList. Of course, if BackPortalList equals NULL, none of the split portals survived and we return NULL.

```
            else
            {
               // There is nothing in the front list simply return the back list
                if (BackPortalList != NULL) return BackPortalList;
                return NULL;

            } // End if no front list

            // If we got here, we are fresh out of portals so simply return NULL.
             return NULL;
```

```
    } // End switch
    return NULL;
}
```

That concludes the ClipPortal function and finalizes our discussion of the portal clipping procedure. The generation of portals is perhaps the most complicated component of the PVS calculator to develop since it is highly recursive. In fact, when we call the ClassifyLeaf function, we are actually invoking a recursive tree traversal function from within a function that is already recursively walking the tree. Although this can be a bit tricky to follow at first, hopefully the underlying logic is clear to you.

17.5.5 Portal Generation Conclusion

You should not be too hard on yourself if some of this lesson has been extremely hard to digest. Although the portal generation process is really just another form of CSG, it does have certain particular rules which make the process appear a lot harder than it actually is. While the ClipPortal function itself might look quite intimidating at first glance, most of the code is obfuscated by linked list management code and other such housekeeping tasks. But notice that the basic idea is CSG through and through. In fact, the entire process of clipping the portal to a solid BSP tree and keeping any pieces that ended up in empty space is taken directly from the CSG material that we learned about in the last chapter.

As a reminder, the ClipPortal method was called from the ProcessPortals function for each node that had two children. Any fragments that were returned to ProcessPortals from ClipPortal were considered valid portals that lived in two leaves. These portals were then added to the PVS processor's main portal array. At the end of the process, this master array will hold every single portal that plugs every single gap between every single leaf in the level. Each portal will also describe which leaves it is contained in and their location with respect to the portal's plane (front or back). In short, we now have the doorways between leaves at our disposal (as a list of portal polygons) and thus we have everything we need to enter the next phase of calculating potential visibility.

17.6 Calculating the Potential Visibility Set

After the last section, we now have all of the information necessary to calculate the PVS. Recall that in order to determine what was visible from one leaf to the next we need to know the size of the doorway (the gap) that joins those two 'rooms'. With our portals now in place, we have exactly that. Each portal describes the precise doorway between one leaf and the next, so the dimensions of the portal provide the dimensions of the gap. The next part of this course is arguably the most exciting – writing our PVS Calculator. While it will be one of the most complex and challenging discussions to date, it will also prove to be one of the most beneficial to our eventual engine (finally coming to fruition in Module III) in terms of sheer performance enhancement.

At a high level, our first task moving forward will be to loop through each portal in our portal list and determine exactly which leaves that portal can 'see'. Each portal in our master portal list will have a leaf visibility list constructed for it. The compilation of the PVS is primarily going to be occupied with calculating the leaf visibility sets for each leaf. Finally, once we know which leaves can be seen by all of the portals, we can easily find out which leaves a particular leaf can see, because it will be the sum of what all of the portals in that leaf can see. For example, imagine that leaf 1 contains portals A, B, and C and that the leaf visibility sets calculated for each portal are given by the following table.

Portal	Visible Leaves
Portal A	1,2,7,101
Portal B	20,21,22
Portal C	30,31,32

It stands to reason that since all of these portals are essentially doorways out of leaf 1, leaf 1 can see everything that can be seen through all of its portals. Therefore, the visibility list for leaf 1 will be the sum of portal visibility sets for each of the portals it contains. With the portal visibility sets at its disposal, the PVS calculator can quickly deduce that the visibility set for leaf 1 would be:

Leaf	Visible Leaves
Leaf 1	1, 2, 7, 20, 21, 22, 30, 31, 32, 101

Thus, after the PVS calculator has calculated the visibility sets for each portal, it will loop through each leaf in the tree, find the portals that are contained in each leaf, and then sum their visibility sets to create the final visibility set for that leaf. Once the visibility set for every leaf has been calculated, the portals can be discarded and the master PVS data array (which contains the visibility information for every leaf in a continuous block) can be compressed and saved out to file with the rest of the leaf tree data.

Summing the portal visibility sets to create the leaf visibility sets is performed in the final stage of the PVS Calculator and it is quite a trivial task. It is the calculation of the visibility sets for each portal which will require the most work.

The steps involved in the PVS Calculator design are outlined below:

- **Step 1: Creation of one-way portals**
  Each portal in our portal array currently lives in two leaves. We will duplicate each portal so that the N portals in our list are converted into N*2 portals. Each portal's duplicate will have its normal negated so that it faces in the opposite direction. We will then assign each original portal to the leaf in its backspace. The leaf contained in each portal's frontspace will be known as the neighbor leaf. This will create a list of portals in which the portals are only owned by one leaf; the leaf from which the back face of the portal can be seen. Each portal will also store the index of the neighbor leaf. Note that this is the leaf that you would arrive in if you traveled from the owner leaf through the back of the portal it owns. The normal of each portal will point into the neighbor leaf and portal flow is assumed to only happen through the backs of portals. That is, if you cannot see the back of a portal, you cannot see through it (more on this later). As an example, imagine we have an original portal P that is contained in leaves 5 and 6, with leaf 5 in its frontspace. Portal P will have its index stored in leaf 6 since this is the leaf that owned the backspace of the portal. Leaf 5 will be stored in the portal as the neighbor leaf (i.e., the leaf we travel into when passing from leaf 6 through the back of the portal). Once this is done, we will then duplicate the portal, reverse the normal, and swap the owner/neighbor relationship in the new duplicate.

  If we imagine that the original portal P contains leaves 5 and 6 in its leaf list, with leaf 5 in its front halfspace, two new portals would be created to replace the original portal and they would have neighbor/owner properties as shown in the following table.

Portal	Front Space	Back Space	Owner	Neighbor
Portal P1	Leaf 5	Leaf 6	Leaf 6	Leaf 5
Portal P2	Leaf 6	Leaf 5	Leaf 5	Leaf 6

  While this may seem like an odd thing to do, it actually simplifies the main PVS processing procedure and speeds up compilation time for the PVS data. Not having these optimizations could mean the difference between the PVS calculator taking 10 minutes to compile versus several hours (if not more).

  We will see why this is so important in a moment. For now, just notice in the table above that a leaf only ever owns portals whose normal face outwards from that leaf. This allows us to establish a portal "flow direction" such that we can assume that we can only see through the back of a portal and never see (or step) through the front of one. This allows us to avoid having to run tests while in the core of the recursive loop to make sure that we do not step into leaves we have already visited or step through portals which face in the opposite direction to which the visibility flow is currently taking us. Essentially, because a leaf only contains the portals that face out of it, we know that we are only ever supposed to see through the backs of portals. Portals that are facing us should be ignored. This prevents us from traversing through portals for which no line of sight could possibly exist between the portal currently having its PVS generated and the target portal. We will discuss this in more detail shortly.

- **Step 2: Portal To Portal Visibility**
  Because the core PVS calculator is basically a highly recursive clipping procedure, it can take a very long time to calculate the visibility information for each portal. The basic procedure is to

build something called an anti-penumbra from a series of clip planes so that we can model the way light would travel out from a portal into the neighboring leaf. The source portal is the portal that is currently having its leaf visibility set calculated and as such is used to construct a viewing volume (a loose analogy that will be more accurately explained shortly). Any portals in neighboring leaves that fall within the anti-penumbra of the source portal are considered visible from the source portal. As such, we recur through that portal and into its neighboring leaf. Once in that leaf, it is marked as visible and its portals are tested for anti-penumbra containment. Any portals in that leaf that fall within the anti-penumbra of the source portal are once again stepped through, taking the recursive process into its neighboring leaf, and so on. Eventually, we will step into a leaf where none of its portals will fall within the source portal's anti-penumbra. In this case, the recursive process ends along that path for the source portal. We have essentially reached a leaf in which the source portal cannot see any of its other portals. Therefore, it cannot see *through* those portals into other leaves.

When we consider that this process will be repeated for each portal, there is going to be an incredible amount of processing to do. As such, we will need to include some small optimization steps before the core process begins to reduce the amount of leaves/portals that would be unnecessarily visited during the key recursive clipping process. The first thing we will do is build a temporary portal visibility list for each portal. That is, each portal will store an array describing which other portals can possibly see it (a very rough approximation). The fact that we have created one way portals makes this process very easy as we will discuss in moment. For example, imagine that we wish to calculate a very rough portal visibility set for portal A. We can loop through all the portals and reject portals from its visibility set based on two key things. If the portal being tested has its normal facing portal A then these one-way portals are facing in opposite directions and portal A cannot possibly see through the back of test portal B (i.e., it cannot see through it). Such portals will not be added to portal A's rough portal visibility list. Secondly, if the test portal is behind portal A then once again, portal A cannot possibly see through it. Remember, our one-way portals have normals that face into the neighbor leaf and as such, visibility flow can only travel through the back of a portal into the leaf it leads into. If portal B is behind portal A, portal A cannot look through the back of portal B, so no visibility exists between them.

At the end of this step, for each portal we will have generated an array of bytes equal to the number of one-way portals in the scene. Each element in each portals array will describe the visibility of the corresponding portal in the master portal list. For example, if portal 5 has the 25^{th} byte in this array set to 1, then it means that portal 5 was found to have some chance of possibly seeing through portal 25. As such, this relationship will have to be examined more closely by the core PVS calculator. Although this is an extremely rough approximation, it does tell us what portal combinations cannot possibly see each other and thus should not be processed during the core recursive process. We will discuss this in more detail later.

- **Portal Leaf Flood Fill**
  After creating the portal visibility array for each portal we will use it to perform a very fast flood fill through the leaf to generate a very rough portal/leaf visibility array. At this stage, no anti-penumbras will be generated and clipped and we will be creating a very rough leaf visibility set

for each portal. It is this set that will be further refined by the core PVS processor to get the final visibility sets for each portal.

In this step a very small recursive function will be invoked for each portal. Starting at the portal neighbor leaf if will flow though all its portals into their neighbor leaves and so on. Every time a leaf is reached by the recursive function, its bit is set in the portal's visibility set. Now, you may be thinking that such a procedure would always recursively flood through all portals until every leaf in the level has been added to the visibility set for each portal. Indeed if it were not for the portal to portal visibility set that we calculated in the previous section, this would be the case. However, you will see in a moment that because we already know what portals a given portal can (roughly) see, the flood fill stops and returns as soon as it reaches a portal that is not set as visible in the source portal's 'portal visibility' array. Therefore, the portal/portal visibility array we process in the previous step is used as input to this step to perform a quick and approximate flood fill through the level, adding any leaves it reaches to the portal's leaf visibility set. This will be a *very rough* PVS and will contain many leaves that cannot actually be seen from each portal. However, it will also reject a lot of leaves and these are leaves that we will not have to step into during the core recursive process.

These last two steps serve no purpose other than to speed up the core PVS calculator. If you have ever had the misfortune of running a PVS calculator that did not employ these optimizations, you will know how vital they are. Complex levels could take many hours (perhaps even days) to compute, but this can be cut down to a mere fraction of the time with the portal/leaf flood fill in place as a preliminary measure.

- **Recursive Anti Penumbra Clipping**
  This final phase is the core PVS calculator that recursively floods through the level building the actual PVS from a combination of the preliminary PVS (built in the portal flood phase in the previous step) and from a good deal of clipping of a visibility volume. This visibility volume is called an anti-penumbra and essentially models everything that can be seen through a combination of two portals. The first portal is always the **source portal** (i.e., the portal for which the leaf visibility set is currently being compiled). The second portal is referred to as the **target portal** and it changes each time we step into a new leaf.

Before we discuss the core process that performs the recursive anti-penumbra clipping to calculate the actual visibility set, we will first talk about what an anti-penumbra is, how we create one, and how it is used to calculate the leaf visibility for each portal.

17.6.1 Anti-Penumbras

In discussions of illumination, an *umbra* describes a volumetric region that is completely in shadow (i.e. the darkest part of a shadow). A *penumbra* describes a partially shadowed volumetric region that exists between light and shadow. An *anti-umbra* is the opposite of an umbra and describes a region of total illumination. Thus, an *anti-penumbra* is a region of partial illumination. The real difference here is with respect to the occlusion or non-occlusion of light. In the case of an umbra and penumbra, light from a

light source is blocked by an object and some region on the opposite side of that object is shadowed. We can think of this as ‘shadow casting’. With anti-umbras and anti-penumbras, we can think instead of the light as passing through a gap and shining into an area.

Figure 17.37 depicts the concepts discussed. In the top diagram we see an occluder that creates areas of shadow opposite the light source. These areas are marked as umbra and penumbra to describe the shadow characteristics. The bottom diagram demonstrates the concept of light flowing through the gap between two occluders. The light creates an anti-umbra and an anti-penumbra as described above.

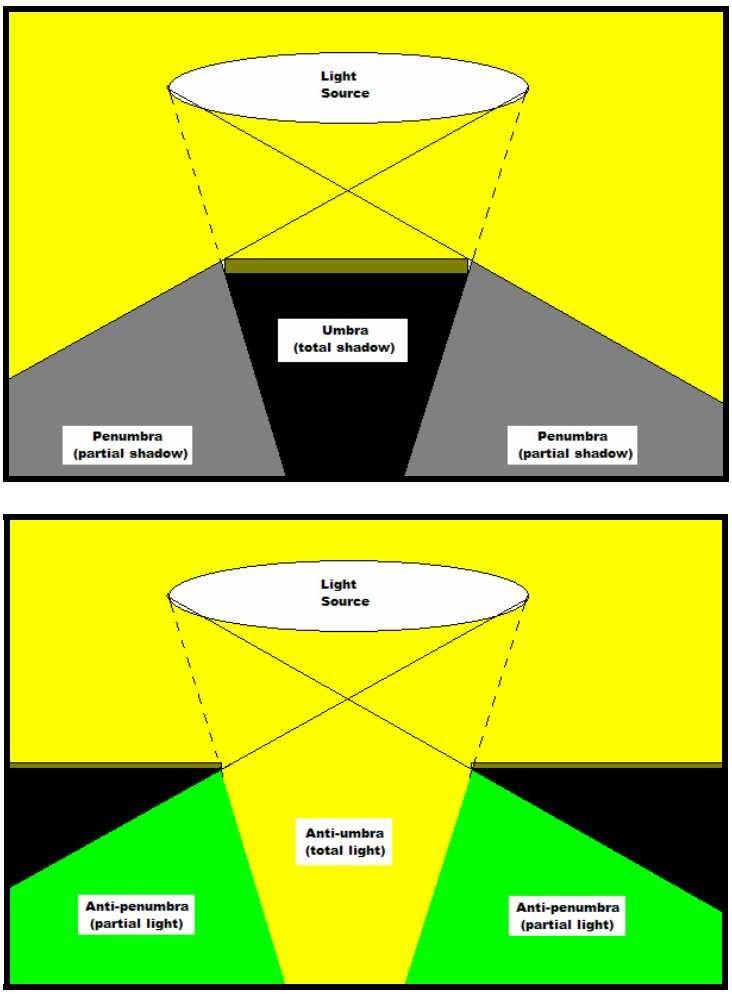

Figure 17.37

For our purposes, the anti-penumbra encompasses the *entire region* where light travels, including the anti-umbra. Thus, by calculating the geometric volume for the anti-penumbra, we are calculating the entire volumetric space where light travelling through a gap can go. Any objects in the anti-penumbra will receive some amount of light. Obviously those directly in line with the light source would be more illuminated, but for our purposes, this is not important. What is important is that from the perspective of the light source, the anti-umbra plus the anti-penumbra represent the total area that can be ‘seen’ (if we take the standard definition that in order for us to ‘see’ something, light must reflect off of it).

So we see that our situation is akin to a doorway between rooms. If one room (A) contains a bright light source and the other (B) does not, so long as the door is closed, B remains dark while A is lit. As soon as the door is opened, light from room A flows into room B and some portion of B is now illuminated. How much of room B is affected depends entirely on the size and shape of the doorway between them, since this is the only means by which light can enter room B.

Some parts of room B likely remain in shadow because they are positioned at such an angle to the doorway that they still remain in the region just outside of the anti-penumbra. So our anti-penumbra describes everything that can be seen in room B through the doorway when standing anywhere in room A. Any areas of B that remain in darkness cannot be seen from room A no matter where one stands in room A because no light has reached them.

Hopefully the applicability of an anti-penumbra to our portals (doorways) between leaves (rooms) is becoming more obvious to you.

17.6.2 Creating Anti-Penumbras

In our PVS system, an anti-penumbra will be constructed using some number of clip planes as we enter each leaf in the recursive process and it will extend between two portals: a source portal and a target portal. Do not worry for now about what portals should be used for the source and target portal; the important point in this section is the realization that building an anti-penumbra from a series of clip planes between the source and target portals will tell us about everything that can be seen from the source portal through the target portal. This is the key idea behind calculating PVS. Before we see this in action, let us first talk about how we build an anti-penumbra between any two portals.

The anti-penumbra is a collection of clipping planes, not unlike those used by D3D to reject geometry outside the viewing frustum. Therefore, although we have used the analogy in an earlier discussion that calculating the PVS is essentially like filling a leaf with light and recording the visible leaves as the ones that get touched by that light, no lighting formulas occur in this process whatsoever. We are simply constructing clip planes to represent the area that the anti-penumbra will touch. Any portals/leaves not inside this collection of clip planes will be considered to be invisible to the source portal.

As we know, to create a plane in 3D space, we require only three points. Our job will be to loop through each edge in the source portal, and for each one of these edges, loop through each vertex in the target portal. With the two vertices from our source edge and the vertex from the target portal we now have access to three points, which allow us to construct a plane. The pseudo-code looks something like the following:

- For Each Vertex In Source Portal (Source Vertex 1)
    - For Each Edge in Target Portal (Target Vertex 1, Target Vertex 2)
        - Create Plane using Source Vertex 1, Target Vertex 1, and Target Vertex 2
        - Is Plane an Anti-Penumbra Clip Plane?
            - Yes -- Add to Clip Plane List
            - No -- Ignore it and move on to next Edge
    - Next Edge in Target Portal
- Next Vertex in Source Portal

This approach obviously generates many planes but only those that are considered to be anti-penumbra planes are added to the clip list -- the rest are ignored. So the important question is “what is an anti-penumbra plane?”

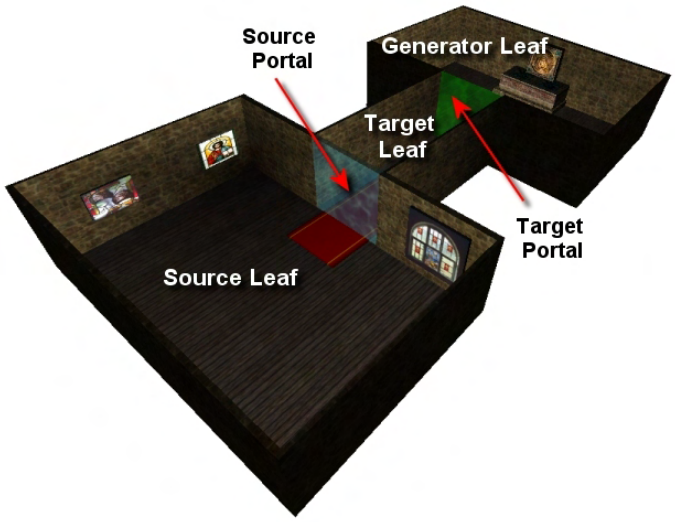

Figure 17.38

A plane will be considered an anti-penumbra plane if it clearly divides the source portal and the target portal. That is, the source portal must be totally on one side of the plane and the target portal must be totally on the other. To show an example of generating an anti-penumbra plane, we will use the simple three leaf construct shown in Figure 17.38. The portal having its leaf visibility information calculated is labeled ‘Source Portal’ in the image. This portal is assumed to be owned by ‘Source Leaf’ and face into the leaf ‘Target Leaf’. The other portal in the target leaf is referred to as the target portal as this is the portal that leads out of the target leaf into the third leaf in the run, the generator leaf. Do not worry too much about why the generator leaf is called what it is at the moment. Just know that for any portal that is current having its leaf visibility set calculated, the source leaf, initial target leaf and the generator leaf will always be visible. This makes sense as the source portal leads directly into the target portal and as such, if you are were located inside the source portal you would always be able to see though this doorway into the target leaf. Therefore, the ***initial*** target leaf of the source portal is always visible.

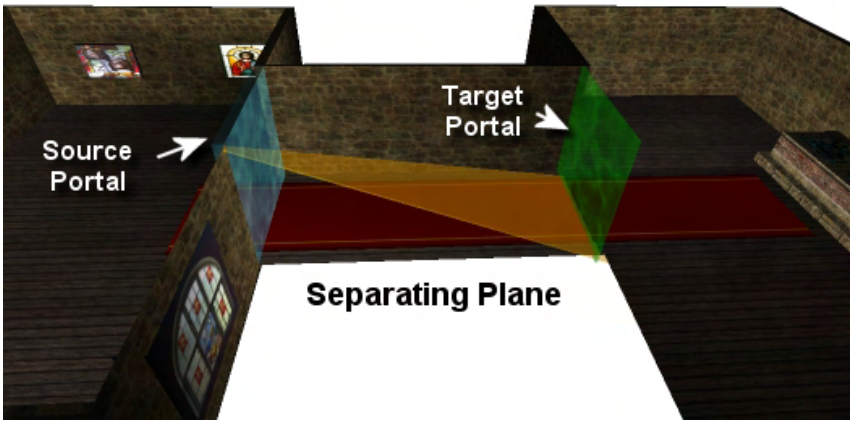

Figure 17.39

Note that we used the word ‘initial’ in the previous sentence as the target and generator portals change throughout the recursive process as we visit different leaves. Similarly, the initial target portal is also always considered visible to the source portal. This is intuitive when we consider that the source portal leads into the target leaf and therefore must have some visibility with respect to the portals leading out of that leaf. Although the target portal will change as we step through each leaf during the PVS calculation process, the source portal will always remain constant as it is the portal currently having its leaf visibility calculated.

The source and target portals are always used to construct the anti-penumbra planes at each step. As mentioned, the construction of the anti-penumbra involves finding all planes that separate the source and

target portals into two separate halfspaces. This is done primarily by looping through each vertex in the source portal and each edge in the target portal and creating a plane from these three points. The two portals are then classified against this plane and considered to be an anti-penumbra plane only if the classifications of each portal are different. In Figure 17.39 we can clearly see a separating plane being created from the top left vertex of the source portal and the bottom edge of the target portal. If we consider the plane normal to be facing upwards, the source portal is clearly in the backspace of the plane and the target portal is in its front space. This is a valid anti-penumbra plane.

In Figure 17.40 we see another plane being constructed from the same vertex in the source portal and the top edge of the target portal. Assuming the normal of this plane is pointing upwards in this image, we can see that both portals exist in the backspace of the plane and therefore this is not a separating plane. This plane would be rejected from the anti-penumbra generation process as it does not describe any extreme visibility angle between the source and target portal.

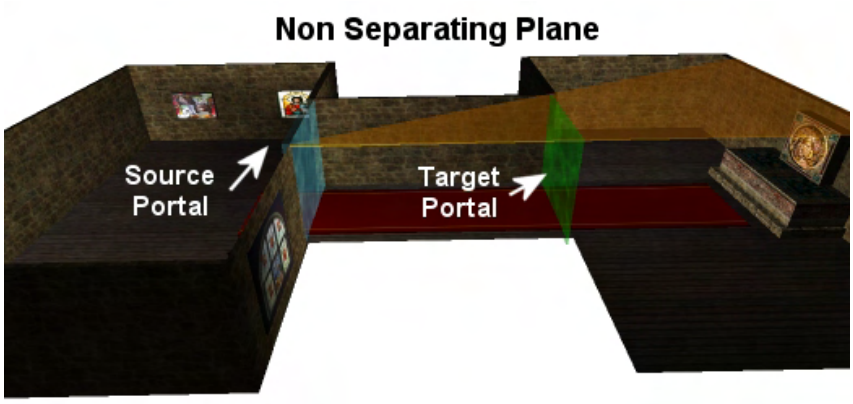

Figure 17.40

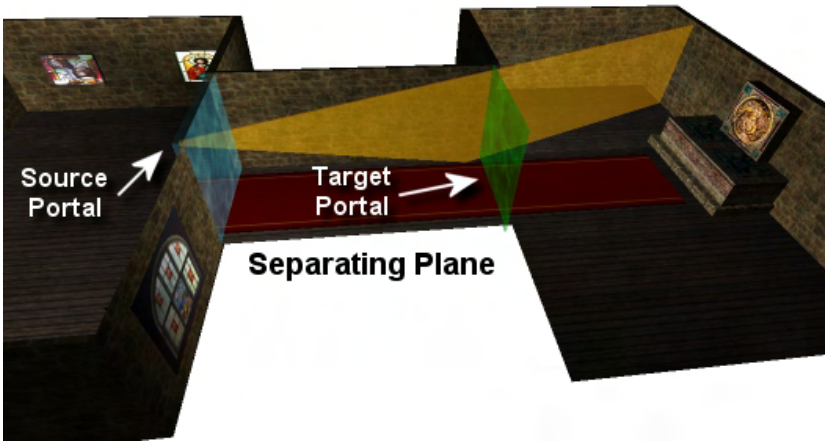

Figure 17.41

In Figure 17.41 we test another plane using the same vertex in the source portal and the far edge of the target portal. Assuming the normal is facing away from us in this example, we can see that the source portal would be contained in the plane's frontspace and the target portal in its backspace. This clearly makes it a separating plane as it describes the extreme viewing angle that can be experienced from the near side of the source portal though the far side of the target portal. This plane would be considered a valid anti-penumbra plane and would be added to the list of clip planes that will be used later for the rejection of portals in the generator leaf.

Finally, we show one more example of a separating plane so that we are in no doubt as to exactly how the anti-penumbra planes should be constructed. In Figure 17.42 this time we use the near bottom vertex of the source portal and the two vertices that form the far edge of the target portal. Assuming the normal is facing away from us in this example, the source portal would be contained in the plane's frontspace and the target portal is contained in the plane's backspace.

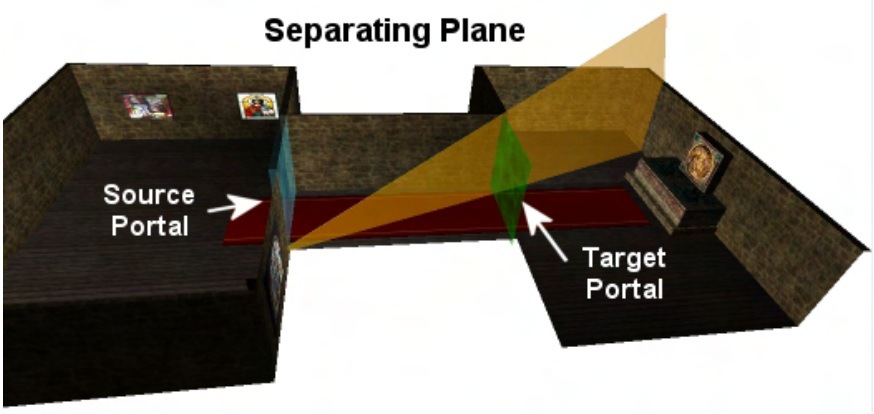

Figure 17.42

When building this view volume from the source portal to the target portal we create planes from every vertex in the source portal to every edge in the destination portal. The result is many accepted planes which describe the extremities of what can be viewed from the source portal through the target portal and into what is called the *generator leaf*. The generator leaf is always the leaf which the target portal leads into. It is the leaf in which the anti-penumbra planes form the volume for which everything inside is considered to be visible from the source portal. To get the general idea across more clearly we see a simplified anti-penumbra constructed using only two planes in Figure 17.43.

In this example we can see that the formation of the planes as they enter the generator leaf describe everything that can be seen from any position in the source leaf. The target leaf is always visible to the source portal as this is the leaf the portal leads into.

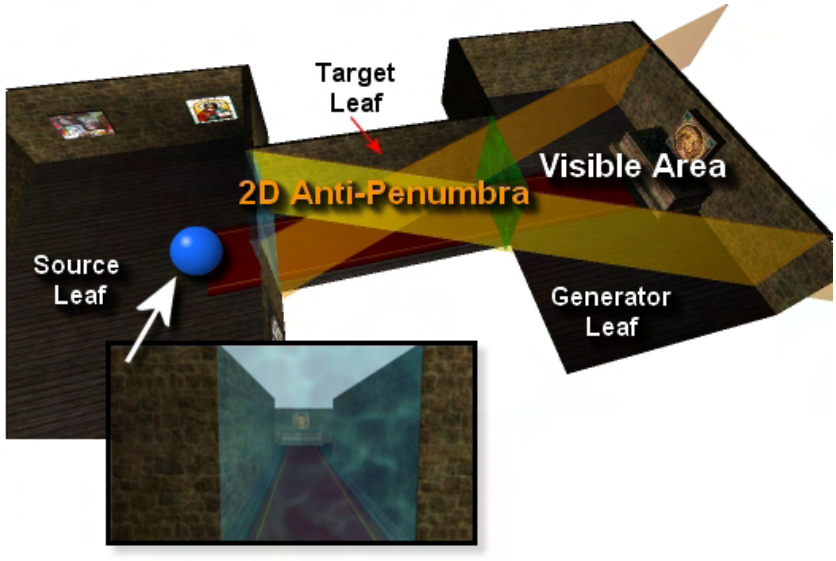

Figure 17.43

In Figure 17.43 the blue sphere represents a potential viewing position where the camera may be located at run time. The square inset in the image shows what can be seen from this point of view. As you can imagine, if the sphere was moved slightly to the left or right it would increase what can be seen in the generator leaf to the left and right of the target portal, respectively. The formation of the anti-penumbra planes in the generator leaf completely and conservatively bound this region so that any area inside those planes is always considered visible. Although we will examine the recursive process in a moment, it is worth noting that if any portals exist in the generator leaf, we recur through the portal into that leaf. No portals are in the generator leaf in this example, but if there were and they were contained inside the anti-penumbra, it means that this doorway is visible (potentially) from the source portal and we should step through that portal and into its neighbour leaf. That neighbour leaf is then considered visible from the

source portal. If a generator portal is outside the anti-penumbra in the generator leaf, we do not have to step through that portal and into its neighbour leaf. It is intuitive that if the doorway into the leaf cannot possibly be viewed from the source portal, then the leaf on the other side of that doorway cannot possibly be visible either.

If portals are located in the generator leaf we refer to them as *generator portals*. This is because, if they do fall within the anti-penumbra, another recursive step is 'generated' as we step through that portal and into its neighbour leaf (marking the neighbour leaf as visible). When we recur into the neighbour leaf of a generator portal, the leaf on the other side becomes the new target leaf and what was previously the visible generator portal becomes the new target portal and the anti-penumbra is constructed all over again between the source portal and the new target portal. The portal in this new leaf then becomes the new potential generator portal and the process continues until we step into a leaf where no generator portals exist inside the anti-penumbra. At this point we have exhausted the visibility of the source portal along that path of portals. We will look at some examples of this entire recursive clipping process in a moment.

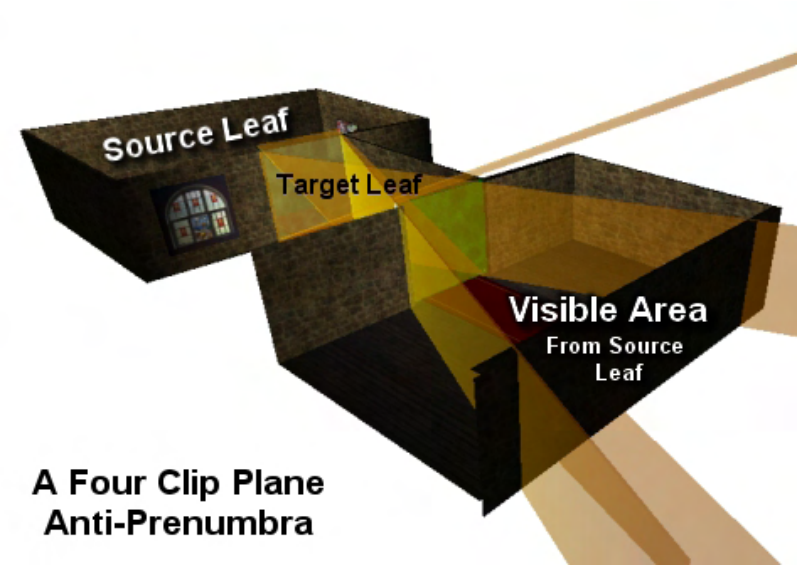

Figure 17.44

To give you a more three dimensional idea of what the anti-penumbra looks like in the generator leaf, we see a four plane example in Figure 17.44. Of course, the real anti-penumbra would have many more planes than this, but it gives us a good idea about the viewing volume created in the generator leaf. Any portals in the generator leaf that lay behind all of these planes are inside the anti-penumbra and should be stepped into.

The reason why we generate planes from every vertex in the source portal to every edge in the target portal is that, while it may generate many duplicate (or nearly duplicate) planes, it makes sure that we get the tightest clip planes possible from that combination. However, there is more we can do to generate more clip planes that may produce some even tighter clip planes. This will allow us to shave off a little excess visibility that may be represented in the generator leaf by the anti-penumbra clip plane.

To get the tightest planes possible for our anti-penumbra, after we have tested every combination of vertices in the source portal with edges in the target portal looking for candidate planes, we can then search for clip planes the other way around as well. That is, we can test every vertex in the target portal against every edge in the source portal. In the above example this would generate the exact same planes and would therefore seem a little pointless. However, there is nothing that guarantees that the portals will be quads (they most likely will not be). Furthermore, the source and target portals may not even be the same shape. Therefore, if we also do the plane collection process in the reverse direction as well (target to source), we will end up possibly generating some unique planes that were not generated the

other way round. These planes may provide a slightly tighter clip. As Figure 17.45 shows, if two portals are different shapes, a completely different set of planes can be generated by reversing the order.

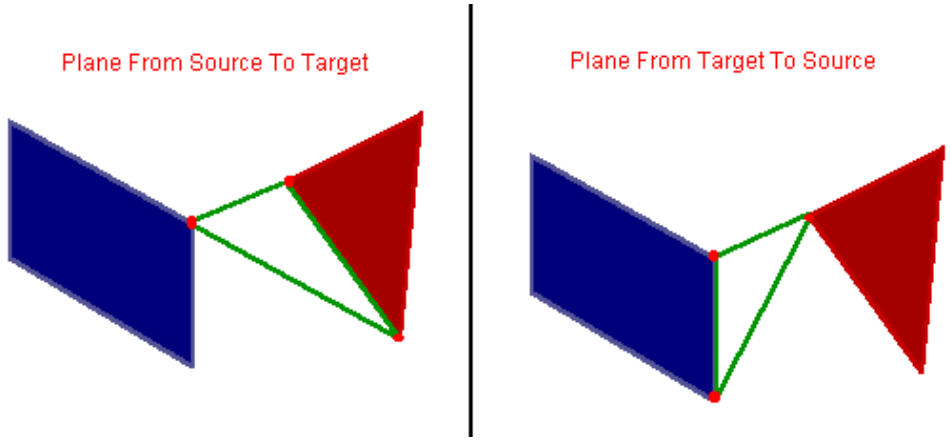

Figure 17.45

We can see in this example that creating a plane from the top left vertex of the quad and the bottom edge of the triangle portal is very different from the plane created using the far vertex in the target portal (the triangle) to the near edge of the source portal.

We now have a very good understanding of what the anti-penumbra is and how it will be constructed. Ultimately, it represents a visibility volume which describes what can be seen from the source portal through the target portal.

17.6.3 How Anti-Penumbras Determine Portal Visibility

Taking all of the previous optimizations out of the equation for the moment, the process of calculating the PVS is one of walking through the leaves of the tree and marking any leaves that we recur into as visible from the current source portal. Every portal is given its turn as the source portal when the time comes to calculate its visibility set. In this section we will step through a very small example that shows the recursive process involved in calculating the leaf visibility set for a single portal.

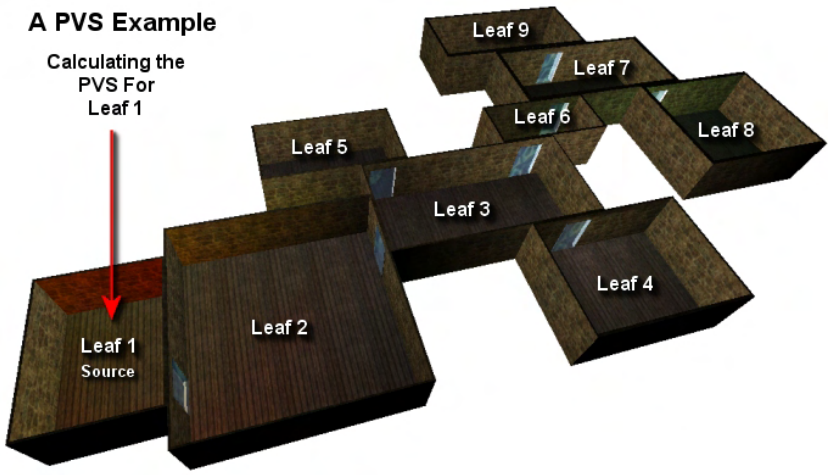

Figure 17.46

In Figure 17.46 we show some example geometry where each room is assumed to be a leaf for the purpose of explanation. The portals are shown as the blue doorways that connect the rooms. In our

following examples we are going to calculate the visibility set for the source portal. This is the only portal leading out of leaf 1 in the diagram. Incidentally, since this is the only portal in leaf 1, we also know that the leaf visibility set we calculate for this portal will also be the leaf visibility set for the source leaf.

When we first enter the recursive process, we know only the location of the source portal. Our first step is to fetch the index of the neighbor leaf from the source portal which will give us the target leaf (shown in Figure 17.47). In the target leaf we enter a loop that will build an anti-penumbra between the source portal and each target portal contained in that room. We then step through that target portal and determine which portals in the generator leaf are within the anti-penumbra and should be stepped through. In this example, there is only one portal in the target leaf, so this is the single target portal we must process. Having located the source and target portals we then construct the anti-penumbra between them as shown in Figure 17.47. These clip planes form a viewing volume in the generator leaf against which all portals in that leaf must now be tested.

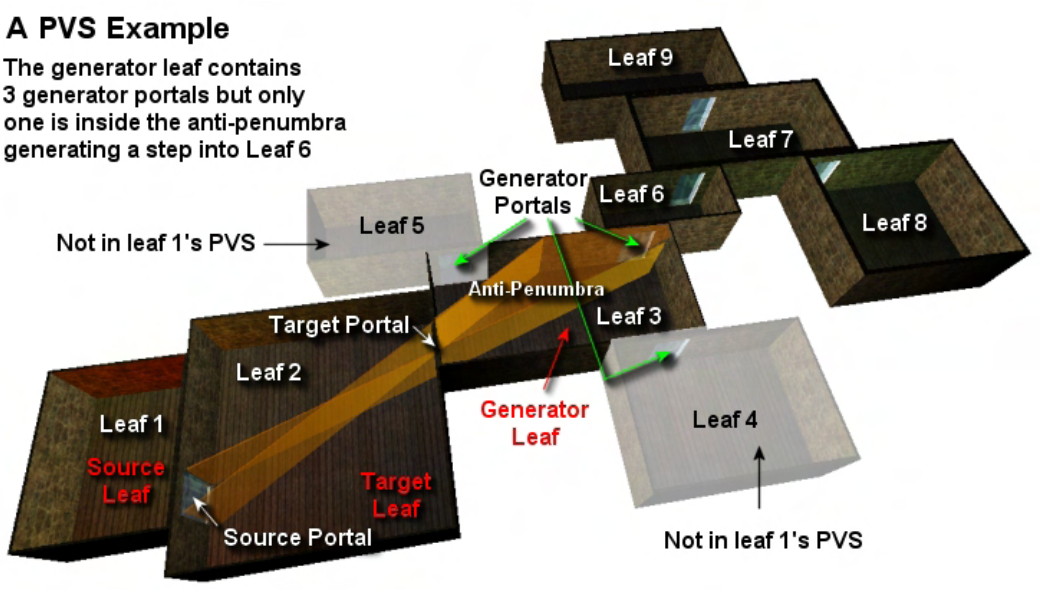

Figure 17.47

> **Note:** Any leaf we step into is instantly marked as visible in the source portal's visibility set. Thus, so far in our example, the target leaf and the generator leaf would have been added to the source portal's PVS.

We must now examine what happens in the generator leaf in Figure 17.47. The generator leaf is leaf 3 in the diagram and it has three portals (referred to as generator portals at this stage) which lead to leaves 4, 5, and 6. Each portal in the generator leaf is tested against the anti-penumbra clip planes and any portals that lay outside the anti-penumbra are considered invisible to the source portal and are ignored. This means that we will never step through these portals into leaves 5 and 6 and thus, we have just rejected leaves 5 and 6 from the source portal's (and therefore the source leaf's) visibility set.

Notice however, that the portal that leads to leaf 6 is contained inside the anti-penumbra. Therefore, we have to step through that portal. Since each portal has stored the index of its neighbor leaf, this will tell us that we need to step into leaf 6 next. When we step into leaf 6, the process repeats again, as shown in figure 17.48. However, when we enter the generator leaf, this becomes the new target leaf and the portal we just stepped through (the generator portal) becomes the new target portal via which a new anti-penumbra is constructed with the source portal.

As Figure 17.48 shows, once we have stepped through the generator portal into its neighbor (leaf 6), leaf 3 (the previous generator portal) becomes the new target leaf and any portals that previously passed the visibility test in the generator leaf become the new target portals. In this instance, where only one of leaf 3's portals was found to be visible in the previous recursion, the portal we stepped through into leaf 6 (i.e., the previous generator portal)

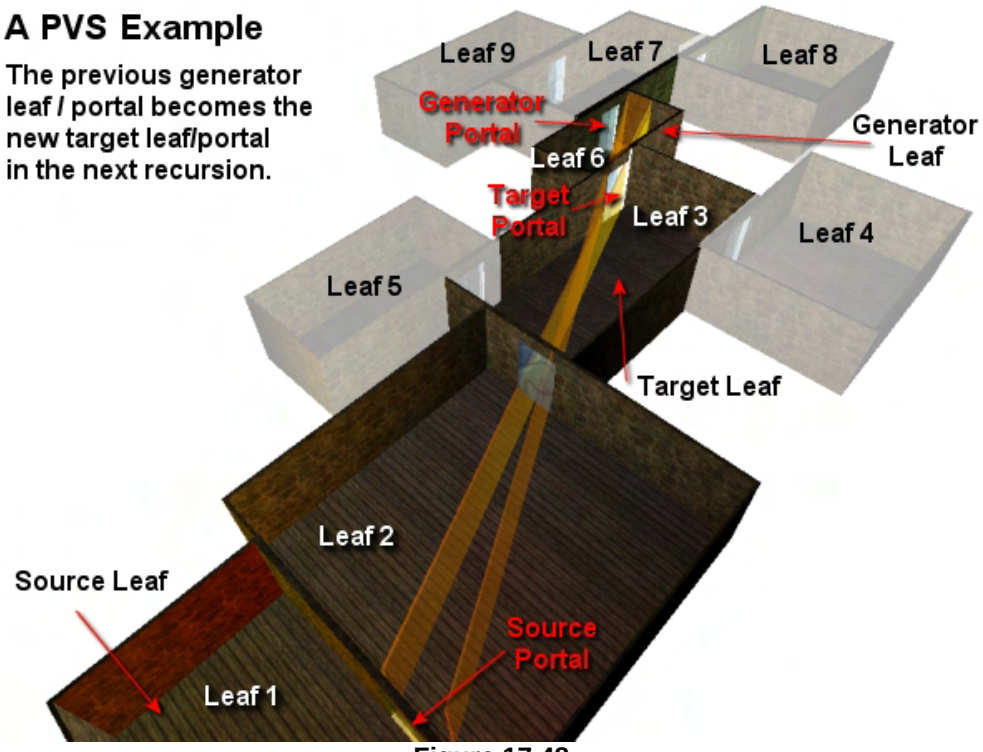

Figure 17.48

becomes the new target portal. In this second step, the anti-penumbra is constructed all over again between the source portal and the new target portal (which was the previous generator portal) which leads us from leaf 3 into leaf 6. Leaf 6, which we have just stepped into, has become the new generator leaf and, as we can see in Figure 17.48, the new source/target portal combination has generated an anti-penumbra that creates a view volume in this leaf. Our next step is to loop through each generator portal in the new generator leaf (leaf 6) and test them for inclusion in the anti-penumbra. Any portals that are contained or partially contained in the anti-penumbra are stepped through and become the new target portal in the next recursion. This same process continues until we step into a generator leaf where no portals are found to be inside the anti-penumbra and the recursion stops along that path. Remember, every visible portal in a given generator leaf has its chance at being a target portal, so you can imagine the high number of recursive iterations that can occur when determining everything that can be seen, even by a single portal.

As can be seen in Figure 17.48, as we stepped into leaf 6 and added it to the source portal's PVS, we found that none of its portals are contained inside the anti-penumbra. Therefore, we never recur into leaves 7, 8, and 9 and they are never added to the visibility set for the source portal. The final visibility set for the source portal in this example would contain leaves 1, 2, 3, and 6. This same process would be repeated for every portal in the level (i.e., every portal would have a chance at being the source portal for the calculation of its PVS).

So to summarize:

Because of the fact that BSP trees have convex leaves, we always know that the leaf on the opposite side of our source portal (i.e., the target leaf) is always visible. We then test each portal in the target leaf

(which we call target portals) and provided that the target portal is not on the same plane as the source portal, it too is always visible from the source portal.

> **Note:** If a target portal is on the same plane as the source portal, then we just ignore it.

If the target portal is visible, then it is obvious that the leaf on the other side of the target portal is also visible (Leaf 3 in our example). This leaf is called a *generator leaf* and it is where the recursive process begins for this current source/target leaf combination. Any portals in the generator leaf (called generator portals) that fall within the anti-penumbra are considered visible. Conversely, generator portals that are outside of it are ignored and not stepped through. Once we have the PVS for every portal in a given leaf, it is a simple matter to find the leaf's PVS. For example, the source leaf can see everything that the source portal can see. Therefore, *a leaf can see everything that all of its source portals can see.*

We now have some understanding of how a PVS calculator begins to calculate the PVS for a given portal. For every source portal in the source leaf, we create an anti-penumbra with every target portal in the target leaf. However, it is vitally important to make the anti-penumbra as small as we possibly can at each step as this allows us to refine our PVS set. If the anti-penumbra planes describe a view volume in the generator leaf that is unnecessarily large, it is possible that some generator portals will be stepped through that are not actually visible from the current source portal. This will make the source portal's (and therefore the source leaf's) PVS unnecessarily generous, which is not something we want.

We can refine the PVS by taking into account the fact that each generator portal that falls within the anti-penumbra at a given step in the process will become the target portal that is used to build the anti-penumbra in the following step. Therefore, if in the previous step only half the generator portal was contained inside the anti-penumbra, we can clip the generator portal (a copy of it) and build the anti-penumbra in the next step using this clipped version.

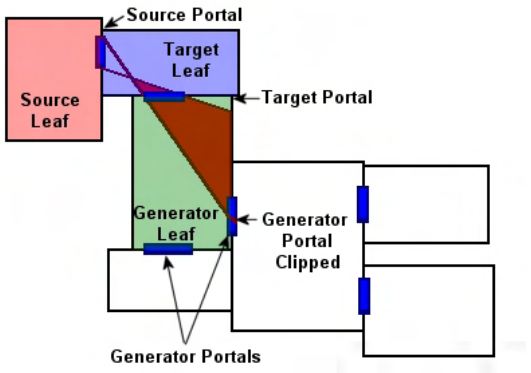

Figure 17.49

In the next step, the target portal (which was the clipped generator portal in the previous step) will be smaller, resulting in a smaller, less spread out anti-penumbra. This may allow us to reject portals in the next step that we would have otherwise had to have visited. To demonstrate this recursive generator portal procedure, we will look at an example from a top down view. The 2D nature of the following diagrams will help clarify what is actually happening.

We show the first step in the process in Figure 17.49. As discussed, the source, target and generator leaves are all marked as initially visible from the source portal in the first step. The clip planes (i.e., the anti-penumbra) are built from the source portal to the target portal. This describes how much of the generator leaf is visible through the target portal when viewed from the source portal. Of the two generator portals in this example, only one is partially within the clip planes. The portal outside anti-penumbra is ignored and will not be processed. The other portal is partially inside, so we clip away the part of the generator portal that is outside the anti-penumbra so we are left with just the fragment that is within the clipping volume. Because the generator portal is partially visible, it means that the leaf on the other side of this portal is also visible. We mark it as such by adding it to the source portal's PVS.

Next, this new leaf becomes the new generator leaf and the old generator leaf becomes the new target leaf. That is, the old (clipped) generator portal becomes the new target portal. So we now build a new anti-penumbra from the same source portal to the new target portal (the old generator portal that was clipped) which fully describes what volume in the new generator leaf is still visible. As we recursively move from leaf to leaf doing this (making the old generator portal the new target portal and rebuilding the anti-penumbra), clipping each generator portal to the anti-penumbra, the anti-penumbra gets smaller and smaller with each iteration until, in the end, no portals in the current generator leaf are inside. Because the generator portal is partially visible, it means that the leaf on the other side of this portal is also visible. We mark it as such by adding it to the source portal's PVS. The generator portal is also clipped, which leaves only a very small portal fragment (see Figure 17.50) surviving that will be used as the target portal in the next step.

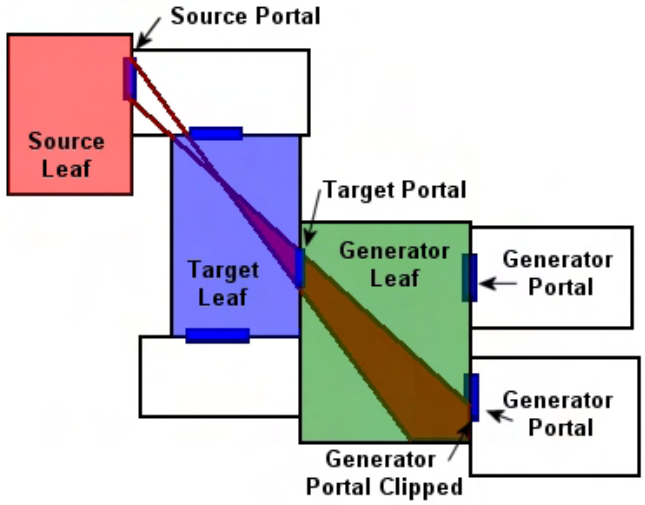

Figure 17.50

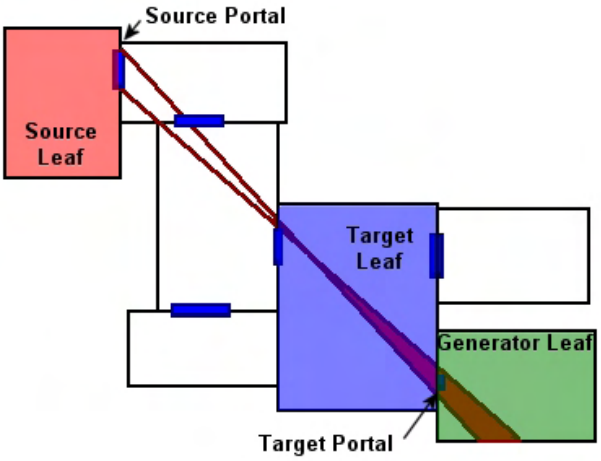

Figure 17.51

Next, this new leaf becomes the new generator leaf and the old generator leaf becomes the new target leaf. That is, the old generator portal becomes the new target portal. So we now build a new anti-penumbra from the same source portal to the new target portal (the old generator portal that was clipped) which fully describes what volume in the new generator leaf is still visible. As we recursively move from leaf to leaf doing this (i.e., making the old generator portal the new target portal and rebuilding the anti-penumbra) and clipping each generator portal to the anti-penumbra, the anti-penumbra gets smaller and smaller with each iteration until, in the end, no portals in the current generator leaf are inside.

17.6.4 Generator Portal Visibility

One of the last things we have to cover before looking at code is how to determine whether or not a generator portal is within the anti-penumbra volume. It turns out that this process is very easy. Figure 17.52 shows that the gray areas that are not visible are on the same side of the clip plane as the source portal.

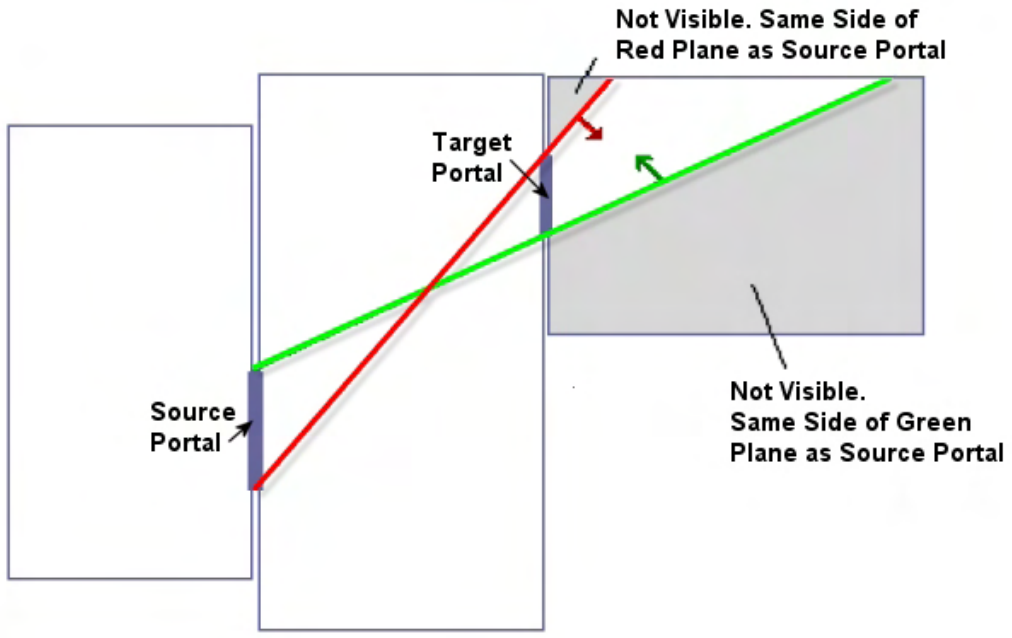

Figure 17.52

Our strategy is now pretty clear. We will check each generator portal against each clip plane of the anti-penumbra and if it is on the same side of the plane as the source portal, then it is not within the anti-penumbra and it can be rejected. This means that we will no longer need to recur into the leaf on the other side of that portal. Conversely, if a generator portal is on the opposite side of the plane with respect to the source portal, then it is within the anti-penumbra and should be tested against the other planes in the anti-penumbra. If a portal is spanning the plane, then it will be clipped to the plane, keeping the piece that is on the opposite side of the plane with respect to the source portal. Thus the entire PVS process is essentially one long recursive clipping process.

Unfortunately, while PVS is just a recursive clipping algorithm, our implementation will require some thought. Just doing a recursive clipping process can be quite slow. For example, the code optimizations we will study in this lesson were able to take a sample level that previously needed 12 minutes to compile a PVS down to a process that completed in only a few seconds.

The problem with the PVS process is that it is very CPU intensive, especially on very large data sets. The key to solving this problem is a little bit of pre-processing to eliminate portals or leaves that could not possibly see one another. This allows us to bail out of certain processes much earlier because we know for sure that nothing beyond a given portal can be seen. For example, imagine that a portal had 1000 portals behind it. If we could tell for sure, before we even started doing the PVS clipping, that

nothing behind this portal could ever be seen, then we could eliminate thousands of clipping and splitting operations and shave minutes or possibly hours off the compilation time.

As briefly discussed earlier in this section when we reviewed the system components we intend to develop, we are going to write some functions that will be called prior to the actual recursive anti-penumbra clipping process that forms the core visibility processor. These routines will be used to trivially reject portals and leaves that we know for sure cannot be seen before the process even begins based on their orientations to one another. However, before we can look at this code, we need to understand the concept of *portal flow*.

17.6.5 Portal Flow

Currently, the problem with our master portal array (populated during the portal generation process) is that although we know which two leaves a portal resides in, we have what is in effect, a two-way portal. The fact that the portal is 'owned' by both leaves can lead to problems during the recursive process. To illustrate this, imagine that you have a portal that acts as the doorway between leaves 5 and 6 and that our PVS calculator uses this portal to step from leaf 5 into leaf 6 during the recursive clipping process. Once we reach leaf 6, we will then need to loop through and traverse though each of Leaf 6's portals. But we need to avoid going back through the portal we just entered so that we do not get caught in a recursive loop. Obviously this issue in and of itself is trivial and easily solved using flags or other such concepts, but remember that we also want to be able to reject portals from our process *before* we even begin our recursive PVS calculations. The easiest way to do that and to solve our recursion problem simultaneously is to use *one-way portals*.

One-way portals allow us to instantly discard any portals from consideration that point in opposite directions or that are situated behind the current source portal being processed. In short, they allow us to determine, prior to the core recursive clipping process, which portals cannot possibly be viewed from each other portal, thus minimizing the amount of testing that will need to be done in the core processor. It is very important that we remove every test we possibly can from the core recursive procedure as it is going to be executed many thousands of times for each source portal. Moving such tests out of the main clipping process can literally shave hours off the final compile time.

A one-way portal is a portal that will only allow entrance or exit in one direction. In our example, we may have a portal that leads from Leaf 5 to Leaf 6, but that portal cannot be used to step from Leaf 6 back into Leaf 5. It resides only in Leaf 5 and will not be considered one of Leaf 6's portals. One-way portals are set up so that, while they are 'owned' by one leaf only, they also contain a variable describing the Neighbour Leaf. The OwnerLeaf is the leaf in which the portal resides and the Neighbour Leaf is the Leaf that the portal leads into when stepped through from the owner leaf. The normal of the one-way portal points into the neighbour leaf, so we can enter through the back of a portal and come out in the neighbour. This is an important point to remember so it bears repeating: **a portal directs the recursive flow from the owner leaf into the neighbour leaf**.

From a practical perspective this means that we will have to have twice as many portals as we originally generated in our master portal array. Using our previous example of a portal owned by both leaves 5 and 6, we will now have to duplicate it so that there are actually two one-way portals instead of one bi-

directional portal. One portal is assigned to Leaf 5 and directs flow into Leaf 6, and that the other will be assigned to Leaf 6 and direct flow into its neighbour leaf, Leaf 5. The result is that we have two portals at the same location in 3D space which direct flow in opposite directions (into the respective neighbour). The generation of this one-way portal array will be the first step taken in the PVS calculation process.

In order to do this we are going to need a new portal structure (we will call it PVSPortal for the sake of our placeholder code discussions) that will be used to represent these temporary one-way portals for the life of the PVS calculation. We must copy over the portals from the original portal list, duplicate them, and then adjust them to fit with the new data requirements required by the PVS calculator. Since each original portal will now be represented by two PVS portals, we will need to create a new array that has enough room for NumberOfOriginalPortals * 2 elements.

Here is our new portal structure.

```
class CPVSPortal
{
public:

    // Constructors / Destructors for this Class
             CPVSPortal( );
    virtual ~CPVSPortal( );

    // Public Variables for This Class
    UCHAR             Status;              // The compilation status
    UCHAR             Side;                // Which direction does it point
    long              Plane;               // The plane on which this portal lies
    long              NeighbourLeaf;       // Leaf into which this portal flows
    long              PossibleVisCount;    // The size of the PossibleVis array
    UCHAR            *PossibleVis;         // "Possible" visibility information
    UCHAR            *ActualVis;           // "Actual" visibility information
    bool              OwnsPoints;          // Does this own the points ??
    CPortalPoints    *Points;              // The vertices making up this portal

};
```

Although the actual source code that we use will be discussed thoroughly in the accompanying workbook, understanding this structure and its members is necessary before examining the code snippets that we will discuss in this chapter. Indeed understanding this structure will play a critical role in understanding the whole compiler works. Therefore, we will discuss the members of this portal structure now. We will review them in a different order to how they are listed in the above structure, in a way that will make the description of each easier to follow.

CPortalPoints *Points

The first member is a pointer to CPortalPoints structure (shown below). This is a simple container for the vertex list and number of vertices. Actually, it is derived from a CPolygon and in a sense is the actual portal itself. We derive from CPolygon so that we can give the portal polygon some new members that pertain to the portal clipping process. The class includes both a Split and Clip function that allows us to split/clip the portal's points to the plane.

```
class CPortalPoints : public CPolygon
{
public:

             CPortalPoints( );
             CPortalPoints( const CPolygon * pPolygon,
                            bool Duplicate = false );
    virtual ~CPortalPoints( );

    CPortalPoints *     Clip( const CPlane& Plane, bool KeepOnPlane );

    virtual HRESULT     Split( const CPlane& Plane,
                               CPortalPoints * FrontSplit,
                               CPortalPoints * BackSplit);

    bool                OwnsVertices; // Are the vertices owned
    CPVSPortal         *OwnerPortal;  // Points to parent portal ;)

};
```

The OwnsVertices Boolean will be difficult to explain at the moment since we have not seen how the clipping process works. For now, let us just touch on it lightly. We know that when performing the recursive clipping process for a given source portal, we will want to clip generator portals to the anti-penumbra. However, we must remember that we will not want to delete the actual master CPVSPortal created at the start of the process as this will be needed by other source portals. So at each recursive step copies of the generator portal are created (from the original) and are passed through the clipping process. If any of these copies get clipped, new temporary portals will be created which own their own vertices and the original copy (created from the master CPVSPortal) will be deleted (just as we always delete the original polygon when it is split). However, to save memory in places where clips do not happen, copies can share the vertex array with the parent they were copied from and as such, new vertices are only generated when the portal copy actually gets clipped. However, at the end of the recursive procedure the copies are discarded. If the copy has not been clipped, then it will still share a vertex pointer with the master CPVSPortal it was copied from and as such, the copy's destructor must know under these circumstances not to delete the vertex array shared with the original PVS portal. That is what the OwnsVertices flag indicates. If it is set to false then it means that the portal is sharing its vertex array with another portal (to conserve memory) and as such, when it is deleted, its vertex array should not be freed from memory.

The OwnerPortal points to the CPVSPortal structure that owns this CPortalPoints structure.

bool OwnsPoints

When we create the CPVSPortal array will create two one-way portals from every original two-way portal. Because these portals will be geometrically exactly the same, with the exception that they have swapped Owner/Neighbor leaves, it would be wasteful if each duplicate stored its own copy of the portal polygon (CPortalPoints). Therefore, each duplicate pair will share the original vertex winding of the original polygon. As an example, this means that while N original portals will be converted into N*2 CPVSPortal structures (i.e., one-way portals), only N portal polygons (CPortalPoints) will be in

memory. As with the OwnsVertices member of the CPortalPoints class, only one of the duplicates will own the CPortalPoints and the other will just share a pointer to it. Only the owner will delete the CPortalPoints object when it is destroyed.

long Plane
This is where we store the portal plane. It will be populated when the CPVSPortal array is first created using the original two-way portal. Each pair of duplicates will share this same plane as it is the plane of the node on which the portal was created. This will be the index of the node stored in the original portal's OwnerNode member.

The node plane is stored in the portal because, as we will see in a moment, during the recursive clipping process, we often have to clip the generator portal to the source portal's plane if the generator portal is spanning the plane of the source portal. This helps narrow the anti-penumbra and also allows us to avoid inverting the anti-penumbra when that generator portal becomes the next target portal. We also have to do the same in reverse and clip the source portal to the plane of the generator portal if the source portal is spanning that plane. Although we will see why this is important later, just know for now that if this step is not taken, the anti-penumbra can essentially become inverted causing endless recursive loops.

It is fairly clear then that if we may need to clip other portals to the plane of a portal, each portal will have to store the plane on which it lies so that it can be used for the clipping operation. It should be noted however that both of the duplicate portals will store the same node plane even though they are supposed to be facing in opposite directions. This is not a problem since we will also store (in the CPVSPortal structure) whether the duplicate is considered to be facing in the opposite direction to the plane normal (one of the two always will be). With this information we know when processing such a portal, that the same plane can be re-used by the clip operation. The difference would be that any fragments of other portals that lay in front of the clip plane are removed instead of fragments that lay in the plane's backspace as is usually the case.

UCHAR Side
As each pair of portals duplicated from the original source portal will share the same plane, we will store in this variable either FRONT_OWNER or BACK_OWNER indicating whether the duplicate is facing in the same direction as the plane or in the opposite direction, respectively. This will come in very useful later in the clipping process when other portals have to be clipped to that portal. If the portal has a Side member set to FRONT_OWNER then it means this duplicate faces in the same direction as the original plane normal and as such, any portal fragments that exist in its backspace should be clipped. If the duplicate has BACK_OWNER stored instead, then it means this is the portal that has had its direction flipped from the original portal and as such is facing into the opposite halfspace with respect to the plane normal. When this is the case, our code will know that any portals that have to be clipped to its plane should have the clip operation flipped so that only fragments in the plane's front space survive. We will see this being used later in the core processor.

long NeighbourLeaf
This member will store the index of the leaf that the one-way portal leads into (i.e., the leaf which its imaginary normal is supposed to be facing into). We enter the neighbor leaf from the owner leaf by passing through the back of the portal. Notice that we do not actually have to store which leaf the portal is owned by within the CPVSPortal structure. The leaf itself will store this information and we do not

need it when doing the visibility tests. This is because we will calculate a visibility list for each portal (i.e. which leaves can be seen from a portal) and the owner of the portal is not needed until the very end of the process when we loop through all of the portals in a given leaf. Just remember that a leaf can see all of the leaves that all of its portals can see. This means that a leaf's PVS is really nothing more than the union of all of its owned portals' visibility sets.

UCHAR *PossibleVis

This is an array of bytes, where each leaf is represented by one bit. Therefore one byte holds the visibility information for eight leaves for this portal. One of the first functions we will write will be called InitialPortalVis and it will be used to quickly reject any portals that cannot possibly be seen. Our goal will be to loop through every portal and check every other portal against it. If a portal is behind the current portal being processed then there is no way the current portal can see it. In this case, we set the appropriate bit in its PossibleVis array to zero, otherwise, we set it to one. At the end of this process, we will have an array of bits in each portal describing only the portals that can possibly be seen. Portals for which no portal flow could ever happen have their bits set to zero in that portal's PossibleVis array. This process is extremely cheap to execute and will allow us to reject many portals before we even start the PVS processing. Although the PossibleVis array is not very accurate, it does allow us to check if a portal can be seen during PVS calculation. If it cannot, then we can just skip it, thus saving many clipping operations and speeding up the overall process. We can think of the PossibleVis array as being a very coarse leaf visibility set for the portal which will be refined and stored in the portal's ActualVis array (described next) when it has had its PVS fully calculated.

UCHAR *ActualVis

This member is an array of bytes which will contain the actual visibility information when the whole recursive PVS process has finished for a particular portal. Remember that PossibleVis is only used to reject portals that obviously cannot be seen, but many hundreds of leaves that did pass the PossibleVis test will be clipped out during the more precise recursive process and thus are not visible from the current portal in the end. So while PossibleVis allows us to cut down on the number of portals that will need to be tested during the recursive clipping phase, ActualVis will contain an even further reduced set than is found in the PossibleVis array. It is the ActualVis array which ends up containing the final leaf visibility set for the portal. When all portals have had their ActualVis arrays calculated, the PVS calculator is complete and its final job is to loop through each leaf and union the ActualVis arrays of each portal contained in that leaf. This will describe the PVS of each leaf, which can then be packaged together into a single array and dispatched to file. This combined block of leaf PVS data is what we refer to as the PVS for the entire scene.

long PossibleVisCount

This member will contain the number of visible leaves that were found during the initial population of the portal's PossibleVis array. For example, if the PossibleVis array determined that there are 25 portals that this portal might be able to see, this member will be set to 25 for that portal. We will see later that this allows us to select the order in which we generate the actual PVS for each portal such that we start with the portal that can see the fewest leaves first. This helps speed up the process so that more complex portals (i.e., portals that have higher visibility) can borrow information from the less complex portals which may have already had their PVS calculated. This will make more sense later.

UCHAR Status
This member tells us if a portal has already had its ActualVis array calculated. You will see how to use this flag later, but just know that it will help us refine and speed up the PVS process. Remember that our goal is to design an algorithm that has as many early-out options as possible to keep our PVS calculator running at a tolerable speed.

We now have a good understanding of the structure that will be used to store our one-way portals during the PVS calculation process so we can start to examine the coding process involved in writing the PVS calculator. We will begin with the creation of the one-way portals.

17.7 Coding a PVS Calculator

Before we start looking at each function that comprises the PVS calculator in detail, let us first run through a high level overview of the functions involved and discuss when they will be called and what task they will be expected to perform. This should keep everything in perspective as we move forward.

ProcessPVS

We will assume during our code discussions that this is the only function that needs to be called after tree and portal generation. It is the top level function responsible for calling all of the other functions in the PVS calculator (described below). When this function returns, the PVS will be generated and we will have a block of zero run length encoded data that describes the visibility of every leaf in the level.

GeneratePVSPortals

This is the first function called by CalculatePVS and it is responsible for allocating our new CPVSPortal array and copying the original portals into it. This function does everything that we just talked in the last section; it takes one portal from the original master portal array, creates two opposite portals from it, and assigns them to each leaf. At the end of this function we will have a new portal array to work with (called pPVSPortals) that will be twice the size of our original bi-directional portal array. Each portal in the array only flows one-way -- into the neighbour leaf.

InitialPortalVis

This is the second function called from ProcessPVS and it is used to fill out each portal's PossibleVis array with a very approximate PVS. If portal B is possibly visible from portal A then its bit in portal A's PossibleVis array is set to 1, otherwise it is set to 0. The function first decides which portals cannot possibly see each other (e.g., portals behind each other or portals flowing in opposite directions) and builds a temporary portal visibility list for each portal. It then calls the PortalFlood function for each portal to do a rough flood through its possibly visible portals to find out which leaves they are connected to. The leaves that are reached by the flood have their bits set in that portal's PossibleVis array to 1

indicating that they are current candidates for visible leaves to the current portal and should be more closely examined when the recursive clipping process in invoked to compile the actual PVS for the portal in question.

PortalFlood

This function is called by InitialPortalVis to perform a flood fill (for each portal) from the current portal's neighbour in all directions until it hits portals which can no longer be seen (very rough approximation) by the source portal. As it flows through each portal and into the portal's neighbouring leaves, these leaves are added to the portal's PossibleVis array. The main PVS calculation process will have to examine the leaves which have their bits set to 1 in this array.

> **Note:** The functions just discussed are not actually part of the PVS calculator as such. They are used to reduce the number of portals/leaves that will have to be considered during the actual PVS process. By doing some rough approximations we can reject some portals/leaves that we can tell are not visible without having to spend time clipping or doing other expensive operations.

CalcPortalVis

This is the function that starts the true PVS process. It is called after every portal has had its PossibleVis array calculated. Basically, it loops through each portal and calculates its actual visibility set. When this function returns, all portals will have their ActualVis arrays correctly filled with their real and final leaf visibility set. For each portal this function will call the RecursePVS function to calculate the actual visibility information for that portal. Portals do not have their visibility sets calculated in order however. Instead, the GetNextPortal method is called to return the next source portal that should have its PVS calculated. This will return a portal which has not yet had its ActualVis array calculated and that has the least number of bits set in its PossibleVis array. This allows us to calculate the PVS for less complex portals first in the hope that later, when we calculate the more complex portals, we can borrow some of the visibility information from the less complex portals that it can see. This aids in speeding up the PVS calculations for those complex portals. We will see how that all works later.

GetNextPortal

When we calculate the PVS information (ActualVis) for each portal, we do not actually do so using the order that they are stored in the portal array. Instead, we use this function to return the index of the next portal that should be calculated. This function returns the CPVSPortal from the master portal array that has not yet been processed (CPVSPortal::Status = `PS_NOTPROCESSED`) and that has the lowest number of bits sets to 1 in its PossibleVis array (PossibleVisCount = lowest). The portal returned from this function (to CalcPortalVis) is fed into the recursive clipping process as the next source portal.

RecursePVS

This function is the heart of the PVS process. Once it has been called by CalcPortalVis, it calls itself recursively until the entire PVS for a given source portal has been calculated. It walks through the leaves of the tree by stepping through the portals, and at each step clips what can be seen to the doorway/portal it just stepped though. As more and more portals are stepped through, the viewable area gets smaller and smaller until eventually no other portals can be seen (and therefore no other leaves are visible) and the recursive process unwinds and a new source portal is chosen.

ClipToAntiPenumbra

Every time a new portal is stepped through, this function is called by RecursePVS to build a new set of clipping planes. These planes will extend from the source portal to the portal just passed through in the previous recursion (the target portal). This function then clips any other portals in the new leaf (generator portals) and if any generator portals survive the clip, we know that we can still see a bit more of our scene through this portal and thus have to recur again. Otherwise, we can see no more and our journey ends there.

ExportPVS

Once we have calculated which leaves every portal can see, we need to know which leaves every other leaf can see. A leaf can see everything that all of its portals can see and thus we simply have to loop through each leaf's portals and collect all of the leaves that its portals can see. Once we have created a visibility array for each leaf, we will compress it (by calling CompressLeafSet) and add it to the master PVSData array.

CompressLeafSet

This function is called by ExportPVS once the PVS for a single leaf has been calculated (by taking the union of all the visibility bits for each of its contained portals). It is passed a byte array (1 bit per leaf) of visibility information and compresses it (using zero run length encoding) into a compressed byte array that is then added to the master compressed PVS data array.

SetPVSBit / GetPVSBit

These two functions are helper functions that allow us get or set a particular bit in a byte array. Both the PossibleVis and ActualVis arrays use one bit per leaf byte arrays and we will need to toggle their bits as a leaf is determined to be visible/invisible. For example, passing in 17 as the DestLeaf parameter will set bit 2 of byte 2 to 1 in the byte array passed by the caller via the VisArray. Just remember that the array starts at bit 0 of byte 0. The PVS calculator will use these two functions to set/retrieve bit information in both the portals PossibleVis and ActualVis arrays.

Since these functions are extremely small utility functions we will cover them here, starting with SetPVSBit. If the third parameter is set to true then it means we wish to set a bit in the passed array. As there are 8 bits per byte we can easily calculate the bit in which the visibility bit for DestLeaf resides by dividing the leaf index (DestLeaf) by 8 (>>3). By ANDing the leaf index with 7 we also locate which bit in the byte in which it resides maps to that leaf. In this case we can shift 1 by the amount to left so that we have a value with the proper bit set. We then OR this value with the corresponding VisArray array byte to toggle that bit set. If the Value parameter is false then we locate the byte in which the leaf resides in the same way but NOT it with the value on the right hand side of the equals sign. This will clear the bit (if not already cleared) in the respective byte in VisArray.

```
void SetPVSBit( UCHAR VisArray[], ULONG DestLeaf, bool Value = true )
{
    // Set / remove bit depending on the value
    if ( Value == true )
    {
        VisArray[ DestLeaf >> 3 ] |=  (1 << ( DestLeaf & 7 ));
    }
    else
    {
        VisArray[ DestLeaf >> 3 ] &= ~(1 << ( DestLeaf & 7 ));

    } // End if Value
}
```

The GetPVSBit function is also extremely simple, using the same bit shifting logic. On the left hand side of the equals sign we locate the byte in which the passed leaf's visibility bit resides and on the right hand side we once again construct that same byte value that has the bit set that we are interested in. We then return the bitwise AND of the left and right hand sides, which will only return true if the same bit is set on both sides of the equals sign.

```
bool CProcessPVS::GetPVSBit( UCHAR VisArray[], ULONG DestLeaf )
{
    return (VisArray[ DestLeaf >> 3 ] & (1 << ( DestLeaf & 7))) != 0;
}
```

We are now ready to step through the code to all of the processes involved in our PVS calculator. We will examine them in the order in which they are encountered during program flow.

17.7.1 The ProcessPVS Function

This is the function that would be called from the application that wishes to generate the PVS data for the tree (after it has been compiled).

> **Note:** While the code shown throughout this textbook should give you a very good understanding of how to code your own PVS calculator, the actual code that we use in the lab project is discussed in the workbook and is part of a larger application. The textbook code is intended to give you the general flow of how and where things happen throughout the process using placeholder code. Please note however,

that the code shown here is almost identical to the code used in the lab project, with the exception of some structures names, namespaces, and simple helper functions which we do not cover here.

This is the top level function that encapsulates the calls to all other modules involved in the process. Seeing it below gives us a good understanding of the order in which things happen. Throughout all the functions discussed, access to a pointer called pTree is assumed. This is the BSP leaf tree that contains the compiled leaf data and the portal information. That is, the master portal array that was initially generated is assumed to be stored in the BSP tree and accessible via its member functions.

```
HRESULT ProcessPVS( )
{
    // Calculate Number Of Bytes needed to store each leafs
    // vis array in BIT form (i.e 8 leafs vis per byte uncompressed)
    PVSBytesPerSet = (pTree->GetLeafCount() + 7) / 8;

    // 32 bit align the bytes per set to allow for our early out long conversion
    PVSBytesPerSet = (m_PVSBytesPerSet * 3 + 3) & 0xFFFFFFFC;

    // Retrieve all of our one way portals
    GeneratePVSPortals();

    // Calculate initial portal visibility
    InitialPortalVis();

    // Perform actual full PVS calculation
    CalcPortalVis();

     // Export the visibility set to the final BSP Tree master array
    ExportPVS( pTree );

    return BC_OK;
}
```

The first thing this function does is ask the tree for its current leaf count. This is needed because we know that later, when we calculate the ActualVis and PossibleVis arrays for each portal, these will need to be large enough to store a bit for every leaf in the tree. As discussed earlier, the number of bytes we need to allocate can be found by adding 7 to the leaf count and then dividing the total number of leaves by 8 (8 bits per byte). You will recall from earlier discussions that we add 7 to force a rounding up so that an extra byte is allocated. If we did not do this, 17 leaves divided by 8 would equal 2 because of the truncation that happens when calculating integers. But in fact, we would need 3 bytes because bit 17 would be the 17^{th} bit in the array and thus the 1^{st} bit in the 3^{rd} byte. Adding 7 before the divide ensures that we always round the byte count up and have a value that correctly describes how many bytes should be allocated to contain 1 bit of visibility for each leaf.

Next we add 3 to this amount and do a bitwise AND to clear out the last two bits. What this does is describe the size of the visibility arrays that we will later allocate to be large enough so that they can be written to with a 32-bit long pointer. As you will see shortly, we will access the visibility arrays with a pointer to type long (for speed), so we have to make sure that we pad out the end of the array with spare bytes so that it ends on a 4-byte boundary. For example, imagine that we allocated three bytes and then tried to write to the first byte with a four-byte pointer (long *). In this case, we would accidentally write

to the fourth byte, causing a page fault. Therefore, if we need 22 bytes, we will allocate 24 bytes instead; the two bytes at the end will serve as padding only and will never be used by us.

> **Note:** We will assume that the result of this calculation (PVSBytesPerSet) is located in a scope from which all functions that we will later call will have access to it during the PVS calculation process.

Once done, we call the function briefly described above to carry out the various tasks of the PVS calculator. GeneratePVSPortals is called first which will build the array of one way CPVSPortal structures that will be used by the PVS calculation process. When this function returns we will then call the InitialPortalVis function which will perform some very fast portal/portal rejection techniques and build the PossibleVis array for each portal. This describes which leaves every portal can see in this quick and cheap broad phase visibility rejection function. When this function returns, we will call the CalcPortalVis function which will perform the actual core clipping process and generate the actual PVS (ActualVis) for each portal. When this function returns every portal in the level will have had its leaf PVS generated and stored in its ActualVis array. We then call the ExportPVS method which uses the portal visibility information to build the visibility information for each leaf and compress it into a final master PVS data array. This is the array that would be saved to disk and loaded by the run-time component.

Let us now examine each of these functions one at a time, leading ultimately to a full understanding of how a PVS calculator works and how one can be implemented.

17.7.2 The GeneratePVSPortals Function

In this function we will create the array of CPVSPortal structures that are used by the PVS calculator. Remember that this array will be twice as large as the portal array currently generated and stored in the BSP tree. Each two-way portal will now be turned into two one-way portals which will be stored side by side in this new array (elements N and N+1 in the CPVSPortal array). The duplicated portals will not allocate their own vertices, they will store pointers to the vertices of the original two-way portals contained in the BSP tree.

The function first retrieves the number of two-way portals and allocates an array of pPVSPortals structures which is twice this size. In this first section of code (and throughout the rest of the functions we examine), we will assume that pPVSPortals is a container of CPVSPortal structure pointers. You can see that we use the container's Resize method to inform it to make room for the needed elements.

```
HRESULT GeneratePVSPortals( )
{
    ULONG i, p, PortalCount;

    PortalCount = pTree->GetPortalCount();

    // Allocate enough PVS portals to store one-way copies in PVS portal array.
    pPVSPortals.resize( PortalCount * 2 );

    for ( i = 0; i < PortalCount * 2; i++ )
    {
```

```
       // Allocate a new portal
       pPVSPortals[i] = new CPVSPortal;
    } // Next Portal
```

Notice above that once we have allocated the PVSPortal pointer array, we loop through every element in that array and assign its pointer a newly allocated CPVSPortal structure. At the end of the above section of code we will have allocated every CPVSPortal structure we need to duplicate all the original portals.

In this next section we will enter the main loop that will fetch every original two-way portal from the original list of portals in the BSP tree and copy it into two one-way portals in our new CPVSPortal array. Inside the loop we first fetch the portal from the tree's list via an assumed tree method called GetPortal which will return the index of a portal stored in the tree. This value is stored in the local variable pBSPPortal. We then allocate a new CPortalPoints structure which will contain the portal polygon (remember that this is derived from CPolygon) that we wish to copy.

```
    for ( i = 0, p = 0; i < PortalCount; i++, p+=2 )
    {
       // Retrieve BSP Portal for easy access
       CPortal * pBSPPortal = pTree->GetPortal(i);

       CPortalPoints *pp = AllocPortalPoints( pBSPPortal, false );
```

The AllocPortalPoints function requires some explanation even though it is a simple housekeeping method and its code will not be shown here in the textbook. Basically it creates a new CPortalPoints structure and either copies its vertices from the passed portal (1st parameter) or if the second parameter is false, it simply stores a pointer to the passed portal's vertex data in the CPortalPoints member. That is, because we have passed false as the second parameter, the returned CPortalPoints structure will not have had its own geometry (vertex data) allocated, but will instead just assign its vertex data pointer to point at the vertex data of the original two-way BSP portal. The false parameter also instructs the allocation function to set the CPortalPoints::OwnsVertices member to false so that the CPortalPoints destructor will know that when it is destroyed, it should not delete its vertex data because it does not own it. This vertex data is owned by the original two-way polygon in the tree.

Now we will fill out the first duplicate in the CPVSPortal array. Variable p starts at zero at the start of the loop and is incremented by 2 for each iteration. This is because we add two duplicate portals to CPVSPortals with each iteration of this loop. Therefore, variable p always contains the index into the CPVSPortals array where these two duplicates should be placed. The first duplicate should be stored in pPVSPortals[p] and the second (opposite facing portal) in pPVSPortals[p+1].

```
       // Create link information for front facing portal
       pPVSPortals[p]->Points = pp;
       pPVSPortals[p]->Side   = FRONT_OWNER;
       pPVSPortals[p]->Status = PS_NOTPROCESSED;
       pPVSPortals[p]->Plane  = pTree->GetNode( pBSPPortal->OwnerNode )->Plane;
       pPVSPortals[p]->NeighbourLeaf = pBSPPortal->LeafOwner[ FRONT_OWNER ];
       pPVSPortals[p]->OwnsPoints    = true;

       // Store owner portal information (used later)
       pp->OwnerPortal = pPVSPortals[p];
```

In the above code we first store the newly allocated CPortalPoints structure pointer in the first duplicated portal's Point member and set the Side member to FRONT_OWNER. Remember that this portal is going to represent the duplicate that is facing in the same direction as the node plane on which the portal was created. We also set its status to PS_NOTPROCESSED which tells us that this portal has not yet had its PVS calculated. Then we fetch the node plane on which the original portal was created (recall that this is stored in the portal's OwnerNode member). Since this duplicate is going to be the one that has the leaf in front of the node plane as its neighbor, we fetch this leaf's index from the portal as well. This index will be stored in the original portal's LeafOwner array in the FRONT_OWNER element. Finally, we set this new portal's OwnsPoints member to true because it is the PVS portal (out of the two duplicates we are creating in this iteration) that will take responsibility for the CPortalPoints structure we allocated for it. The other duplicate will still store a pointer to it, but it will have a value of false as its OwnsPoints member. Again, this allows both duplicates to share a single CPortalPoints structure without them both trying to delete this same object when the portals are released from memory. Only the owner of the CPortalPoints object (the one-way portal we have just created in the above code) will delete this array. At the bottom of the above section of code you can see that we store a pointer to the one-way portal in the CPortalPoints::OwnerPortal member. Specifying the owner in this way will come in handy later.

> **Note:** Remember that the CPortalPoints structure is really just a CPolygon structure containing a few extra member variables (such as the OwnerPortal member). It is this member of the CPVSPortal that contains the actual geometry for the portal.

In the next section of code we create the second duplicate one-way portal using the original portal currently being copied. We then store it next to the previously created one-way portal in the CPVSPortal array. Notice that this portal stores a pointer to the same CPortalPoints structure (after all, these portals describe the same physical portal polygon), but this time we record that this portal is owned by the leaf in front of the plane and as such its neighbor is the portal situated behind the node plane. That is, this portal's plane is assumed to have a normal facing into the back leaf of the original node. However, notice that we store the same node plane in both cases. This is fine, because we know that this portal points into the backspace of the node plane and we will invert the plane normal of this duplicate prior to clipping any portals to its plane (shown later).

```
        // Create link information for back facing portal
        pPVSPortals[p+1]->Points        = pp;
        pPVSPortals[p+1]->Side          = BACK_OWNER;
        pPVSPortals[p+1]->Status        = PS_NOTPROCESSED;
        pPVSPortals[p+1]->Plane = Tree->GetNode(pBSPPortal->OwnerNode )->Plane;
        pPVSPortals[p+1]->NeighbourLeaf = pBSPPortal->LeafOwner[ BACK_OWNER ];
        pPVSPortals[p+1]->OwnsPoints    = false;
   } // Next Portal

     // Success!!
     return BC_OK;
}
```

Notice also that this portal does not own the CPortalPoints structure even though it stores a pointer to it. As mentioned, this is so that it will not try to delete this object when the portal is deleted. We will leave that task to the destructor of the first duplicate we created above it in the code.

That is the first stage of the PVS calculator covered. When this function returns we will have an array of one-way portals. Every original portal from the BSP tree will have been duplicated into two one-way portals that face in different directions and have different neighbor leaves. Pairs of duplicates will share a single CPortalPoints structure that contains the portal geometry and each CPortalPoints structure will contain a pointer to the vertex array in the original two-way portal from which it was cloned.

We saw earlier that after the GeneratePVSPortals function returns program flow back to the ProcessPVS function, we then issue a call to the InitialPortalVis function. This is the function that is responsible for doing the cheap visibility test for each portal. It builds each portal's PossibleVis array. This function will naturally be covered next.

17.7.3 The InitialPortalVis Function

The next function called by ProcessPVS is InitialPortalVis. Its job is to build a rough approximation of leaves that might be visible from each portal. This will allow us to reject as many leaves as possible before entering the recursive PVS process. If we did not include this step, our PVS would take much longer to calculate. Because we now have portals that only flow one way, it makes it quite easy for us to tell that some portals cannot possibly be visible from another portal.

For example, if a portal flows to the right (i.e. its neighbour leaf is to the right of the node plane) then we know immediately that any other portals that lay to the left of this portal cannot be seen. In short, we know that Portal A cannot possibly see Portal B when B is behind it. Consequently it is also unable to see into any of the leaves that Portal B leads to. If we know beforehand that a portal cannot possibly see a leaf, then we do not have to go through the lengthy process of clipping all of the portals in that leaf during the PVS process. This is especially true when we know that all of those portals would be completely clipped away anyway. This will save us a great deal of time.

Figures 17.53 through 17.55 depict portals that may be trivially rejected by our function. For each portal, InitialPortalVis will loop through every other portal in the list and perform two tests. If a portal passes both of the tests, then it can (potentially) be seen by the current portal. Otherwise, we know for certain that it cannot.

The InitialPortalVis function will loop through each portal and first construct a temporary byte array describing which portals can be seen by the current portal (the 'portal visibility list'). For example, if portal 2 has the 5^{th} byte in this temporary array set to 1, it means portal 2 can possibly see the 5^{th} portal. This test will be performed for every other portal in an inner loop which, upon completion, will have set the corresponding bytes in this array to 1 for any portals in the PVS portal array which are considered initially visible. This provides us with the first major step forward -- which portals can be seen by the current portal being processed. Any bytes set to zero in this array indicate portals that the current portal cannot possibly see through the back of (i.e., the direction of visibility through a portal) because it is either facing towards the current portal or is situated behind it.

Once we have the temporary array describing which portals the current portal can see, we will call the PortalFlood function (more on this shortly) and pass it this portal visibility array so it can then calculate which *leaves* might be seen by the current portal. The leaves which may *possibly* be visible will have

their bits set in that portal's PossibleVisibilitySet (CPVSPortal::PossibleVis array) which will be used later when we calculate the PVS and create each portal's ActualVisibilitySet (CPVSPortal::ActualVis). So this function will first start off by looping through each portal. In this loop an inner loop will be instantiated that will loop through every other portal in the scene and we will run two tests on it to see if the test portal is potentially visible from the current portal being processed.

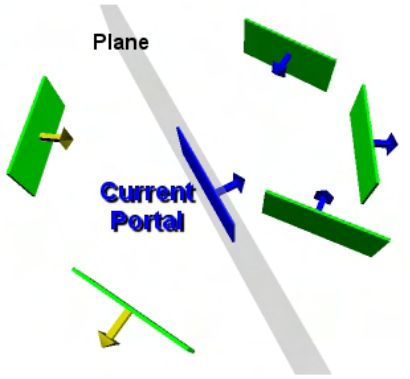

Figure 17.53

The diagram we will use to demonstrate these tests is shown in Figure 17.53. The central blue portal is the current portal that is about to have its initial (possible) visibility calculated. The plane on which this portal lies is also shown. In this image there are five other green portals (with normals indicating their flow direction into their neighbor leaves) and it is each of these we will need to test against the current portal. Basically we need to determine if flow can ever exist between the current portal and each of these portals based on the portal orientations and spatial relationships to one another.

The first test we will perform is whether or not the test portal is situated behind the current portal. By 'behind' we mean that it is situated behind the portal with respect to the portal's flow direction. If it is, then no flow could possibly happen from the current portal to the test portal because a portal only has visibility through the back of the other portal (and thus, into that test portal's neighbor leaf). If the test portal is behind the current portal, this cannot possibly be the case. Such portals are rejected immediately and do not have their corresponding bytes set to 1 in the portal visibility list being temporarily compiled for the current portal. In Figure 17.54 we can see that with this simple test, two of the five possible portals are rejected since they lay behind the portal's plane. Thus, they are located in the opposite halfspace with respect to the current portal's view direction. It should be noted however that these portals are only rejected if they lay *completely* behind the current portal. If the test portal is spanning the current portal's plane then it will still be marked as visible at this time because at least some of that test portal will be visible to the current portal (the section in the portal's frontspace).

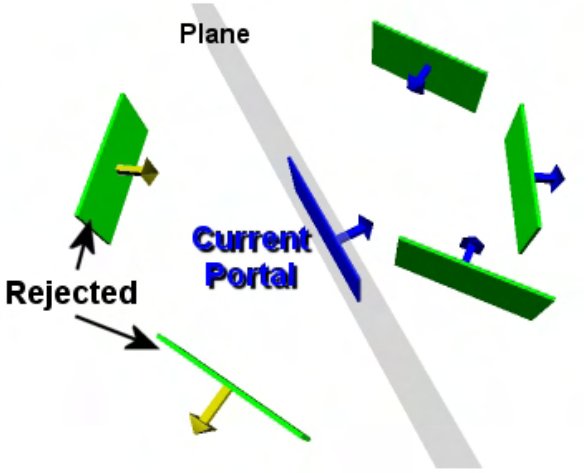

Figure 17.54

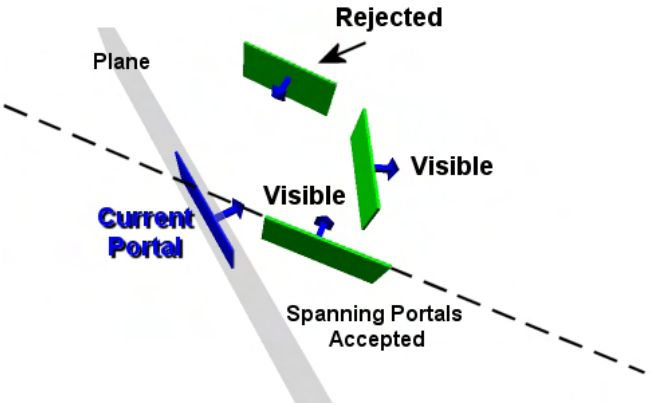

Figure 17.55

If the test portal is not situated completely behind the current portal's plane then it will have survived the first test and at this time is still considered as possibly visible. We then feed it into the second test that classifies the current portal's location with respect to the test portal. With our one way portals, a given portal can only see through another portal if the direction in which the current portal is facing flows through the back of the test portal. Therefore, as we can see in figure 17.55, this cannot possibly be the case if the current portal is completely in front of the test portal's plane. If it is, then it must mean that the current portal's normal and the test portal's normal are facing into each other and therefore, we have visibility flow in opposing directions. When this is the case the test portal is also skipped and is not added to the portal visibility list for the current portal. In Figure 17.55 we can see that this test has rejected yet another portal. This leaves us with just two portals in the current portal's visibility list that are flagged as potentially visible. Note once again than in this second test, the test portal is only rejected if the current portal lies completely in the test portal's frontspace. If the current portal is spanning the test portal's plane then it means at least some small portion of the current portal must be able to see the back of the test portal. Therefore, some small amount of visibility still exists between the current portal and the back of the test portal.

Once every portal has been pumped through these two tests for the current portal being processed, we will have collected (in a temporary byte array) the visibility status of each portal with respect to the current portal being processed. This is then used to perform a flood fill from the current portal through any visible portals in this array. This flood fill will start off at the neighbor leaf of the current portal and will recursively walk through any portals contained in that leaf which also have their visible bytes set to 1 in the portal's temporary portal visibility array.

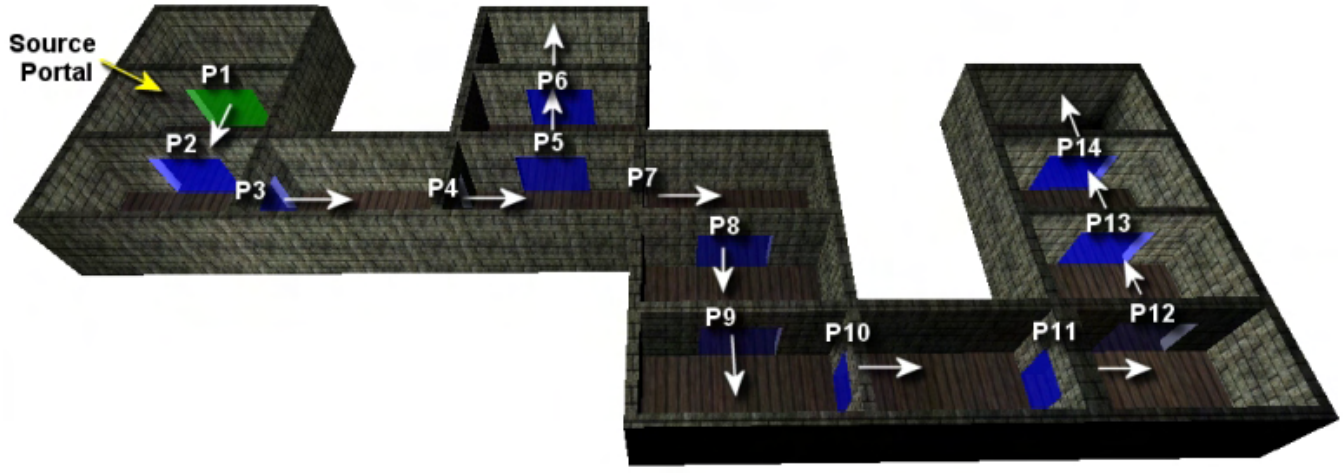

Figure 17.56

In Figure 17.56 we see some example geometry and the portals contained in each leaf. Portal P1 is assumed to be the portal currently having its visibility set calculated. The portal flood procedure will

start off in the neighbor leaf of the current portal and the leaf will have its bit set in the CPVSPortal::PossibleVis array. We will then iterate though any portals in that leaf, stepping through them into their neighbor leaves, which will have their bits set in the portal's PossibleVis array as well. Now, if this was all we were to do, the recursive procedure would simply flood through every portal in the level making every leaf 'wet', adding it to the current portal's (P1) possible visibility set. However, prior to performing this procedure to calculate leaf visibility, we first performed our two tests against each portal that allowed us to build an array of portal visibility information from the current portal P1. As discussed, any portals that are located behind the current portal or that have normals facing in the opposite direction to the current portal are considered non-visible. During the flood fill, when we enter a new leaf and test each of its portals (which always flow out of the leaf into the neighbor), we will only step through that portal and into its neighbor leaf if that portal's byte has been set to 1 in the source portals portal visibility array.

For example, imagine we are calculating the possible leaf visibility set for portal P1 in Figure 17.56. The white arrows in the diagram show the flow as we traverse through the portals from leaf to leaf. We can see for example that we would first add the neighbor leaf to P1's possible visibility set and would then flow through its portal P2, into its neighbor leaf. This leaf would also be added to the portal's visibility array. We would continue to step though P3 and P4, adding every leaf we visit (leaves that get 'wet' by the flood) to the possible visibility array in the source portal. When we pass through portal P4, something interesting happens; its neighbor leaf has two portals (P5 and P7) so we should recur through them both. However, the normal for portal P5 is facing in the opposite direction to the normal of the source portal P1 and therefore, this portal would have its corresponding byte in P1's portal visibility array set to 0, informing us that no visibility flow can happen between these two portals. This is actually fairly intuitive when you look at their spatial arrangement. Because portal P5 is not flagged as visible, we skip this portal and do not step into it. Thus we do not visit P5's neighbor leaf or the neighbor leaf for portal P6. We have just rejected two leaves from the source portals PossibleVis array.

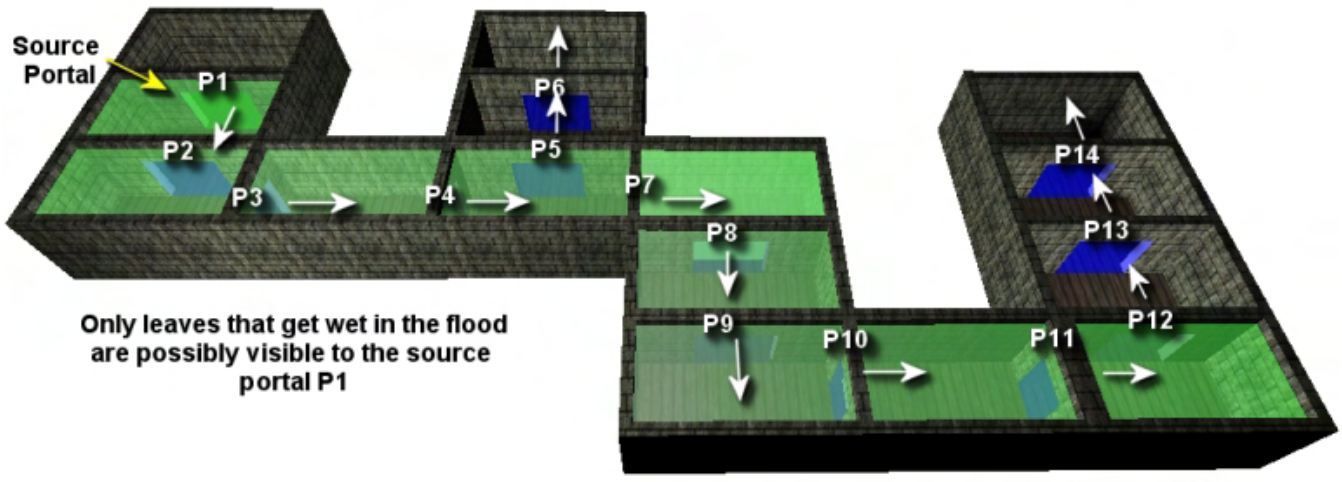

Figure 17.57

Back in the neighbor leaf of P4 we can see that after skipping portal P5 we recur through the other portal in that leaf P7 and we continue to flow through a combination of portals right up to and including portal P11, setting the bit for each leaf we walk through to 1 in the source portal's possible visibility array.

Once in the neighbor leaf of P11, we find it has one portal (P12) but that its visibility byte in the source portal's portal visibility array is set to zero because it flows in an opposite direction to the source portal (P1). Therefore we never step though this portal or into any of the leaves and portals it leads to (P13 and P14). As you can see, even in this simple example, we have now rejected 5 leaves from the source portal's PossibleVis array. When we get around to calculating the actual PVS (ActualVis array) for the source portal, we know that these portals and their neighbor leaves should never be traversed into since they cannot possibly be visible from the source portal.

At the end of the InitialPortalVis function that we are about to write, every portal in the scene will have had its PossibleVis array calculated and the bits of any potentially visible leaves set to 1. Although this is a very crude approximation of the portal's PVS, it does serve as a foundation upon which we can build the actual PVS for each portal (ActualVis).

> **Note:** It is quite common during development to turn off the generation of the actual PVS calculation and simply use the PossibleVis array for each portal to calculate the PVS. While this represents only a very rough approximation of what it and is not visible, and should never be used in commercial game code, it does allow the developer to quickly compile and run the game many times with some degree of PVS (even if it is too generous) without having to wait for the full PVS calculator to generate its much tighter visibility set.

Let us now look at the code that does everything we have discussed in this section. At the end of this function (InitialPortalVis), the PossibleVis array for every portal will have been calculated and will contain a very approximate leaf visibility set.

The code first allocates a byte array large enough to store a visibility status byte for each one-way portal in the level. This code assumes the existence of a GetPVSPortalCount function which will return the number of PVS portals (one-way portals) in the portal array. This temporary array will be re-used in each iteration of the outer loop to store the visibility status of every other *portal* in the scene. We then set up the outer loop to loop through each PVS portal that we generated earlier and fetch a pointer to that portal and its plane.

```
HRESULT InitialPortalVis()
{
    CPortalPoints  *pp;
    ULONG           p1, p2, i;
    CPlane          Plane1, Plane2;
    UCHAR          *PortalVis = NULL;
    CPVSPortal     *pPortal1, *pPortal2;

    // Allocate temporary portal visibility buffer
    PortalVis = new UCHAR[ GetPVSPortalCount() ];

    // Loop through the portal array allocating and checking
    // portal visibility against every other portal
    for ( p1 = 0; p1 < GetPVSPortalCount(); p1++)
    {
            // Retrieve first portal for easy access
            pPortal1 = GetPVSPortal( p1 );

            // Retrieve portal's plane
            GetPortalPlane( pPortal1, Plane1 );
```

pPortal1 is the current portal we are processing the preliminary visibility information for, and the function GetPVSPortal is assumed to be a function that will return a pointer to the CPVSPortal pointer in the requested position in the CPVSPortal array. What is vitally important to note is the use of the GetPortalPlane method. We might think that this function is unnecessary, considering the portal structure stores the plane, however you will recall that both duplicate portals created from an original portal store the same plane, even though they are supposed to be pointing in different direction. The GetPortalPlane method tests to see if the passed portal has its Side member set to BACK_OWNER. If so, then this is the duplicate portal that is pointing in the opposite direction to the normal of the node plane on which the portal was originally created. In this instance, the GetPortalPlane function will negate the plane normal and distance before returning the node plane. If the passed plane is the FRONT_OWNER, then the node plane is returned unchanged. Essentially, this function makes sure that we get the node plane back facing in the correct direction corresponding to the one-way portal.

Since pPortal1 (the current portal being processed) will have its CPVSPortal::PossibleVis member pointing to a byte array that contains the preliminary leaf visibility set for this portal (1 bit per leaf), we had better allocate the memory for this array next and initialize it to zero. You will recall that PVSBytesPerSet was calculated earlier (in ProcessPVS) to contain the number of bytes that will be needed to store 1 bit per leaf for each leaf in the tree.

```
            // Allocate memory for portal visibility info
            pPortal1->PossibleVis = new UCHAR[PVSBytesPerSet];
            ZeroMemory( pPortal1->PossibleVis, PVSBytesPerSet );

            // Clear temporary buffer
            ZeroMemory( PortalVis, GetPVSPortalCount() );
```

Notice in the above code how we also clear the PortalVis byte array that will be used to store a byte per portal in the initial portal visibility phase. Remember, the contents of this array will be calculated first, so we know exactly which other portals could possibly be visible from the source portal (pPortal1). This same array will be reused during each iteration of this loop to store the portal visibility bytes for each portal that we process.

With the arrays initialized, it is now time to loop through every other portal and perform the two tests discussed earlier. Only if the test portal passes both tests will it have its corresponding byte set to 1 in the PortalVis array. The first part of the loop tests to see if the current test portal is the same as the current source portal, and if so, just skips the tests. We also fetch the test portal and its plane using the same GetPortalPlane function described earlier to make sure that the plane normal is facing in the same direction as the portal.

```
            // For this portal, loop through all other portals
            for ( p2 = 0; p2 < GetPVSPortalCount(); p2++)
            {
                // Don't test against self
                if (p2 == p1) continue;

                // Retrieve second portal for easy access
                pPortal2 = GetPVSPortal( p2 );
```

```
                // Retrieve portal's plane
                GetPortalPlane( pPortal2, Plane2 );
```

At this point we have the source portal (pPortal1) and the test portal (pPortal2) and our first test will be to loop through each vertex in the test portal and classify it against the source portal. As soon as we find a vertex in the test portal that is not in front of the current portal, we break from the vertex loop. This will tell us outside the loop that the test portal is not completely behind the source portal and cannot be rejected from the possible visibility set just yet.

```
                // Test to see if any of p2's points are in front of p1's plane
                pp = pPortal2->Points;
                for ( i = 0; i < pp->VertexCount; i++)
                {
                  if ( Plane1.ClassifyPoint( pp->Vertices[i] ) == CP_FRONT ) break;
                } // Next Portal Vertex

                // If loop reached end, there were no points in front so continue
                if ( i == pp->VertexCount ) continue;
```

However, if at the end of the loop the loop variable ‘i’ is equal to the vertex count of the test portal, we know that none of its vertices were ever found to be in front of the source portal and as such we can skip the rest of this loop. No visibility can exist through this portal from the source portal as it is situated in the source portal’s backspace. The test portal will not have its visibility byte set to 1 in the PortalVis buffer.

However, if some of the vertices in the test portal were found to be in front of the source portal, we must perform the second test in the hope that it may yet be rejected. In this next test we test each vertex in the source portal against the plane of the test portal and break as soon as we find a vertex that lives in the test portal’s back space. If the vertex loop does not exit prematurely, then it means that the source portal is total in the test portal’s frontspace and thus they must be facing each other. Since portal flow can only happen from the source portal through the back of the test portal, the source portal must not be able to see through the test portal. In this case, the test portal is skipped and does not have its corresponding byte in the PortalVis array set to 1.

```
                // Test to see if any of p1's portal points are Behind p2's plane.
                pp = pPortal1->Points;
                for ( i = 0; i < pp->VertexCount; i++)
                {
                  if ( Plane2.ClassifyPoint( pp->Vertices[i] ) == CP_BACK ) break;
                 } // Next Portal Vertex

                // If loop reached end, there were no points in front so continue
                if ( i == pp->VertexCount ) continue;

                // Fill out the temporary portal visibility array
                PortalVis[p2] = 1;

            } // Next Portal 2
```

Outside the inner loop we will have filled out the PortalVis buffer with information describing which portals are visible from the source portal and which ones are not (and therefore will stop the flood). The

last thing we do for the current source portal is call the PortalFlood function which will perform a flood fill starting from the source portal's neighbor leaf through all visible portals. Any leaves that get 'wet' by the flood will have their visibility bit set to 1 in the source portal's PossibleVis array. Notice that before we call this function, we set the source portal's PossibleVisCount to zero as we have not yet found any visible leaves. This will be incremented in the portal flood function every time a new leaf is traversed into. We will look at the PortalFlood function next. Notice how the PortalVis buffer we have just compiled for the current source portal is passed into the function as it contains the information that is used to block the flood at non-visible portals.

```
            pPortal1->PossibleVisCount = 0;
            PortalFlood( pPortal1, PortalVis, pPortal1->NeighbourLeaf );

        } // Next Portal

    // Clean up
    if (PortalVis) delete []PortalVis;

    return BC_OK;
}
```

At the bottom of the function, after exiting the outer loop, the PossibleVis array for every portal in the level will have been calculated and we will be ready to start calculating the real PVS for each portal with the anti-penumbra clipping we discussed earlier. Before the function returns, the temporary memory that was allocated for the portal visibility information is discarded. We no longer the need the information since each portal now stores which leaves are considered visible by the portal flood. It is this set that will be refined in the next phase.

17.7.4 The Portal Flood Function

Because we have calculated which portals can see each other in the calling function (InitialPortalVis) and we have passed that visibility buffer into this function, it becomes trivial to perform a flood fill out from the current portal to see which leaves it can get to before it hits portals that it cannot see (i.e.,. stopping the flood). We are certainly all familiar with flood fills used in paint applications, where the color fills an area within some specified set of bounds. We can think of this function as basically doing the same thing.

We start by passing in the portal we are calculating and the portal's neighbor leaf. Once in that leaf, we can check whether any portals in that leaf are visible from the source portal, and if so, walk through that portal into its neighbor leaf. We keep doing this recursively until we hit a place where the portals are no longer visible from the source.

This is a very small recursive function and very simple compared to some of the more complex recursive function we have written in the past. The function is initially called from the InitialPortalVis function and is passed the source portal whose PossibleVis array we wish to populate, the portal visibility buffer containing the visibility of each portal with respect to the source portal, and the

neighbor leaf of the source portal, which is the leaf in which the flood will begin. We will show the first half of the function first and then discuss it.

```
void CProcessPVS::PortalFlood( CPVSPortal * SourcePortal,
                               unsigned char PortalVis[],
                               unsigned long Leaf )
{
    CBSPLeaf * pLeaf = pTree->GetLeaf( Leaf );

    // Test the source portals 'Possible Visibility' list
    // to see if this leaf has already been set.
    if ( GetPVSBit( SourcePortal->PossibleVis, Leaf ) ) return;

    // Set the possible visibility bit for this leaf
    SetPVSBit( SourcePortal->PossibleVis, Leaf );

    // Increase portals 'Complexity' level
    SourcePortal->PossibleVisCount++;
```

The first thing this function does is fetch the leaf pointer from the BSP tree using the passed leaf index. It then uses the GetPVSBit utility function to determine whether the leaf we have just stepped into already has its bit set to 1 in the source portal's PossibleVis array. If it is, then it means we have visited this leaf before during the flood and should take no action and just return. Continuing to step through the portals in this leaf under these circumstances could allow us to get stuck in a recursive flow loop. For example, we move from Leaf A into Leaf B into Leaf A and so on forever (or at least until we get a stack overflow). This provides loop protection by saying, "we have been here before, so do not process this leaf and its portals again". Finally, in the above code you can also see that, provided we have not been here before, we use the SetPVSBit utility function (discussed earlier) to set the bit that corresponds to the passed leaf index in the source portal's PossibleVis array. Notice that since we have stepped into a visible leaf, we increment the portal's PossibleVisCount member so that at the end of the flood (for the current source portal) we will know how many leaves were considered visible.

With this leaf added to the source portal's possible visibility set, our final task is to loop through any other portals owned by this leaf and step through them into their neighbor leaves. The leaf itself stores the indices of the two way portals that were originally created, so we will have to bear that in mind when using the leaf portal indices to fetch the one-way portals from the CPVSPortal array. This is no problem however, since we know that all we have to do is multiply the original indices by 2 to get the position in the one-way portal array where the two duplicates were made. We can then use that index to fetch the one-way PVS portal and, if this is the duplicate that has the current leaf as its neighbor leaf, we know it is not the correct duplicate. We are after the second duplicate in this instance, where its owner is equal to this leaf, so we increment the portal index we calculated and grab it from the PVSPortal array.

```
    // Loop through all portals in this leaf (remember the portal numbering
    // in the leaves match up with the originals, not our PVS portals )
    for ( ULONG i = 0; i < pLeaf->PortalCount; i++)
    {
        // Find correct portal index (the one IN this leaf (not Neighbouring))
        ULONG PortalIndex = pLeaf->PortalIndices[ i ] * 2;
        if ( GetPVSPortal( PortalIndex )->NeighbourLeaf == Leaf ) PortalIndex++;
```

At this point we have the current portal in this leaf that we wish to step through into its neighbor leaf, but if this portal does not have its byte set to 1 in the passed PortalVis buffer, we know that this portal was found not to be visible from the source portal and we can skip it. This halts the flood in that direction. If this is not the case, we continue to flood through the portal into the neighbor leaf. Below is the remainder of the function.

```
        // If this portal was not flagged as allowed to pass through, skip it
        if ( !PortalVis[ PortalIndex ] ) continue;

        // Flood fill out through this portal
        PortalFlood( SourcePortal,
                     PortalVis,
                     GetPVSPortal( PortalIndex )->NeighbourLeaf );
    } // Next Leaf Portal
}
```

This function returns program flow back to the InitialPortalVis function when all leaves that could be flooded into through all visible portals have been reached and flagged as visible in the portal's PossibleVis array. When the InitialPortalVis function returns back to the ProcessPVS function, the PossibleVis array will have been populated for each portal. The master function next invokes the actual PVS processor -- the CalcPortalVis function.

Below we see the main parent function ProcessPVS and highlight (in bold) the functions we have examined so far. As you can see, the CalcPortalVis function is the next process we need to execute and when this function returns, the actual PVS for every portal will have been created.

```
HRESULT ProcessPVS( )
{
    // Calculate Number Of Bytes needed to store each leafs
    // vis array in BIT form (i.e 8 leafs vis per byte uncompressed)
    PVSBytesPerSet = (pTree->GetLeafCount() + 7) / 8;

    // 32 bit align the bytes per set to allow for our early out long conversion
    PVSBytesPerSet = (m_PVSBytesPerSet * 3 + 3) & 0xFFFFFFFC;

    // Retrieve all of our one way portals
    GeneratePVSPortals();

    // Calculate initial portal visibility
    InitialPortalVis();

    // Perform actual full PVS calculation
    CalcPortalVis();

     // Export the visibility set to the final BSP Tree master array
    ExportPVS( pTree );

    return BC_OK;
}
```

17.7.4 The CalcPortalVis Function

CalcPortalVis calculates each portal's ActualVis array. We can think of the ActualVis array as a localized per-portal PVS. The ActualVis array will be a subset of the PossibleVis array calculated in our last lesson, because many of the 1 bits in PossibleVis will be set to 0 in ActualVis when we determine that those leaves are not truly visible.

This is the top-level function that begins the recursive process of stepping through the various leaves in the tree and marking them as visible. The first thing we need to do is to loop through each portal in our array and calculate the ActualVis for it. Figure 17.58 provides some insight into the recursive clipping process that will be involved in this function and its recursive helper function.

We loop through each one-way portal in our array and start a recursive process that uses this portal as the current source portal. The source portal's neighbor leaf becomes the first target leaf. The first target leaf can always be seen from the source portal because the source portal is connected to it directly. We then loop through each portal in the target leaf and build an anti-penumbra between the source portal and the target portal. (Remember that each portal in the target leaf is called a target portal.)

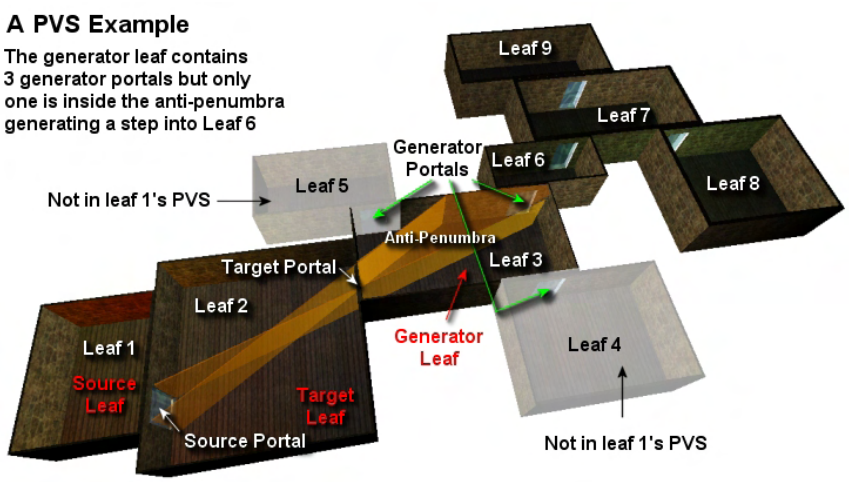

Figure 17.58

If a target portal is visible from the source portal, then we know that we must be able to see into the target portal's neighbor leaf (which we call the generator leaf). We then check all portals in the generator leaf and clip them to the anti-penumbra. If any of these generator portals survive the clipping process, it means that the source portal can see the generator portal. This in turn tells us that the source portal must also be able to see into the generator portal's neighbor leaf.

> **Note:** A generator portal is named as such because if it is visible from the source portal, it 'generates' another recursion.

This is where the recursive part comes into play. Once we have found a generator portal that is visible from the source portal, we repeat the process. Only this time, the generator portal becomes the new target portal and we rebuild the anti-penumbra between the source portal and the new target portal (the old generator portal). The neighbor leaf of the old generator portal (which is now the new target portal) becomes the new generator leaf and the whole routine happens again. We check all the generator portals in the new generator leaf, clip them to the new anti-penumbra, and if any portals survive, then they

become target portals themselves in the next recursion and the anti-penumbra is rebuilt. We then recur into the next leaf, and so on.

When we conclude that a portal is visible and step through it into its neighbor leaf, we set that leaf's bit in the current source portal's ActualVisBits array to 1. This tells us that this leaf is indeed visible from the source portal. This same recursive process is done for every portal in our array (i.e., every portal in our array will have its turn at being the source portal and will have its ActualVisBits array calculated in this manner).

This function uses a data structure that we have not yet discussed, but which will make more sense once we look at the next function (RecursePVS). Because we will need to recur through this function many times, it will be helpful to have a data structure where we can pass information from the previous recursion to the next. For example, when the RecursePVS function calls itself, the current generator portal needs to be passed into the next recursion as the target portal. We also need to be able to access the source portal at all times, regardless of what instance of the function we are in, so that we can set the bits for each visible leaf we encounter. So before we look at the code to the CalcPortalVis function, we will quickly discuss the PVSDATA structure:

```
typedef struct _PVSDATA             // Structure to hold pvs processing data
{
   CPortalPoints   *SourcePoints;   // Current source portals points
   CPortalPoints   *TargetPoints;   // Current target portals points
   CPlane           TargetPlane;    // The target's plane
   UCHAR           *VisBits;        // Visible Bits being calculated
} PVSDATA;
```

This structure is mainly used so that we can access data about the generator portal that was selected in a previous iteration of the recursive function. Since the previous generator portal becomes the target portal in the next recursion, this allows us to find a generator, fill out the information about it in one of these structures, and then pass on this structure to the next recursion so that we can access and use it as the target portal. There are also some other fields in here which are not explicitly connected to the target portal.

The SourcePoints and TargetPoints pointers will point to the actual vertices for the source and target portals. Earlier, we discussed how a generator portal is clipped to the anti-penumbra, and if any of it survives, we recur again, sending the new clipped portal into the next iteration as the new target portal. We do not actually have to send the generator portal itself into the next recursive call; we only need to send the new clipped points (the vertices). Therefore, at each recursive step, TargetPoints will hold the new clipped target portal points that survived the previous function call (when it was the generator portal). The clipped TargetPoints will then be used to rebuild the anti-penumbra planes between the source portal and the new target portal. We will discuss this later, but we also clip the source portal during the recursive process. This is done to help refine our PVS and get as close as possible to a perfect visibility set. So not only will we clip the generator to the anti-penumbra, but we will also build a second anti-penumbra from the generator portal to the target portal and clip the source portal to these planes. This means that at each step, the anti-penumbra will get smaller at both ends, and will increase our chances of shaving a few more polygons out of the portal's PVS. For now, there is no need to worry about all of this since we will discuss it all in detail later.

TargetPlane is the plane of the target portal. Remember that the target's plane is just the previous generator portal's plane. Finally, the BYTE pointer VisBits will be used in a very interesting way to speed up our PVS calculator. We will discuss this when we look at the RecursePVS function.

The first section of the function is shown below.

```
HRESULT CalcPortalVis()
{
    ULONG   i;
    PVSDATA PVSData;

    // Clear out our PVSData struct
    ZeroMemory( &PVSData, sizeof(PVSDATA) );

    // Lets process those portal bad boys!! ;)
    for ( i = 0; i != -1; i = GetNextPortal() )
    {
        CPVSPortal * pPortal = GetPVSPortal( i );
```

The first thing we do in the above code is instantiate a PVSDATA structure and initialize it to zero. Then we do something a little bit different; instead of just looping through each portal in the array and calculating the PVS for them one at a time, we enter a while loop and call a function called GetNextPortal. This function returns the portal index of the portal to be calculated next, until all portals have been processed. When this happens, it will return -1, which means that we will have calculated the PVS for each portal in the list.

The obvious question is why not just loop through the portal array in linear order and go through them one at a time? Although we will not fully know the answer to this question until we look at the next function, it turns out that we can speed up our PVS calculations if we calculate the PVS for the least complex portals first. The least complex portals in the list are the portals which have the fewest number of bits set in their PossibleVis arrays. In other words, we choose portals that can see the least amount of leaves first. If we calculate the quickest ones first, then there is a good chance that when we come to calculate more complex portals (i.e., portals that can see more leaves and will take longer to calculate), we may be able to reuse the information from the less complex portals to speed things up.

The GetNextPortal function iterates through the CPVSPortal array and returns the index of the portal with the fewest number of bits set in its PossibleVis array which has not already been used. When a portal has had its PVS calculated, we set the portal's Status member to PS_PROCESSED so that it is never returned from the GetNextPortal function again.

Next we fill in our PVSData structure so that PVSData.SourcePoints holds the vertex list for the source portal. The source portal is the portal we have just chosen to calculate the PVS for (selected by GetNextPortal). We will need access to the source portal's points because we may need to clip them, as we will discuss later. This structure will also store a pointer to the source portal's PossibleVis array which will be needed during the recursive clipping process, along with the plane of the source portal. This data structure will be passed into the RecursePVS function where much of the main work happens.

```
            // Fill our our initial data structure
            PVSData.SourcePoints    = pPortal->Points;
```

```
            PVSData.VisBits         = pPortal->PossibleVis;
            GetPortalPlane( pPortal, PVSData.TargetPlane );
```

As discussed, this data structure's primary job is to provide access to the previous generator portal and the source portal as we step from one recursion to another. The generator portal in one recursion will become the target portal at the next recursion of the function and this data is passed between instances of the function using this structure. At first it may seem strange to send in the plane of the source portal as the TargetPlane member in the data structure. But remember that on our first call to RecursePVS, we will not yet have a target portal. The RecursePVS function will need to detect if it is in its first recursion and behave differently when this is the case. We will use this plane on the first recursion just to check that the new target portal is not on the same plane as the source portal. Essentially, by storing the source plane in the very first call, we tell the recursive method that this is the first time through, so do not try to build an anti-penumbra; just choose a target portal and step through it. This is done automatically since we ignore portals that are co-planar to the source portal. Since it is wasteful to have a whole new plane variable called SourcePlane just to hold a variable for the top level recursion, we decided to use (or misuse if you prefer) TargetPlane to hold the source portal's plane for this one time. This allows us to find valid target portals by testing against it.

Next we allocate memory for the current source portal's ActualVis array. After RecursePVS returns, this array will hold the real PVS for this portal. We can then set this portal's status flag to PS_PROCESSED so that it is ignored by future calls to GetNextPortal.

```
            // Allocate the portals actual visibility array
            pPortal->ActualVis = new UCHAR[ m_PVSBytesPerSet ];

            // Set initial visibility to off for all leaves
            ZeroMemory( pPortal->ActualVis, m_PVSBytesPerSet );
```

Next we call the RecursePVS function, which is the main recursive processing routine that creates the anti-penumbras and calculates the actual PVS (ActualVis array) for the current source portal. The RecursePVS call takes three parameters, shown below.

```
            // Step in and begin processing this portal
            RecursePVS( pPortal->NeighbourLeaf, pPortal, PVSData );

            // We've finished processing this portal
            pPortal->Status = PS_PROCESSED;

        } // Next Portal

    // Success!!
    return BC_OK;
}
```

The first parameter is the index of a leaf in the leaf array. Normally, this leaf index will be the neighbor leaf of a generator portal that we have just accepted and stepped through. This means that on the next recursion, the generator portal will become the target portal and this leaf will become the new generator leaf. We can then loop through the portals in this new leaf to try to find additional visible generator portals.

The next parameter we pass in is a pointer to the source portal (i.e. the portal we are about to calculate the PVS for). This pointer will remain constant through each recursion. This allows us to access the source portal's ActualVis array so that we can set the bits for visible leaves to 1 as we find them.

The final parameter is the address of the PVSData structure. Some of the members are unused at this moment because it is the source portal that we are passing in. For each recursion after the first one, this data structure will hold the TargetPoints for the new target portal. The target portal will be the generator portal from the previous recursion (or what was left of it after clipping it to the anti-penumbra) and the TargetPlane will contain the plane of this portal as well.

Finally, notice that after the RecursePVS function returns, the PVS for the current source portal will have been created, so we set the portal's Status flag to PS_PROCESSED. This will let the GetNextPortal method know that this portal has been processed already and should not be returned as a source portal again. By the time the outer loop of the above function exits, the PVS for every portal in the level will have been computed and all the hard work done.

Before we examine the RecursePVS function which is arguably one of the most complex we have discussed so far (although not that large) we will take a look at the GetNextPortal method which was used by this function to select the portals for PVS calculation, in order of complexity.

```
ULONG GetNextPortal( )
{
    CPVSPortal * pPortal;
    long PortalIndex = -1, Min = 999999, i;

    // Loop through all portals
    for ( i = 0; i < GetPVSPortalCount(); i++ )
    {
        pPortal = GetPVSPortal(i);

        // If this portal's complexity is the lowest and it has
        // not already been processed then we could use it.
        if ( pPortal->PossibleVisCount < Min && pPortal->Status == PS_NOTPROCESSED)
        {
                    Min = pPortal->PossibleVisCount;
                    PortalIndex = i;

         } // End if Least Complex

     } // Next Portal

     // Set our status flag to currently being worked on =)
     if ( PortalIndex > -1) GetPVSPortal( PortalIndex )->Status = PS_PROCESSING;

     // Return the next portal
     return PortalIndex;
}
```

17.7.5 The RecursePVS Function

This function is the heart of the PVS calculator. It is called from CalcPortalVis to generate the PVS for a given source portal. RecursePVS and its helper function, ClipToAntiPenumbra, represent the recursive engine that is responsible for crawling through all of the leaves (starting at the source portal's neighbor leaf) and marking them as visible in the source portal's ActualVis array. Since this is a fairly complex function, we will take it one step at a time.

```
HRESULT RecursePVS(     ULONG Leaf,
                        CPVSPortal * SourcePortal,
                        PVSDATA & PrevData )
{
    ULONG           i,j;
    bool            More;
    ULONG          *Test, *Possible, *Vis;

    PVSDATA         Data;
    CPVSPortal     *GeneratorPortal;
    CPlane          ReverseGenPlane, SourcePlane;
    CPortalPoints  *SourcePoints, *GeneratorPoints, *NewPoints;

    // Store the leaf for easy access
    CBSPLeaf * pLeaf = pTree->GetLeaf( Leaf );

    // Mark this leaf as visible
    SetPVSBit( SourcePortal->ActualVis, Leaf );
```

The first thing we do (after setting up some local variables) is create a pointer to the target leaf whose index is passed in as the Leaf parameter. We do this by passing the index into the BSP tree's GetLeaf method which is assumed to return the relevant leaf pointer in this placeholder code.

The leaf index passed in as this parameter describes the target leaf which ***was*** the neighbor leaf of the previous generator portal that was found in a previous instance/recursion of the function. The first time this function is called by CalcPortalVis, we will not yet have a previous generator portal, so this leaf index will actually describe the source portal's neighbor leaf. This is the leaf at which the flood begins for the source portal. Regardless of whether this is the first instance or not however, this leaf will be the target leaf in this instance of the function and is the leaf we have arrived at after stepping though a previous generator portal (or the source portal if this is the first recursion). Remember that every generator portal that passes the visibility test will be walked through by this function so that we arrive at the generator portal's neighbor leaf (which is the leaf we get to if we walk through the generator portal). This function will then call itself again passing in the generator portal's neighbor leaf as the Leaf parameter so that on the next recursion, it will become the target leaf. The target leaf is always the leaf used by this function to search for generator portals contained within it in the hopes of stepping through into their neighbor leaves.

If we have managed to get to this leaf, then it must be visible from the source portal, so we set this leaf's bit to 1 in the source portal's ActualVis array as you can see above. This means that when this function is called, the Leaf passed in will have already passed the visibility test in the previous recursion. For example, when we first call this function from the CalcPortalVis function, we pass in the source portal's

neighbor leaf. We know that it is going to be visible from the source portal because it is the leaf that the source portal leads into. Because of this, we need to set its bit to 1 in the source portal's ActualVis array. If this function has been called from a previous recursion, then this leaf is the leaf that we have stepped into after walking through a generator portal.

Our next task is to configure the local PVSDATA structure that we instantiated on the stack at the top of the function. This is like the PVSDATA structure passed into this function from the caller and we will fill it with details about any generator portals that we discover in this recursion. For example, if we find a generator portal that is visible in the current target leaf (the Leaf parameter), we will transfer its details into this data structure and pass it to the next recursion of the function (much as we did when we first called the function from CalcPortalVis). This means that every time the function is called (except for the first time), the PrevData parameter to this function will contain a data structure containing the generator portal found in the last recursion and any information we need pertaining to it. This previous generator portal can then be used as the target portal in this instance of the function.

```
    // Allocate our current visibility buffer
    Data.VisBits = new UCHAR[ m_PVSBytesPerSet ];

    GetPortalPlane( SourcePortal, SourcePlane );
```

The first thing we do when setting up the PVSDATA structure that will be passed into the next recursion of the function (assuming visible generators are found in the current leaf we are processing) is allocate memory for storing some visual information. Recall that in the CalcPortalVis function we set the first data structure's VisBits pointer to point at the source portal's PossibleVis array. Every time we find a new generator portal, we will be able to refine this PossibleVis array as we work our way from portal to portal. We use this array to give us the opportunity for an early-out option, as it will constantly keep track of the leaves we have visited and leaves we do not have to visit.

> **Note:** Please remember that the GetPortalPlane method is assumed to return a plane that matches the direction of the passed portal.

For example, imagine we that have a target portal which can see five portals to the left and five portals to the right. The target portal might possibly be able to see all of these portals (and all of their neighbor leaves) and therefore may have all of these bits set to 1 in its PossibleVis array. Now assume that in the generator leaf (which the target portal leads into) there are two generator portals, one on the left leading to the other portals on the left, and one on the right leading to the other portals on the right. The left generator portal might be able to see many more portals to the right than the target portal can, but also, the generator portal would not be able to see any of the portals to the left of the target portal because these would be behind the generator portal's plane. Therefore, we are only interested in leaves that can be seen from the target portal when looking through the current generator portal. In other words, we do not want to know about leaves that the generator portal can see but the target portal cannot see. We also do not want to know about portals that the target portal can see and the generator portal cannot see. We can only see leaves from the source which both the target and the generator portals can see because this is the current combination of portals that the source portal is supposed to be looking through.

If we do a logical AND with the generator portal's PossibleVis array and the target portal's PossibleVis array, we manage to zero out all of the bits from the source portal's PossibleVis that cannot been seen using both the target and generator portal combination we are currently processing. This means that

with every recursion of the function along a given path, we manage to zero the bits out of leaves that cannot possibly be seen using the current combination of target/generator portals.

This also means that at every level of recursion, we can check the bits in the data structure's (Data) VisBits array against all of the bits in the source portal's ActualVis array, and if there are any set in Data.VisBits which are not set in the ActualVis array of the source portal, then we still have some possible visible leaves to test. Otherwise, if there are no bits set in Data.VisBits which are not already set in the source portal's ActualVis array, it means that there is nothing visible in this leaf which we have not seen before and we can just skip this generator portal. This will allow us to avoid visiting the same portals and leaves unnecessarily when using different combinations of target and generator portals.

No doubt some of this can be a bit confusing, as there is a lot to consider. We will look at some diagrams in a moment to help clear up some of these concepts and clarify why we have set up this PVSData structure and why we have allocated an empty VisBits array for it.

Our next step is to create some local pointers of type unsigned long. The first pointer (called Possible) points to the temporary VisBits array that we have just allocated and have yet to populate, and the second points to the source portal's ActualVis array.

```
    // Store data we will be using inside the loop
    Possible    = (ULONG*)Data.VisBits;
    Vis         = (ULONG*)SourcePortal->ActualVis;
```

The reason we do this is that we will be checking every bit in the VisBits array against every bit in the source portal's ActualVis array to determine whether or not we can see anything new in this leaf. If there are many leaves in the level, then this will be an expensive loop. Normally, because these are byte arrays we would have to check every byte from one array with every byte in the others. By setting up these two long pointers, we can compare four bytes at time, which will make the testing four times faster (this will make a more sense in a moment when we see these pointers being used).

It may appear that we are currently missing something. After all, we have not yet used the temporary Data.VisBits array that we allocated above. All we have done is allocated enough memory to hold a bit for every leaf in the BSP Tree. This is the piece that will fall into place once we find a next generator portal to process.

With our initial data structures set up, it is now time to loop through each portal in the target leaf (the leaf index passed into this function) and check whether we can see any of them. In each iteration of this loop we test a single generator portal and, if found to be of interest, we will perform some anti-penumbra clipping on it in the hopes of stepping through it, if it should survive the clipping process.

```
    // Check all portals for flow into other leaves
    for ( i = 0; i < pLeaf->PortalCount; i++ )
    {
        // Find correct portal index (the one IN this leaf (not Neighbouring))
        ULONG PortalIndex = pLeaf->PortalIndices[ i ] * 2;
        if ( GetPVSPortal( PortalIndex )->NeighbourLeaf == Leaf ) PortalIndex++;

        // Store the portal for easy access
        GeneratorPortal = GetPVSPortal( PortalIndex );
```

Just inside the start of the generator portal loop, we fetch a pointer to the generator portal stored in that leaf that matches the index of the current loop variable. We are essentially just looping through the portal indices stored in the current leaf, but we must remember that these portal indices reference the original two-way portal array. Therefore, we must multiply the index by two to get the index into the one-way CPVSPortal array where the two duplicates of the original portal we are processing in the leaf are stored. PortalIndex in the above code is therefore the index of the first of the two duplicates in the CPVSPortal array that were created from portal[i] in the current target leaf. Since the first one-way portal of the pair in the array might not be the one owned by this leaf (it might have this leaf as its neighbor), we must test to make sure that its neighbor leaf is not equal to the target leaf index. If it is, then this one-way portal is not owned by the target leaf and therefore, the one following it in the array must be the one we want. In this case, we just increment the portal index and feed it into the GetPVSPortal function which is assumed to return the CPVSPortal pointer stored at the relevant index in the one-way portal array.

Next we check whether the target portal (the previous generator portal stored in the PrevData structure passed from the previous recursion) can see the leaf that this generator portal leads to. If the target portal does not have the generator portal's neighbor leaf set in its PossibleVisBits array, then it cannot see this portal and we continue on to the next one.

```
        // We can't possibly recurse through this portal if it's neighbour
        // leaf is set to invisible in the target portals PVS
        if ( !GetPVSBit( PrevData.VisBits, GeneratorPortal->NeighbourLeaf ) )
           continue;
```

While it might seem logical to think that a target portal can always see a generator portal, this is not necessarily the case. A target portal will not be able to see its own duplicate portal (the portal in the same space that faces the opposite way) so this prevents our stepping back into the leaf we just entered through and getting caught in an endless recursive loop between two leaves. Remember that the target portal's duplicate portal will be owned by the current leaf, so we must ignore it. Because a portal will never be able to see its duplicate (because it is ON_PLANE with itself and therefore would not have had its bit set to 1 in its PossibleVis array by the InitialportalVis function), this test allows us to avoid this problem and reject any other generator portals in the current leaf that are ON_PLANE with the target portal. Notice above however, that we are using PrevData->VisBits for this comparison instead of using the target portal's PossibleVis array. This temporary VisBits array is important and we will need to discuss it in more detail in a moment. Remember however that during the first call to the function, PrevData->VisBits will be a pointer to the source portal's PossibleVis array but will change as we recur.

The next section of code is a little complicated but it provides a significant performance optimization to the recursive engine by offering early outs. Study the following code for a few moments and get a feel for the variables used and what seems to be happening.

```
        // If the portal can't see anything we haven't already seen, skip it
        if ( GeneratorPortal->Status == PS_PROCESSED )
            Test = (ULONG*)GeneratorPortal->ActualVis;
        else
            Test = (ULONG*)GeneratorPortal->PossibleVis;

        More = false;
```

```
        // Check to see if we have processed as much as we need to
        // this is an early out system. We check in 32 bit chunks to
        // help speed the process up a little.
        for ( j = 0; j < m_PVSBytesPerSet / sizeof(ULONG); j++ )
        {
            Possible[j] = ((ULONG*)PrevData.VisBits)[j] & Test[j];
            if ( Possible[j] & ~Vis[j] ) More = true;

        } // Next 32 bit Chunk

        // Can we see anything new ??
        if ( !More ) continue;
```

In order to understand this code we need to take some time to discuss the temporary Vis array in more detail. While the previous code snippet demonstrates exactly how it is used, even this small snippet of code can be extremely difficult to visualize.

Earlier we discussed the fact that if we AND the generator portal's PossibleVis array with the target portal's PossibleVis array, we end up with only the bits set in the local Vis array that *both* portals can possibly see. This makes sense because we are only interested in knowing how much of the generator portal's visibility set we can see while looking through the target portal. This has the potential to significantly reduce the generators portal's bit set, and in turn, the leaves that we have to process. What is even better is that it is entirely possible that the generator portal itself may have already had its ActualVis array (its own PVS) array already calculated if this portal was selected before the current source portal. In this case we can use the ActualVis array for the AND operation with the source portal's PossibleVis array and shave even more bits out of this temporary array, since we know that the generator portal's ActualVis array will be a lot more accurate than its PossibleVis array. As the prior code snippet illustrates, we can first check the generator portal's status flag, and if it has already had its ActualVis array calculated (status = PS_PROCESSED) then we can setup a pointer to this array (test) and use it instead of the (not as good) alternative of using the generator portal's PossibleVis array.

Being able to use the ActualVis array will be quicker because it means that many of the leaves will have already been tested and set to zero because they could not actually be seen from the generator portal when it had its ActualVis calculated. This time-saver is the reason why we used the GetNextPortal function to return the least complex portals first in the previous function we discussed. If we calculate the least complex portals first, then hopefully a more complex one can use much of this information during traversal to reject many leaves and zero them out immediately.

Now that we have a pointer (test) to either of the generator portal's visibility arrays (actual or possible), we can bitwise AND this array with the target portal's PossibleVis array (stored in PrevData.VisBits and passed from the previous recursion) and store the result in the Data.VisBits array that we allocated in this function a little earlier. Remember that the Data.VisBits array is pointed to by the long pointer called Possible. This means that at the end of the loop, this array will store only the bits that can be seen by both the target portal *and* the generator portal together. Notice that because we use long pointers, we can do the loop in 32-bit chunks for speed and therefore, compare 32 leaves per iteration.

> **Note:** The Data.VisBits (pointed to by Possible) buffer compiled here is passed into the next recursion as the PrevData.VisBits parameter and as such this process is ongoing and the PrevData.VisBits member passed to each recursive step acquires more zeros with each portal that we pass through.

Now that we have this array, our next job is to test it against the source portal's ActualVis array (pointer to long pointer Vis) which contains all the visible leaves we have found so far. If there are any bits set in Possible which are not set in Vis, then it means that we have to carry on because there are some leaves through this generator portal which have not yet been examined. If there are no bits set in Possible that are not set in Vis, then we can skip this portal because all of the bits have already been set in the source portal's ActualVis array. There is no point in stepping down that path and performing a myriad of anti-penumbra clipping operations only to flag leaves as visible that we have already visited.

Note: In short, the above code is saying, "First give me only the leaf bits that can be seen though both the target and generator portals since this is the combination of portals through which the source portal is currently looking". The resulting bits are stored in Possible (i.e., Data.VisBits). We then essentially say "Now test if this buffer of leaves that can be seen by both the target portal and the generator portal contains any leaves which we have not already flagged as visible in the source portal's ActualVis array". If not, there is nothing new to see through this combination of portals so we do not step through the generator portal.

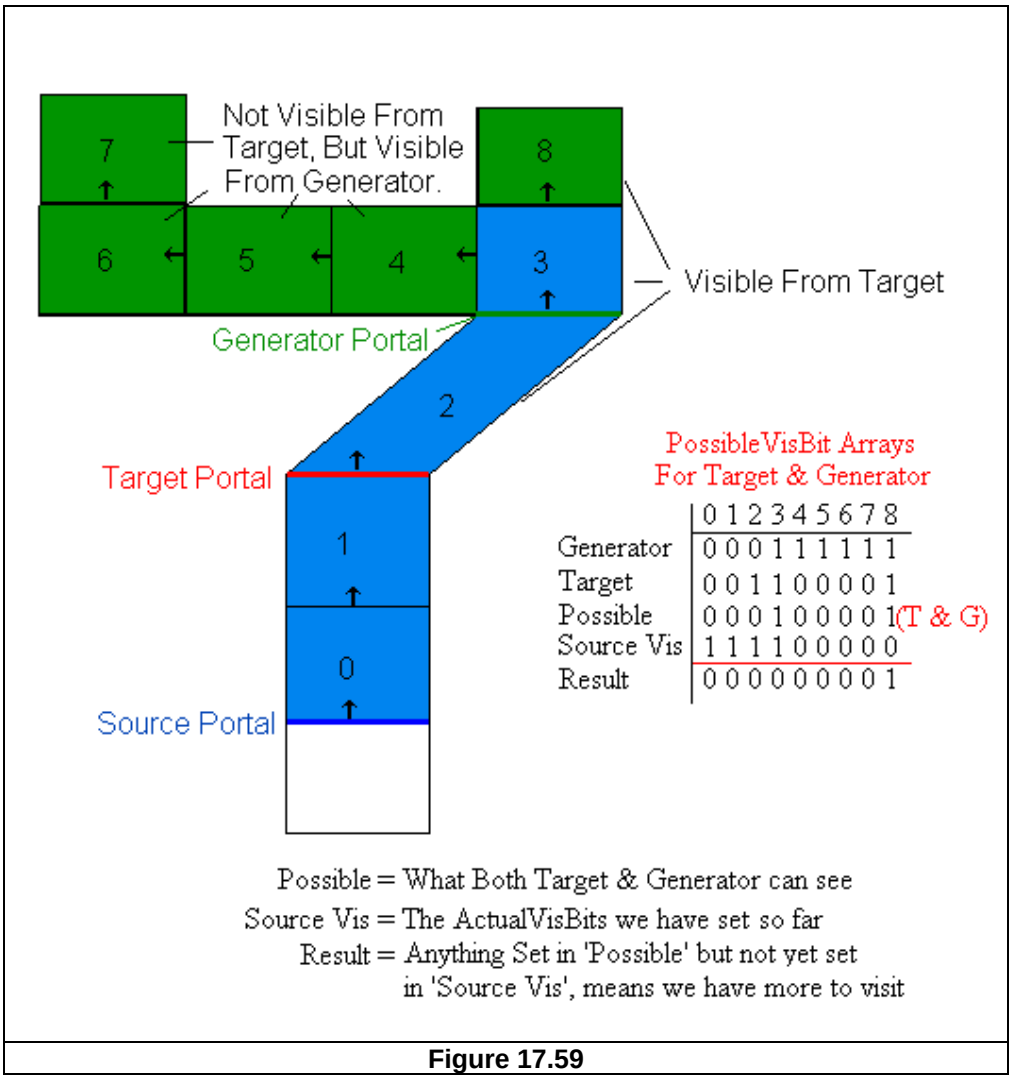

Figure 17.59

Figure 17.59 demonstrates a situation where we are midway through calculating the ActualVis array for the source portal. You can see that we have already stepped through leaves 0, 1, 2 and 3 and we have flagged them as visible (see 'Source Vis' in the bit table). Our next job is to see if there is anything visible in leaf 3 (something that we have not yet seen) that we should see.

First of all, the generator portal can see leaves 3, 4, 5, 6, 7, and 8, so it has these bits set in its PossibleVis array. This is shown in the bit table and labeled 'Generator'. The target portal can see leaves 2, 3 and 8, and as such, will have these bits set in its PossibleVis array. (The target portal cannot see through portal 4 because they are both front facing.) We can see the target portal's bits in the bit table labeled 'Target'. What we do next is a bitwise AND between the generator bits and the target bits and store the result in Possible (remember that this is really Data.VisBits). This will leave us with only the bit set for the leaves that can be seen by both the target and generator portals. Because leaves 4, 5, 6 and 7 cannot be seen by the target portal, their bits are set to zero and we know we will never have to visit them through this combination. We can only see what is visible through each target portal, and those leaves are not. This allows us to zero out the leaves in the generator portal's PossibleVis array that we cannot possibly see and thus avoid visiting them.

Now that we have this array, we check it against the source portal's ActualVis array (called 'Source Vis' in the table in Figure 17.59) and if we find any bits not set to 1 that are set to 1 in the Possible array, then there may still be new things to see, so we must continue through the generator portal (providing we later find it is within the anti-penumbra). Otherwise, we can skip this portal because nothing new can be seen through the current target/generator combination.

Notice in the example that there was 1 bit (leaf 8) that was not yet set in the source portal's ActualVis array, but was set in the Possible array. This means that that we still have to visit leaf 8. By looking at the diagram, we can see that this does in fact hold true. Leaf 8 does need to be examined because it can be seen from the source portal.

That is basically what that last section of code does -- it allows us to exit early if nothing new can be seen, and avoid recursion over the same data over and over again. This is a real time-saver since the Possible array (Data.VisBits) is passed on to the next recursion of the function if a generator is found. This means that the zeroing out effect is on-going because in our example, the Possible array will be passed to the next recursion, where it will be used as the target argument. Every time the function is called, the PrevData.VisBits array passed to each function will contain more and more zeros, until we can start skipping portals and entire sections of the level, either because they have already been visited, or because they are not visible through the portals that we have traveled through up to that point. Please take a few extra moments to study the previous code and Figure 17.59 until you are sure that you understand how this works.

One other item that may be confusing is that at first glance it seems impossible that we would visit the same leaves twice (which would seem to diminish the enhancement offered by the previously discussed optimization). Figure 17.60 however demonstrates a small but quite common case where the code we just discussed will help speed things up.

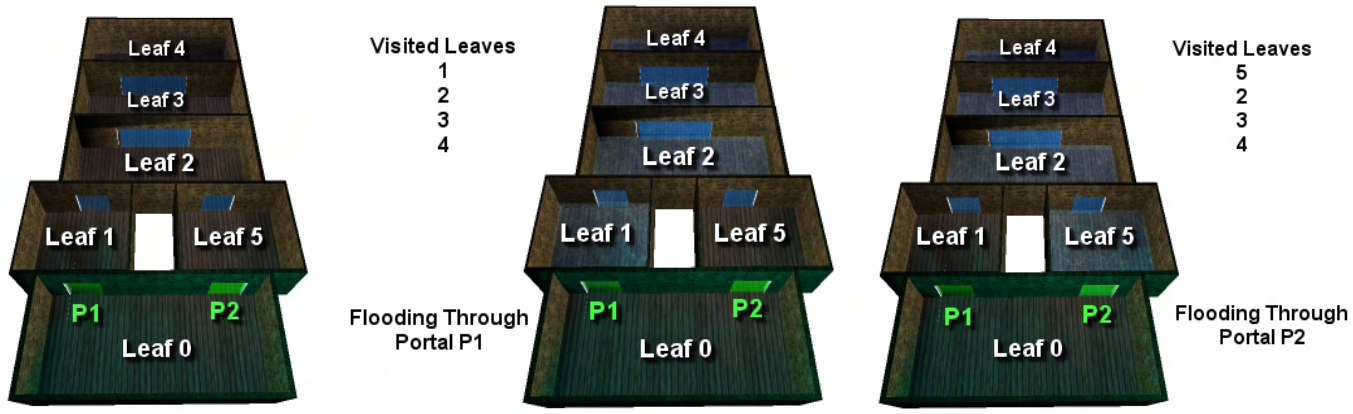

Figure 17.60

In Figure 17.60 we see that the source portal's neighbor leaf has two target portals. If we start with the portal P1 for example, we end up in leaf 1, then 2, 3, and finally 4. While traveling through each leaf, we are performing the usual clipping and testing of generator portals against the anti-penumbra. When we hit leaf 4, we have reached the end of the road because there is no leaf to see, so we abort the recursive process and unwind all the way back to leaf 0. If we repeat the process for the target portal in leaf 0 (portal P2), all is well until we exit leaf 5 and go into leaf 2. In leaf 2, we have to perform all of the same steps as before for leaves 2, 3, and eventually leaf 4, and as we can see, we are just revisiting places that have already undergone calculation and have already been determined as visible. It is not hard to imagine this example taking on a much more realistic scale (like in an actual 3D game level) where situations like the source portal in Figure 17.50 could frequently pop up and cause hundreds of leaves to be recalculated two or more times. We might find a situation where more than two target portals (like those shown in the diagram) cause thousands of redundant and unnecessary anti-penumbra clipping calculations.

> **Note:** Without these early-out cases, the PVS calculator will still work, albeit significantly more slowly. As mentioned earlier in the lesson, these modifications were able to reduce compilation time for one of our test levels from over 10 minutes to only a few seconds. This is obviously an incredible savings given the relatively small amount of code that is necessary to achieve it.

If we have made it this far in the function code without skipping the generator portal, then it is becoming more likely that the generator portal may be visible from the source portal, and thus requires full processing. Therefore, we copy the generator's plane into the Data.TargetPlane member so that if we do have to recur through the generator, this portal plane can be used as the target plane in the next recursive call. Remember that any generator portals that get accepted in this instance of the function will be stored in this data structure and passed on to the next recursion, so that we can use it as the new target portal in that instance.

```
        // The current generator plane will become the next recursions target plane
        GetPortalPlane( GeneratorPortal, Data.TargetPlane );
```

Our next test is to make sure that the generator portal is not ON_PLANE with the target portal. If it is, then they cannot see each other and we can skip this generator.

```
        // We can't recurse out of a coplanar face, so check it
        ReverseGenPlane.Normal   = -Data.TargetPlane.Normal;
```

```
        ReverseGenPlane.Distance = -Data.TargetPlane.Distance;
        if (FuzzyVectorCompare( PrevData.TargetPlane.Normal,
                                ReverseGenPlane.Normal,
                                0.001f ) ) continue;
```

Note that for this test we are using a generator plane with a reversed normal and are comparing this normal against the normal of the target portal (PrevData.TargetPlane). We do this because we need to check that the portal we have just entered this leaf through is not on the same plane as any we are about to exit this leaf through. Thus, we need to check if any of the portals in this leaf are co-planar with the portal we have just entered through. Because the portal we have just stepped through will belongs to the previous leaf that we were in, it means that its normal will be facing into the current leaf (since the current leaf is its neighbor leaf). The other portals we are checking in the current leaf are owned by the current leaf and have their normals pointing out of this leaf into their neighbor leaves. This means that even if one of the portals belonging to the current leaf is on the same plane as the portal we entered this leaf through, the normals of the two portals will be pointing in opposite directions. So we need to flip one of the portal normals for the comparison test. In order to compare the vectors, we just subtract them from each other, and if the absolute value returned is zero (with tolerance) then we have a match. This generator reversed plane will also come in handy later on as we shall see. Note that in the above code this normal compare (with tolerance) is assumed to be done by a utility method called FuzzyVectorCompare that accepts the two vectors (the normals) that we would like to compare and an epsilon value to use for the comparison (0.001 in this example). If the function returns true, the two vectors are considered equivalent and we will skip this generator portal and move on to the next one in the leaf. Thus, we will not step though it since the target portal could not possibly see through the back of it.

Our next test determines whether any part of the generator portal lies behind or is co-planar with the source portal's plane. Recall that in our InitialPortalVis function, portals that were behind other portals were not included in that portal's PossibleVis array because a portal cannot see a portal that is behind it. A generator portal spanning the plane of the source portal would still be in the source portal's PossibleVis array however and steps must be taken when this is the case to make sure that we build an anti-penumbra of the correct shape. Figure 17.61 shows an example of situation.

A source portal might be able to see a generator portal, but it might not be able to see **all** of it. In Figure 17.61 we can see that a section of the generator portal that is behind or co-planar with the source portal's plane cannot be seen by the front of the source portal and would lead to an incorrect and

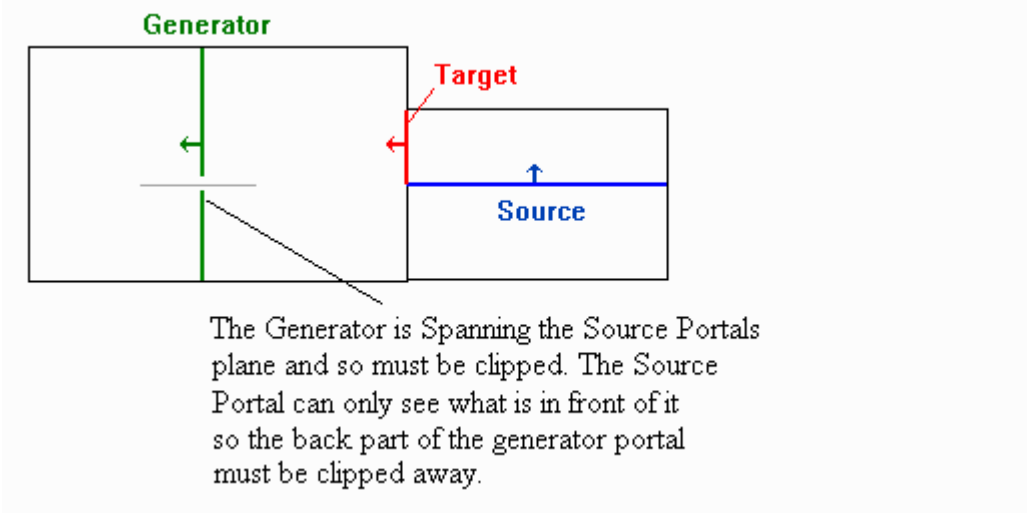

Figure 17.61

overgenerous visibility set for the current source portal. Therefore, we have to clip the generator portal to the source portal's plane so that we are only left with the front part of the generator portal.

```
        // Clip the generator portal to the source. If none remains, continue.
        GeneratorPoints = GeneratorPortal->Points->Clip( SourcePlane, false );
        if ( GeneratorPoints != GeneratorPortal->Points )
            FreePortalPoints( GeneratorPortal->Points );
        if (!GeneratorPoints) continue;
```

In the above code, we call the CPortalPoints::Clip function to clip away any part of the generator portal's geometry that is behind the source portal's plane. We are certainly familiar with how to clip and split polygons at this point in the course. We pass in the generator portal's Points and get back a pointer to a new CPortalPoints structure containing the clipped portal points. Only points in front of the plane passed into the function (SourcePlane) survive the clip and are returned. We store the result in the local pointer GeneratorPoints. The FALSE parameter simply states that we do not want portals on the same plane as the source portal to be accepted in the clip operation. It is quite important to get rid of on-plane portals as well, because when we need to build our anti-penumbra a bit later, we will completely separate the source and target portals into two separate spaces. The generator portal will become the next recursion's target portal and will be used to build the clip plane. The more important point to remember for now is that there is no way for two co-planar faces to see each other.

> **Note:** The clip function will return a new clipped copy of the portal's geometry which we can store and continue to clip recursively as we progress through the level. The original CPortalPoint structure's vertices are not deleted since they will be needed for all the other portals we wish to calculate the PVS for. When we clip any portals in this function, we are working with temporary copies that we pass through the recursive process, which are discarded at the end.

The next step we take in the above code is check to make sure that the generator points were not completely clipped out of existence. If they were, then it means that we have clipped the generator portal completely away and none of it can be seen from the source portal. In this case, the Clip function will return NULL. We will check for this condition and skip this generator portal when it happens, because it cannot possibly see the source portal in that case.

The next section of code is specifically written to handle the case when this is the first call to the function. As discussed earlier, the first time this function is called, we only pass the source portal into the data structure and thus there are no previous generator portals to use as a target portal.

When we called this function initially from CalcPortalVis, we did not give the passed data structure's TargetPoints (PrevData) member any value (it was left as NULL). Because this pointer gets assigned to the current generator portal's points later on in this function, if this member is NULL, then it must mean that this is the first time the function has been called for this source portal. In this case, the current generator portal must be in the source portal's neighbor leaf (i.e., the first target leaf), and consequently must be a target portal that is visible from the source portal. When this is so, we simply copy over the new generator portal information into this function's data structure and recur through the target portal into the target portal's neighbor leaf. This will be the first generator leaf. No clipping happens in this first case; we simply collect a target portal and step through it. It is not until we do this that we have a target leaf and a generator leaf.

```
        // The second leaf can only be blocked if coplanar
        if ( !PrevData.TargetPoints )
        {
            Data.SourcePoints = PrevData.SourcePoints;
            Data.TargetPoints = GeneratorPoints;
            RecursePVS( GeneratorPortal->NeighbourLeaf, SourcePortal, Data );
            FreePortalPoints( GeneratorPoints );
            continue;

        } // End if Previous Points
```

The above function will only be called the first time this function is called in the recursive process for each source portal. In this initial call we are not actually looking for generator portals, but are instead searching for our first batch of target portals. When the function recurs, the generator portal we have just found will be the target portal. Notice also how we pass in the portal's neighbor leaf as the next leaf to visit. This means that in the next instance of the function we will have stepped through the target portal and will be in the generator leaf. While it may seem strange or perhaps even unnecessary, our next step will be to clip the generator portal to the target portal's plane. After all, the target portal's neighbor leaf *is* the generator leaf, so technically these portals are in the same leaf. Indeed, since leaves in a BSP tree are always convex, there is no way the generator portal could ever span the target portal. Although this is true, we are using this code as a safety measure, just in case a portal has been corrupted due to floating point accumulation errors or something of that nature. Our portals should never suffer from this problem in practice, but we will play it safe anyway.

```
        // Clip the generator portal to the previous target.
        // If none remains, continue.
        NewPoints = GeneratorPoints->Clip( PrevData.TargetPlane, false );
        if ( NewPoints != GeneratorPoints ) FreePortalPoints( GeneratorPoints );
        GeneratorPoints = NewPoints;
        if (!GeneratorPoints) continue;
```

Although we have not yet discussed this, we will see later that, in addition to building an anti-penumbra between the source and target portals, we will also build an anti-penumbra between the generator and target portals and clip the source portal to it as well. This will allow us to both reduce the size of the temporary target portal during each recursion as well as reduce the size of the temporary source portal. The smaller the source and target portals become during each recursive step, the smaller our anti-penumbras will become. This means we will clip away many more unseen portals and leaves than would otherwise be the case.

Earlier in the code we clipped the generator portal to the source portal so that if the generator portal was spanning the source portal's plane, we made sure that the generator was split. This left us with only the section of the generator portal that the source portal could see. Now we are going to do the same in reverse (see Figure 17.62).

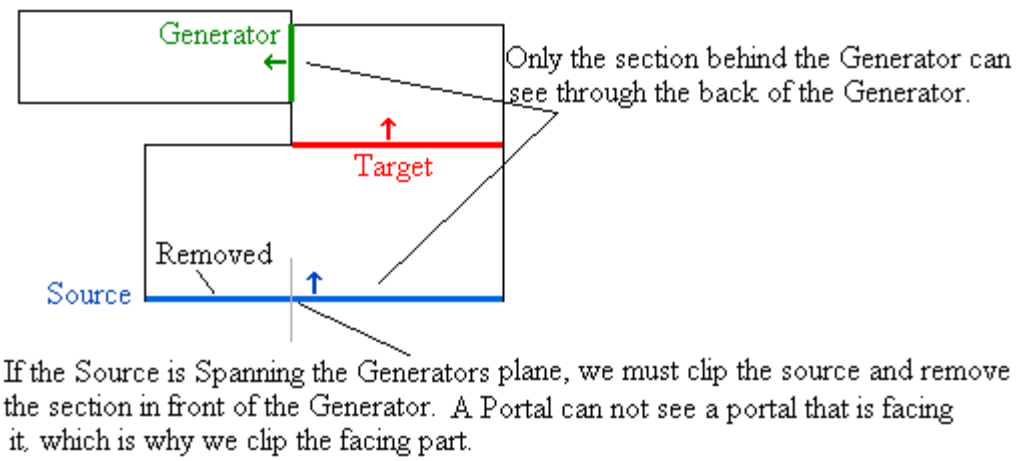

Figure 17.62

Remember that our source portal's PossibleVis array will include any portals that are spanning another portal's plane. In Figure 17.62, we can see that the source portal is indeed spanning the generator portal's plane. As we already know, the only section of the source portal that should be able to see through the generator portal is the section of the source portal that is behind the generator portal. In this case, some of the source portal is in front of the generator portal and is 'facing' the portal. Since facing portals cannot see each other, we have to remove the section of the source portal that is in front of the generator.

The problem is that our Clip function (as is standard for all clippers) clips away the section of the polygon *behind* the passed plane, but we want to do the opposite in this case. That is, we want to keep the piece of the source portal behind the plane and lose the piece in front of the generator plane. This is why we created a reversed generator plane earlier. Instead of having to write another function to remove front pieces, we send in the generator plane with a reversed normal so that the correct section of the source portal gets removed using the same clipper function. This lets the CPortalPoints::Clip function act as if it is removing the back section of the source portal when we are actually removing the front section due to the inverted plane normal.

Here is the code that clips the source portal to the reversed generator plane.

```
        // Make a copy of the source portals points
        SourcePoints = new CPortalPoints( PrevData.SourcePoints, true );

        // Clip the source portal
        NewPoints = SourcePoints->Clip( ReverseGenPlane, false );
        if ( NewPoints != SourcePoints ) FreePortalPoints( SourcePoints );
        SourcePoints = NewPoints;

        // If none remains, continue to the next portal
        if ( !SourcePoints ) { FreePortalPoints(  GeneratorPoints ); continue; }
```

Here we make a copy of the source points and then store them in a local variable called SourcePoints. It is important that we do not alter the actual (master) source points that were passed into this function

from the previous recursion because we are actually in the middle of a loop at the moment. We are looping through each generator portal in the current leaf, so we need to make sure that the original source portal points are left unharmed so that they can be used in the next iteration of the loop. Remember that we will need these points for testing against other generator portals also. The 'true' parameter to the CPortalPoints copy constructor tells it that it should copy that passed source vertices and not just store a pointer to the master vertex set.

If none of the source portal remains after the clipping operation, then the source portal had no points behind the generator plane and we cannot possibly see through it. Therefore, we skip this portal and move on to the next generator in the current leaf.

If all of our portals have survived up to this point then it means that we have rejected any trivial and obvious cases and must now build our anti-penumbra to clip the generator portal so that we are left with only the portion of the generator portal that can be seen through the source and target combination of portals. Fortunately, we are nearly at the end of the code for this function, and all we have to do now is call the ClipToAntiPenumbra function to clip the portals. The ClipToAntiPenumbra function is responsible for actually building the anti-penumbra, as well as clipping the generator portal to it.

In this next section of code, we use a global variable called CLIP_TEST_COUNT to specify how many times we want to call the ClipToAntiPenumbra function. This allows us to set clipping levels between 0 and 3. A setting of 3 will perform four calls to the function and will take longer to compile, but it will create the most accurate PVS. You can set it to any of the other values during level development to speed up the compile process. You will probably only need to set it to the highest level when doing the final compile of your scene, so by default we have set it to level 2.

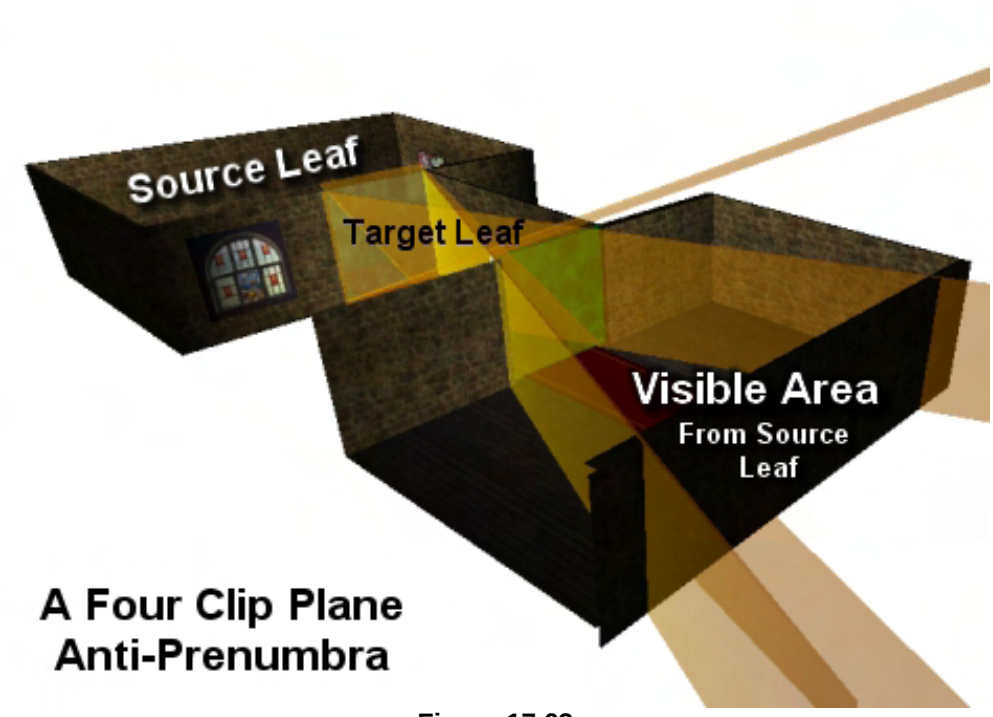

Figure 17.63

For now, just remember that the anti-penumbra is basically just a list of clip planes. Each plane in the list separates the source and target portals so that they both lay on opposite sides of the plane. Figure 17.63 provides a quick refresher of the anti-penumbra theory we discussed earlier. We will talk more about how to actually build the anti-penumbra when we discuss the ClipToAntiPenumbra function a bit later in this lesson.

Next we will look at how we call ClipToAntiPenumbra from the RecursePVS function. At each stage, we test the global variable CLIP_TEST_COUNT to see if it is set high enough to perform each clipping call.

```
        // Lets go Clipping :)
        if ( CLIP_TEST_COUNT > 0 )
        {
            GeneratorPoints = ClipToAntiPenumbra( SourcePoints,
                                                  PrevData.TargetPoints,
                                                  GeneratorPoints, false );
            if (!GeneratorPoints) { FreePortalPoints( SourcePoints ); continue; }

        } // End if 1 Clip Test
```

The first call we make (if CLIP_TEST_COUNT is set higher than 0 -- which it always should be) passes in the source portal, the target portal, and the generator portal. ClipToAntiPenumbra will build an anti-penumbra from the first portal (SourcePoints) to the second portal (TargetPoints) and will clip the third portal (GeneratorPoints) to that anti-penumbra. If the function call returns NULL, then the generator portal was fully outside of the anti-penumbra and cannot be seen from the source portal. If this is the case, then our work is done and we can ignore this portal and move on to the next one in the leaf.

If CLIP_TEST_COUNT is set higher than 1, then we call the ClipToAntiPenumbra function again, switching the order of the SourcePoints and TargetPoints arguments. This builds an anti-penumbra from the target portal to the source portal and clips the generator portal once again. While it would seem at first that building the anti-penumbra from source to target would generate exactly the same clip planes as generating it from target to source, we saw earlier that this would only be true if all portals were of the same shape and size (which is rarely the case).

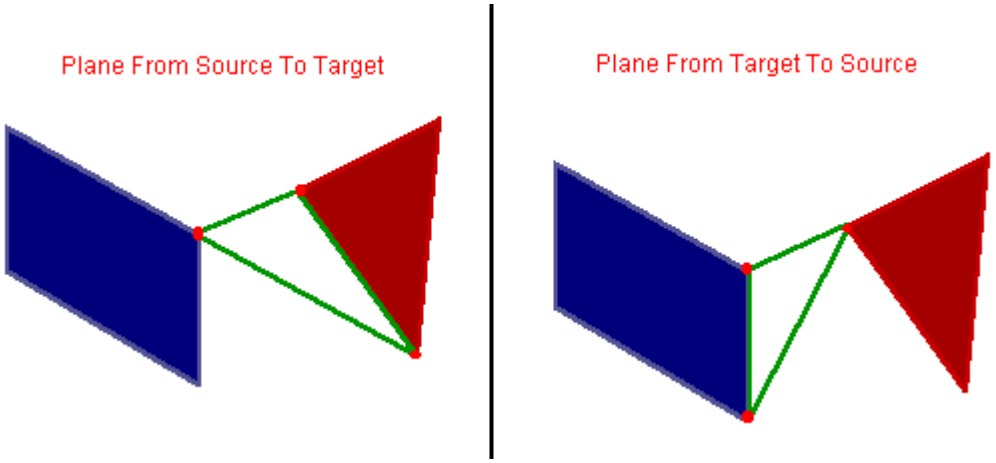

Figure 17.64

Figure 17.64 depicts a square source portal and a triangular target portal. We can see that the clip planes generated by switching the source/target order are quite different, and one combination might allow us to shave a little more off the generator portal than the other. By building the anti-penumbra and clipping to it using both combinations, we make sure that we find the most narrow clip planes possible. It is true that in some cases, both combinations might build the exactly the same anti-penumbra and thus the

second call to ClipToAntiPenumbra would be redundant. However, it is well worth it to include this concept, because in many cases a generator portal might be completely clipped away by the second call, which may not have been the case had we just relied on the first call. Not only will this give us a more accurate PVS, but it will also allow us to prevent further recursion through that portal, which will speed up our calculations. Next we see the second clipping call:

```
        if ( CLIP_TEST_COUNT > 1 )
        {
            GeneratorPoints = ClipToAntiPenumbra( PrevData.TargetPoints,
                                                  SourcePoints,
                                                  GeneratorPoints,
                                                  true );
            if (!GeneratorPoints) { FreePortalPoints( SourcePoints ); continue; }

        } // End if 2 Clip Tests
```

The fourth parameter (the Boolean) to the ClipToAntiPenumbra function requires a quick explanation. When we build our anti-penumbra from the source portal to the target portal, the planes will be created so that they are all facing inwards. In other words, anything outside the anti-penumbra (behind the clip planes) should be clipped away. When we change the order of the source and target portals in the second call however, the winding order will be different and the anti-penumbra is created with outward-facing normals instead. Anything that was behind the planes is now inside the anti-penumbra rather than outside. This means that we will need to toggle the clipping logic in the ClipToAntiPenumbra function so that in this case we keep what is behind and lose what is in front of the clip planes. The Boolean variable tells the function to reverse the clipping process to handle this case. Figure 17.65 depicts this process with the reversed plane normals. On the left we see the anti-penumbra planes being constructed from Source to Target, which generates a plane which, after the crossover in the target leaf, forms an inward facing view volume in the generator leaf. We can see then that any generator portal fragments that lay behind one of these planes get clipped away. When we build an anti-penumbra from target portal to source portal, the normals face into the opposing halfspace and we reject any generator portal fragments that lay in front of a clip plane.

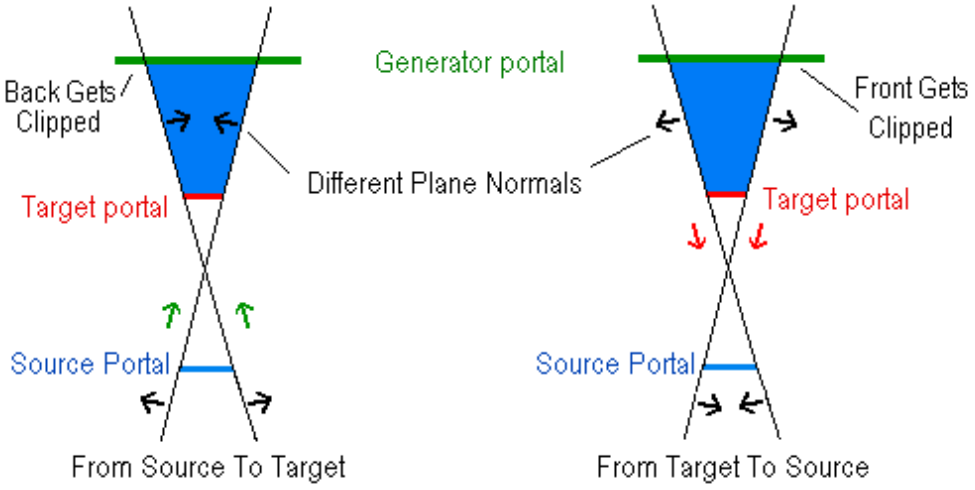

Figure 17.65

The third and fourth calls to the ClipToAntiPenumbra function do virtually the same thing as the first two, only this time they create the anti-penumbra using the target generator portal combination and clip the source portal to it. This means that our source portal will also get smaller with each recursion, resulting in the anti-penumbra that is built each time getting smaller and smaller. Again, this greatly increases our chances of removing more generator portals further down the line.

```
        if ( CLIP_TEST_COUNT > 2 )
        {
            SourcePoints = ClipToAntiPenumbra( GeneratorPoints,
                                               PrevData.TargetPoints,
                                               SourcePoints, false );
            if (!SourcePoints) { FreePortalPoints( GeneratorPoints ); continue; }

        } // End if 3 Clip Test
```

```
        if ( CLIP_TEST_COUNT > 3 )
        {
            SourcePoints = ClipToAntiPenumbra( PrevData.TargetPoints,
                                               GeneratorPoints,
                                                SourcePoints, true );
            if (!SourcePoints) { FreePortalPoints( GeneratorPoints ); continue; }

        } // End if 4 Clip Test
```

So we have actually built four anti-penumbras: two were used to clip the generator portal to the source portal's visibility volume and two were used to clip the source portal to the generator portal's visibility volume. If at any point the source or generator points returned from the ClipToAntiPenumbra call equal NULL, then we know that the portal was completely outside the anti-penumbra, and as a result, the source portal cannot possibly see the generator portal. In this case, we can abort and avoid stepping through this portal.

With all of the clipping now done, reaching this point in the code means that we still must be able to see the generator portal from the source portal through the current target portal. Thus, we must step through that portal and carry on our recursion into the generator portal's neighbour leaf. We store the newly clipped source and generator points in Data so that they can be passed on to the next recursion of this function. Remember that this generator portal will become the next recursion's target portal.

```
        // Store data for next recursion
        Data.SourcePoints = SourcePoints;
        Data.TargetPoints = GeneratorPoints;

        // Flow through it for real
        RecursePVS( GeneratorPortal->NeighbourLeaf, SourcePortal, Data );

        // Clean up
        FreePortalPoints( SourcePoints );
        FreePortalPoints( GeneratorPoints );

    } // Next Portal

    // Clean up
    if (Data.VisBits) delete []Data.VisBits;
```

```
    // Success
    return BC_OK;
}
```

We have now reached the end of this function. Notice that when the function calls itself, it passes in the generator portal's NeighborLeaf so that this leaf will become the current leaf in the next recursion. This means that we are stepping though this portal into that leaf to test the generator portals in that leaf. Our current generator portal is stored in the PVSData structure and passed on to the next recursion so that it can be used there as the new target portal. Finally, we free up any memory we may have allocated for this recursion and exit.

At this point, the hard part is essentially over. We will now examine some placeholder code for a ClipToAntiPenumbra function, which obviously played a pivotal role in the previously discussed function.

17.7.6 The ClipToAntiPenumbra Function

The job of this function is to loop through each edge in the source portal passed into the function and construct a plane using each point of the target portal, and then test whether this plane divides the two portals. We will be looking for the case where the source portal lies on one side of the plane and the target is located on the other. This indicates we have found one of the separating planes we are looking for. If the plane does indeed separate the two portals into two different sub-spaces, then this is considered a valid anti-penumbra clip plane and should be used to clip the generator portal. If the plane does not divide the two portals, then it is ignored

Figure 17.66 depicts an example of both a 'non-separating' and a 'separating' plane. Separating planes are the ones we are trying to find since they describe the extents of the view volume in the generator leaf.

Figure 17.66

Let us now examine the code for this function a few lines at a time:

```
CPortalPoints * CProcessPVS::ClipToAntiPenumbra( CPortalPoints * Source,
                                                 CPortalPoints * Target,
                                                 CPortalPoints * Generator,
                                                 bool ReverseClip )
{
    CPlane          Plane;
    CVector3        v1, v2;
    float           Length;
    ULONG           Counts[3];
    ULONG           i, j, k, l;
    bool            ReverseTest;
    CPortalPoints  *NewPoints;

    // Check all combinations
    for ( i = 0; i < Source->VertexCount; i++ )
    {
        // Build first edge
        l = ( i + 1 ) % Source->VertexCount;
        v1 = Source->Vertices[l] - Source->Vertices[i];
```

We start a loop to iterate through each edge (two vertices) in the source portal using v[i] and v[l] as the two vertices each time. ‘l’ is set up so that it loops back around to zero because the last edge will be between the last vertex and first vertex in the source portal. We use subtraction on these vertices to find the edge vector and store it in vector v1.

To create a valid plane we need to take one point from the target portal and create a vector (v2) from one of the source vertices to the target vertex. This is done for every vertex, creating a different plane during each iteration of the loop.

```
        // Find a vertex belonging to the generator that makes a plane
        // which puts all of the vertices of the target on the front side
        // and all of the vertices of the source on the back side
        for ( j = 0; j < Target->VertexCount; j++ )
        {
            // Build second edge
            v2 = Target->Vertices[ j ] - Source->Vertices[ i ];
```

By performing the cross product on these two vectors we will get the normal of the plane that the edge vectors lie on. If the initial length of this normal is equal to zero (with tolerance) then these two vectors do not lie on or make a valid plane and we should move on to the next point in the target portal.

```
            Plane.Normal = v1.Cross( v2 );

            // If points don't make a valid plane, skip it
            Length = Plane.Normal.x * Plane.Normal.x +
                     Plane.Normal.y * Plane.Normal.y +
                     Plane.Normal.z * Plane.Normal.z;
            if ( Length < 0.1f ) continue;
```

If the plane is valid then we will need to test that it does separate the source and target portals. Before we can use this plane however, we must normalize the plane normal and setup the plane structure.

```
            // Normalize the plane normal
            Length = 1 / sqrtf( Length );
            Plane.Normal *= Length;

            // Calculate the plane distance
            Plane.Distance = Target->Vertices[ j ].Dot( Plane.Normal );
```

Notice how we calculate the plane distance by taking the dot product of any vertex known to be on the plane (we use the target vertex) and the plane normal. We now have a valid plane in the variable called plane (containing a unit normal and a distance to the origin). Now we must see what side of the plane the other points in the source portal are on.

```
            // Find out which side of the  separating plane has the source portal
            ReverseTest = false;
            for ( k = 0; k < Source->VertexCount; k++ )
            {
                // Skip if it matches other verts
                if ( k == i || k == l ) continue;

                // Classify the point
                CLASSIFY Location = Plane.ClassifyPoint( Source->Vertices[ k ] );
                if ( Location == CP_BACK )
                {
                    // Source is on the negative side, so we want all pass
                    // and target on the positive side.
                    ReverseTest = false;
                    break;

                } // End If Behind
                else if ( Location == CP_FRONT )
                {
                    // Source is on the positive sode, so we want all pass
                    // and target on the negative side.
                    ReverseTest = true;
                    break;

                } // End if In Front

            } // Next Source Vertex
```

In the code above, we loop through each vertex in the source portal and classify it against the plane. We need to skip past the two source vertices (i & l), because these were used to create the plane (so they must lie on the plane). As soon as we find a vertex that is either to the front or to the back of the plane then we know that the whole portal must be in front or behind the plane and we can break from the loop. The loop just provides a way to skip past any co-planar vertices. Remember that we will need to remove any piece of the generator portal that is on the same side as the source portal (see Figure 17.67).

Because our clip function will remove backspace fragments, we must set the ReverseTest flag to TRUE if the source portal is in front of the current plane. This is because we want to clip away any areas of the generator portal that are in front of the plane (the same side as source portal). Since our clip function clips away anything that is behind the plane, by setting ReverseTest flag to TRUE, we can flip the normal of the clip plane prior to clipping the generator portal.

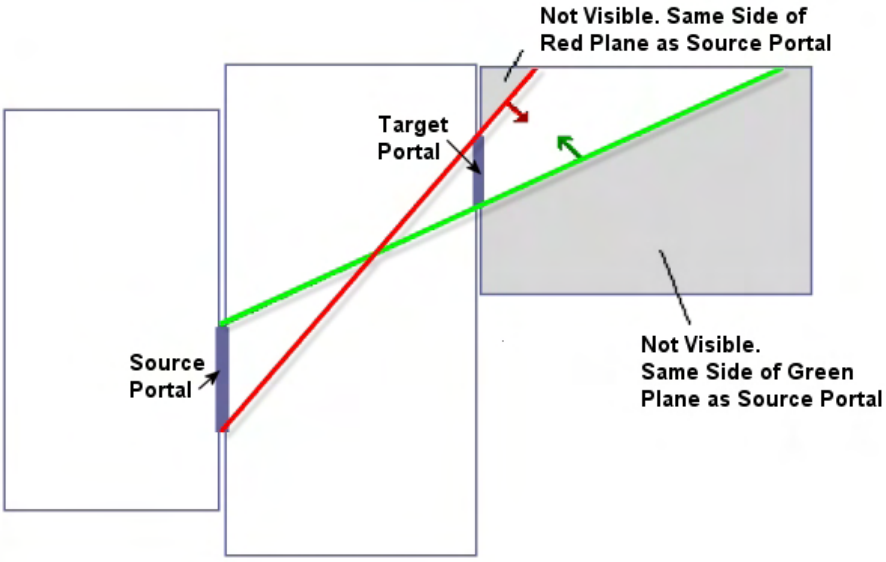

Figure 17.67

```
            // Planar with the source portal ?
            if ( k == Source->VertexCount ) continue;

            // Flip the normal if the source portal is backwards
            if ( ReverseTest ) { Plane.Normal = -Plane.Normal;
                                 Plane.Distance = -Plane.Distance; }
```

If we do not break from the above loop prematurely, it must mean that all of the points are co-planar with the computed plane and that it is not a separating plane. We can see that if k equals Source->VertexCount, then we skip this plane because it is not part of the anti-penumbra. k will only equal VertexCount if the loop is allowed to finish. Next, if the ReverseTest flag was set to TRUE in the loop, then we flip the direction of the plane normal so that the source now lies on the back of the plane instead of the front.

Now that we have a potential dividing plane and have made sure that the source portal is on the back of that plane, we can test the target portal to see if it is on the front side of the plane. If it is, then it is a separating plane and should be used to clip the generator portal. We loop through each vertex of the target portal (excluding the vertex that was used to create the plane) and classify it against the plane. If at any point we find a vertex that is behind the plane, then we bail out, because this cannot possibly be a dividing plane as some of the target portals points are on the same side as the source portal.

```
            // If all of the pass portal points are now on the positive
            // side then this is the separating plane.
            ZeroMemory( Counts, 3 * sizeof(ULONG) );
            for ( k = 0; k < Target->VertexCount; k++ )
            {
                // Skip if the two match
                if ( k == j ) continue;

                // Classify the point
```

```
                CLASSIFY Location = Plane.ClassifyPoint( Target->Vertices[ k ] );
                if ( Location == CP_BACK )
                    break;
                else if ( Location == CP_FRONT )
                    Counts[0]++;
                else
                    Counts[2]++;

            } // Next Target Vertex

            // Points on the negative side ?
            if ( k != Target->VertexCount ) continue;

            // Planar with separating plane ?
            if ( Counts[0] == 0 ) continue;
```

When we get out of the loop, we check to see if the loop was allowed to run its full cycle. If not, it means that we left the loop early because we found a target point that was behind the plane. If this is the case and k is not equal to the target portal's number of vertices, we just skip this plane and move on, because it is not a dividing plane.

Also, if counts[0] == 0 (which was used to record the number of points that were in front of the plane) then every point must be on the plane and again, this is not a dividing plane.

Assuming we pass the prior tests and the code continues, then this is indeed a plane that we want to use in our anti-penumbra and we clip the generator to this plane. You may remember however, that in the RecursePVS call we sometimes passed in TRUE as the final parameter when we needed to reverse the clipping operation and keep the back bit of the generator portal and discard the front bit. In our current situation we likewise must check if this parameter is TRUE, and if so, flip the normal of the plane prior to the call. That is, if the ReverseClip parameter was set to true, the caller would like to remove any portion of the generator portal that is in front of a clip plane instead of behind it.

```
            // Flip the normal if we want the back side
            if ( ReverseClip ) { Plane.Normal = -Plane.Normal;
                                 Plane.Distance = -Plane.Distance; }

            // Clip the target by the separating plane
            NewPoints = Generator->Clip( Plane, false );

            if ( NewPoints != Generator ) FreePortalPoints( Generator );
            Generator = NewPoints;

            // Target is not visible ?
            if (!Generator) return NULL;

        } // Next Target Vertex

    } // Next Source Vertex

    // Success!!
    return Generator;
}
```

This is no different than many of the other calls we have made to clip portals. If the Clip call returns NULL, then the generator portal was completely outside the anti-penumbra and nothing survived. Otherwise, it returns the new clipped vertex list for the generator portal back to the RecursePVS function.

> **Note:** The functions discussed so far in this lesson can be complicated on first read, but they are important to understand. Please be sure to review them a few times if you are having difficulty.

17.7.7 The ExportPVS Function

After the CalcPortalVis function returns program flow back to the ProcessPVS function, every portal will have had its own PVS calculated and stored in its ActualVis array. Recall that this array describes every leaf that the portal can see. However, the PVS rendering code we discussed earlier is not really interested in what the portals can see, it wants to know what a leaf can see (because that will tell us what camera in that leaf can see). The ExportPVS function will handle this conversion for us, using the portals' ActualVis arrays to build a visibility set for each leaf. Once done, all of the leaves' visibility information will be zero run length compressed and stored in one master array inside the tree. This array will represent the final Potential Visibility Set that we save to disk and eventually use in our rendering component.

As it turns out, this function will be very small since we have already done all of the hard work. All we must do is answer the question, "How do we know which leaves a given leaf can see?" Of course, we already know the answer to that: a leaf can see everything that all of its portals can see. So to get a complete visibility set for each leaf, we will just iterate through every portal owned by that leaf and concatenate all of the bits in their ActualVis arrays into one final result.

A temporary buffer (called LeafPVS) will be used to collect and store the bits for each leaf as we go along. This leaves us with an uncompressed buffer much like the ActualVis array that the portals use -- where one bit per leaf is used to indicate visibility. This buffer has the bits set for the leaves that all of its portals can see and thus we have a complete visibility set for that leaf. The next step is to take this buffer and send it to the CompressLeafSet function to compress the bits using zero run length encoding. Then we can insert the results into the master PVS data array stored either in the tree or sent out to file. Remember that every leaf will have its compressed PVS set stored in this one large array that the leaves of the BSP tree can index into. Earlier you will recall that we added a PVS member to the BSP tree's leaf structure. Every leaf will have a PVS index member that specifies where in the master PVS data block its PVS set starts. This index will also need to be set in this function.

```
HRESULT CProcessPVS::ExportPVS( CBSPTree * pTree )
{
    UCHAR * PVSData = NULL;
    UCHAR * LeafPVS = NULL;
    ULONG   PVSWritePtr = 0, i, p, j;

        // Reserve Enough Space to hold every leafs PVS set (plus some to spare)
        PVSData = new UCHAR[(pTree->GetLeafCount() * m_PVSBytesPerSet];
```

```
        // Set all visibility initially to off
        ZeroMemory( PVSData, pTree->GetLeafCount() * m_PVSBytesPerSet);

        // Allocate enough memory for a single leaf set
        LeafPVS = new UCHAR[ m_PVSBytesPerSet ];
```

At the head of the function we allocate an array where the master PVS data block will be stored. This array should be large enough to store N bytes for each leaf in the tree, where N is the number of bytes needed to store 1 bit for every leaf in the tree. In other words, this array has to be large enough to contain the visibility information of every leaf, for every leaf. We will hopefully not need anywhere near this much room to store that data since it will be compressed as it is added, but we can always shrink this array later when we know the final size of the compressed data block. We also allocate the temporary buffer that will be used to hold the leaf's uncompressed visibility set. We will reuse this same buffer for each leaf which is why it is allocated to be large enough to hold a bit for every leaf in the tree.

The PVSWritePtr variable is very important because we will use it to keep track of where we want the compressed data to be written in the master array. We will set it to 0 initially because we want the first leaf's PVS to be compressed into the master array starting at the beginning. We will see how this works in a moment. Now we are ready to loop through every leaf in the global BSP tree's leaf array and collect the visibility bits from each of its contained portals.

```
        // Loop round each leaf and collect the vis info
        // this is all OR'd together and ZRLE compressed
        // Then finally stored in the master array
        for ( i = 0; i < pTree->GetLeafCount(); i++ )
        {
            CBSPLeaf * pLeaf = pTree->GetLeaf(i);

            // Clear Temp PVS Array Buffer
            ZeroMemory( LeafPVS, m_PVSBytesPerSet );
            pLeaf->PVSIndex = PVSWritePtr;
```

For each leaf, we first clear the temporary buffer (LeafPVS) and set the current leaf's PVS index member equal to PVSWritePtr. This tells the leaf where its compressed PVS set will begin in the master PVSData array so that we can access its bits when rendering the tree. As we write each leaf's buffer to the array in compressed format, this variable will be updated to point to the position where the next leaf should be written when being compressed. For the first leaf, we already know that this will be at position 0.

Note that a leaf will always be visible to itself, so we set this leaf's bit in the temporary buffer to 1 by calling the SetPVSBit function.

```
            // Current leaf is always visible
            SetPVSBit( LeafPVS, i );
```

Now we will loop through every portal in the leaf and do a bitwise OR between the temporary buffer (LeafPVS) and the current portal's ActualVis array. This makes sure that all bits set to 1 in the ActualVis array in every portal are also set to 1 in the temporary buffer. You should understand the calculation for fetching the one-way portals for the current leaf as we have seen it several times now.

Just remember, the leaves of the tree store portal indices into the original two-way array of portals and we need to convert this into the correct index in the one-way portal array.

```
            // Loop through all portals in this leaf
            for ( p = 0; p < pLeaf->PortalCount; p++ )
            {
                // Find correct portal index (the one IN this leaf)
                ULONG PortalIndex = pLeaf->PortalIndices[ p ] * 2;
                if ( GetPVSPortal( PortalIndex )->NeighbourLeaf == i )
                   PortalIndex++;

                // Or the vis bits together
                for ( j = 0; j < m_PVSBytesPerSet; j++ )
                {
                      LeafPVS[j] |= GetPVSPortal( PortalIndex )->ActualVis[j];

                } // Next PVS Byte

            } // Next Portal
```

Now we will loop through every portal in the leaf and do a bitwise OR between the temporary buffer (LeafPVS) and the current portal's ActualVis array. This makes sure that all bits set to 1 in the ActualVisBits array are also set to 1 in the temporary buffer.

When the above loop finishes we will have collected all of the bits from all of the portals owned by this leaf and we will have a complete visibility set for it. Now we just call the CompressLeafSet function to add it to the master PVSData array.

```
            // Compress the leaf set here and update our master write pointer
            PVSWritePtr += CompressLeafSet( PVSData, LeafPVS, PVSWritePtr );

        } // Next Leaf
```

When we call CompressLeafSet, we pass in the temporary leaf visibility buffer along with the location within the master array where we want the compressed bits to be written (PVSWritePtr). We also pass in as the first parameter the beneficiary of the compressed data. After the function has compressed the bits and written them to the passed master array, the function returns the number of bytes that the leaf PVS buffer was compressed to before it was added to the master array. All we have to do now is add this number to the PVSWritePtr and we will have the updated location to begin writing the next leaf's PVS in our next iteration. This also gives us the correct value for the next leaf's PVSIndex member used during rendering.

When the loop ends, our scene PVS is complete and is stored in the PVSData array allocated at the top of this function. This array is ready to be saved to file and used by the runtime component. Now we can release the temporary buffer memory that we allocated at the start of this function.

```
        // Clean up after ourselves
        delete []LeafPVS;
        LeafPVS = NULL;

        // Pass this data off to the BSP Tree (data, size, compressed)
```

```
        pTree->SetPVSData( PVSData, PVSWritePtr, PVS_COMPRESSDATA ) ;

        // Free our PVS buffer
        delete []PVSData;

    // Success!!
    return BC_OK;
}
```

At the bottom of the function the master PVSData pointer is passed to the BSP tree's SetPVSData method. This method is also passed the compressed size of the data, so it will resize the passed PVSData array (actually done via a copy into a smaller array) and store it in one of its member variables. Other processes such as those that save the tree to file can then access the PVS data.

17.7.8 The CompressLeafSet Function

CompressLeafSet is responsible for taking the information out of the passed leaf visibility buffer, compressing it using zero run length encoding, and adding it to the master PVSData array. You will recall that it is invoked in ExportPVS like so:

```
// Compress the leaf set here and update our master write pointer
PVSWritePtr += CompressLeafSet( PVSData, LeafPVS, PVSWritePtr );
```

The function is passed the leaf visibility buffer and the position to start writing in the master PVSData array. Remember that PVSWritePtr equals 0 the first time this function is called (for leaf 0's visibility set), so we will be telling the function to start writing the compressed information at byte 0 in the PVSData array. CompressLeafSet will return the number of compressed bytes written to the PVSData array during the current call. This value was added to the write pointer in previous function to allow us to skip past all of the compressed data that has just been written to the master PVSData array. The write pointer then points to the offset in the array where we should start writing the next leaf's compressed data the next time this function is called.

```
ULONG CProcessPVS::CompressLeafSet ( UCHAR MasterPVS[],
                                     const UCHAR VisArray[],
                                     ULONG WritePos)
{
    ULONG   RepeatCount;
    UCHAR  *pDest = &MasterPVS[ WritePos ];
    UCHAR  *pDest_p;

    // Set dynamic pointer to start position
    pDest_p = pDest;

    // Loop through and compress the set
      for ( ULONG j = 0; j < m_PVSBytesPerSet; j++ )
    {
        // Store the current 8 leaves
            *pDest_p++ = VisArray[j];
```

```
        // Don't compress if all bits are not zero
            if ( VisArray[j] ) continue;

        // Count the number of 0 bytes
            RepeatCount = 1;
            for ( j++; j < m_PVSBytesPerSet; j++ )
        {
            // Keep counting until byte != 0 or we reach our max repeat count
            if ( VisArray[j] || RepeatCount == 255) break;
            else
              RepeatCount++;

        } // Next Byte

        // Store our repeat count
        *pDest_p++ = RepeatCount;

        // Step back one byte because the outer loop
        // will increment. We are already at the correct pos.
            j--;

    } // Next Byte

    // Return written size
      return pDest_p - pDest;
}
```

First we set up two pointers (pDest and pDest_p) so that they point to the correct byte in the PVSData array to start writing the new information. The pDest pointer is not altered after that since its job is to store this starting point for current leaf set. Our outer loop then iterates over every byte in the leaf visibility buffer. (We will actually use pDest_p to write to the PVSData array.)

If the current byte in VisArray is non-zero, then we simply copy it over into PVSData unaltered. This is because we can only compress zeroes, and thus we skip around to the next iteration of the loop. When we do encounter a zero value, then this is the start of a zero run and we know that the next byte that has to be written into the master array is the actual number of zeroes that will follow. We set the RepeatCount variable to 1 at this point because we know that there is at least one zero in the run that we have collected so far. We then execute an inner loop to iterate through the leaf's visibility bits until we hit a non-zero byte or we have reached a run count of 255 (the maximum value capable of being stored in a single byte). Each time we hit another zero, we increase the counter (RepeatCount) by one, thus keeping track of the current length of the run. After exiting the inner loop, the current run length is recorded and we pass control back to the outer loop.

Notice that we decrement the loop counter j by one before we iterate once more in the outer loop. We do this because j is the non-zero byte that will need to be copied into the PVSData array on the next iteration of the outer loop. If we did not do this, as the outer loop iterates and adds 1 to j, we would skip right past the byte that we need to write.

Conclusion

There is no doubt that this was a challenging chapter. Calculating a Potential Visibility Set is certainly no easy task and it would be quite natural for you to require more than one pass through the material before you begin to feel comfortable with the processes and procedures introduced. One of the things we tried to do in this chapter is include a decent amount of implementation specific concepts beyond just the theory of PVS. The hope is that this will set the stage for your studies when you move on to look at the actual lab project code and work your way through the true implementation in the workbook.

We have now reached the end of this course. It is probably fair to say that for many of you, the topics that we covered over the last few months were a bit more difficult than those that we encountered in Module I of this series. But if you take a step back for a moment and have a look at how far you have come in a relatively short while, you should be very proud of yourself. You now have detailed knowledge of many of the most fundamental processes involved in building a 3D game engine. You have looked at rendering, animation, lighting, collision detection, spatial partitioning, and a host of other core topics. The question you probably have at this point is "where do we go from here?" After all, even having reached the end of Module II, a rather large course to say the least, you have yet to have constructed a real game, or even a real game engine for that matter. In truth, this is a very important point and bears some additional discussion.

Module I provided you with the basic set of beginner-level knowledge that you will need when programming 3D applications. We looked at mathematics, lighting, texturing, cameras, alpha blending, and the like. Module II took your skill set to an intermediate level by introducing more complex topics like BSP trees, collision detection and response systems, skeletal character animation, and so on. You probably noticed that there were only a handful of major underlying themes that ran throughout this entire course, even though the things that we built around them seemed very different at times. Module II was primarily a course on geometry management through the use of hierarchies. While other concepts were floated around the periphery, you will note that this has been a key theme in virtually every lesson beyond the first one. We did not cover fancy lighting techniques or special effects; instead we dug deep into the notion of hierarchies and similar ideas and examined ways that we could speed things up by accounting for spatial relationships between the components of our scene. If you think that at this point we are done with hierarchies, guess again. We will see our old friends again as we move into the final phase of this training program.

With that said, you are probably wondering what Module III has in store for you, since you are quite aware at this point that you have still not reached the end of the road.

Well, for starters, it is important to point out that we have not yet even begun to address the topic of game engine design. You might be a little surprised to hear this (maybe even especially after this final chapter on BSP/PVS), but it is true. All we have really done to date is establish the core knowledge base that we will need in order to begin the process of assembling our final game engine. While you could theoretically write a simple rendering engine (and maybe grow it out into a game with some work) using the concepts we covered up to this point, it is not what we would recommend. After all, there are still many things that we have yet to integrate, even if we do have some very impressive pieces of individual technology in our toolbox. Consider the fact that as of right now, our demos are still using fixed function

vertex lighting, which is not exactly the most attractive lighting model, is it? Or think about the fact that for the most part, we are still using only a single texture per-polygon. As you are probably aware from your exposure to games and the game industry, there are lots of things that still need to be discussed before your game engine can begin to take on more modern appearance (bump maps, environment maps, stencil shadows, shaders, etc.). So we have a ways to go yet.

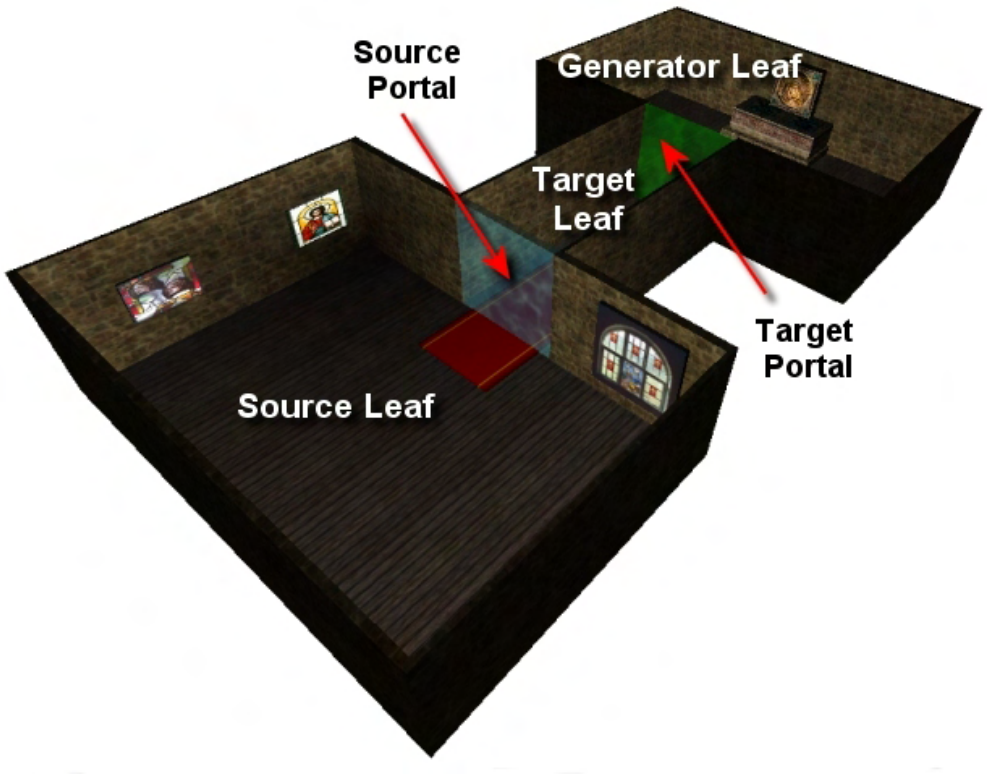
In Module III we will finally begin to wrap up all of these ideas and assemble some very powerful game technology. We will examine the programmable pipeline and introduce the concept of shaders. We will look at various multi-texturing techniques that can significantly improve our visuals. We will talk about various lighting models that provide very realistic results. And of course, we will introduce special effects so that we can include tracers and lasers and explosions and dust trails and the like in our games. And most importantly, we will talk about how all of these components can be properly integrated together into a real commercial-quality game engine. This will involve the introduction of scene graphs, scripting languages, data streaming, and a slew of other vitally important concepts that need to be considered when designing a proper game engine.

Does this mean that we will throw away all of the code that we have written? No. There is plenty of reusable code that will be carried over into future development efforts. What it does mean is that we will be moving away from our very handy but quite limited code framework, whose time has finally come to be put to rest. Actually, we will continue to use it for one-off technical demonstrations when appropriate, but ultimately, a new architecture will need to emerge to take its place.

So those are our goals. Non-trivial goals for sure, but they will introduce some of the most exciting content in the series. We hope that you have enjoyed your studies thus far and that you truly understand the ideas that we have introduced. While it can be a little intimidating at times (game programming is certainly not for the weak and timid), just keep in mind that you have now covered some of the most technically challenging subjects that are on the agenda. Of course, there will be other hard subjects that will come our way, but if you have made it this far, then you should find the series finale a wonderful and rewarding experience.

Good luck to you as you prepare for the final phase. We look forward to completing our journey together and seeing where you will eventually take these ideas on your own.

Workbook Seventeen:
Potential Visibility Sets



Introduction

In this lesson we will continue to add to the lab project implemented in the previous lesson (lab projects 16.2 and 16.3) to facilitate the calculation and rendering of geometry using potential visibility sets. It is imperative that you have read the accompanying text book before continuing with this work book. PVS and portal generation theory will not be discussed in this work book as its intention is to focus on the implementation of these processes into our compiler tool. It is expected that have read the text book and fully understand the theory and placeholder code described there.

In lab project 17.1 we will evolve the development time compiler tool initially implemented in lab project 16.2 by adding two new processing modules to it that collectively make PVS calculation for the input geometry set possible. In addition to the hidden surface removal, BSP leaf tree compile and T-junction repair modules added to our tool in the previous lesson, we will now add a portal generation processing module and a PVS calculation processing module. This will complete the construction of our compiler tool allowing it to compile and save geometry out to an IWF file along with its leaf based PVS data.

Lab project 17.2 will involve a very minor evolution from lab project 16.3 requiring only a few lines of code to be changed in order for it to render geometry using a PVS. As you have no doubt guessed, this lab project (just like 16.3) is being used to represent the run-time component demonstrating how the pre-calculated PVS data can be loaded from file and rendered efficiently by a rendering engine.

Lab Project 17.1: Adding a PVS Calculator to the BSP Compiler

In the first implementation of our BSP compiler tool in the previous chapter, we saw how the compiler itself was constructed as a series of separate processes that were glued together by the CCompiler class. The CCompiler class itself had no idea how to compile a BSP tree, perform HSR or remove T-Junctions from compiled geometry but did know the order in which these processes had to be carried out. The CCompiler class itself had the simple task of loading the geometry from an IWF file and passing this data to the individual processes in a very specified order. The various processes were all implemented in their own classes such as CProcessHSR, CProcessTJR and CBSPTree and as such, as long as CCompiler had knowledge of these objects it could invoke their ::Process methods to instruct them to perform their specific tasks on the data set. With the exception of the application's **main** function having to initially inform the CCompiler object of the IWF file that was to be loaded, all it had to do was issue a call to the CCompiler::CompilerScene function to set this chain of events in motion. When this function returned program flow back to the application's **main** function, the CCompiler class had all the information it needed stored in its compiled BSP leaf tree. The application would finally issue a call to the CCompiler::SaveScene method which would take the information stored in the BSP tree and save it out to file.

The CCompiler::CompileScene function was essentially nothing more than a series of calls to functions that invoked the various processes. We saw that it would first invoke the CProcessHSR module to

perform hidden surface removal on the data set in an attempt to remove hidden surfaces and any illegal geometry that may exist in the data set. After this process returned and had performed its task, the CBSPTree module would be invoked to compile the leaf BSP tree. After the BSP tree had been compiled and program flow had once again returned back to the CCompiler::CompileScene method, the next and final module to be invoked was CProcessTJR which would iterate through the polygons in the compiled BSP tree and would fix any T-Junctions that were found to exist. This would involve T-Junctions that were either introduced via the myriad of clipping operations that were performed via BSP tree construction or that existed in the original loaded dataset.

With the need to now introduce two new processes into the compiler, the CProcessPRT and CProcessPVS modules will be introduced in this lesson and added to the list of processes the compiler must perform. These processes will handle the generation of portals for the data set and the calculation of its leaf based PVS respectively. The CCompiler class will need to be updated to be aware of these new modules and provide a means for storing and passing the compilation options for these modules into the modules themselves.

Because of the modular design of the compiler, the additions to the CCompiler class will be extremely light. The CCompiler::CompileScene method will be updated to invoke additional processes. The order of scene compilation will now be as follows:-

1. Load in the IWF data from file
2. Perform 'Hidden Surface Removal' on loaded geometry to removal illegal surface fragments
3. Compile BSP leaf tree
4. **Generate portals for compiled tree**
5. **Calculate PVS for BSP tree using portals generated in step 4**
6. Perform T-Junction repair on final BSP tree geometry
7. **Construct mesh from BSP geometry and save to file along with PVS and portal Data**

Steps 4 and 5 in the above list are clearly the additions to lab project 16.2 and will be the focus of this work book. These processes will be wrapped in the CProcessPRT (PRT is short for Portal) and CProcessPVS classes respectively.

Step 7 is not actually invoked by the CCompiler::CompileScene method but is activated by the application's main function called the CCompiler::SaveScene method. This function is clearly not a new function and its code is actually unchanged from the previous lesson. However, you will recall that this simple function uses our custom CFileIWF class to perform its IWF file loading and saving. It is the code to this class (in particular its WriteTree method) which has been modified so that it now knows how to write out the additional PVS and portal information that will be stored in the tree.

> **Note:** Although there is no need to save the portals out to file it can sometimes be useful to have them around. You can decide whether you will need them or not and alter the saving code accordingly.

Finally, before we start looking at the code to the new classes and the modifications to previously existing classes, it should be noted that the structures of our CBSPTree class will need to be modified to store both portal information and PVS data. Remember from the text book that all this information needs to be stored in the BSP tree. That is, we need the BSP tree to maintain a list of all the portals that were generated by the portal generation process. Furthermore, we need each of these portals to store in which

leaves they were found to reside. We also need each leaf in the BSP tree (each CBSPLeaf structure) to store an array of portal indices into the tree's portal array describing exactly which portals were found to reside in that leaf. With respect the calculation of the PVS set, the CBSPTree class must also have a place to store the compiled PVS data (the compressed visibility bit set for each leaf in the tree) and each leaf in the tree must be modified to also store a PVS index. The leaf's PVS index will describe the location in the tree's main PVS array where its visibility information will begin. You are reminded that after the PVS has been calculated, the visibility information for every leaf in the tree will be stored in this one master PVS data array which is why each leaf needs to know where within that array its visibility information is located.

We will start our discussion of the lab project 17.1 source code by examining the changes to the top level object that binds everything together, the CCompiler class.

The CCompiler Class - Updated

The CCompiler class has changed very little from its initial conception in lab project 16.2. The complete class declaration is shown below with any new members highlighted in bold. Remembering that the CCompiler class stores a set of compilation options for each process that it invokes, we can see that it now has two new member variables PRTOPTIONS and PVSOPTIONS. These are structures that contain the compilation options for the portal generator module and the PVS calculator module respectively. Notice, how two new methods have also been added called PerformPRT and PerformPVS. These are the methods called from the CCompiler::CompileScene method to invoke the portal generation and PVS calculation modules. This is not a new concept to us as we discussed how each process invoked by the compiler has a matching member function that performs this task (such as PerformHSR and PerformTJR etc).

Excerpt from CCompiler.h

```
class CCompiler
{
public:

    // Constructors & Destructors for This Class.
             CCompiler();
    virtual ~CCompiler();

    // Public Functions for This Class.
    bool            CompileScene     ( );
    void            Release          ( );
    void            SetFile          ( LPCTSTR FileName );
    void            SetOptions       ( UINT Process, const LPVOID Options );
    void            GetOptions       ( UINT Process, LPVOID Options ) const;
    void            SetLogger        ( ILogger * pLogger ) { m_pLogger = pLogger; }
    CBSPTree       *GetBSPTree       ( ) const { return m_pBSPTree;   }
    bool            SaveScene        ( LPCTSTR FileName );

    void            PauseCompiler    ( );
    void            ResumeCompiler   ( );
    void            StopCompiler     ( );
    bool            TestCompilerState( );

    COMPILESTATUS   GetCompileStatus ( ) const { return m_Status; }
```

```
    void            SetCompileStatus ( COMPILESTATUS Status ) { m_Status = Status; }

    // Public Variables for This Class.
    vectorMesh      m_vpMeshList;       // A list of all meshes loaded.
    vectorTexture   m_vpTextureList;    // A list of all textures loaded.
    vectorMaterial  m_vpMaterialList;   // A list of all materials loaded.
    vectorEntity    m_vpEntityList;     // A list of all entities loaded.
    vectorShader    m_vpShaderList;     // A list of all shaders loaded.

private:

    // Private Functions for This Class.
    bool            PerformHSR( );      // Hidden Surface Removal
    bool            PerformBSP( );      // Binary Space Partition Compilation

    bool            PerformPRT( );      // Portal Compilation
    bool            PerformPVS( );      // Potential Visibility Set Compilation

    bool            PerformTJR( );      // T-Junction Repair

    // Private Variables for This Class.
    HSROPTIONS      m_OptionsHSR;       // Hidden Surface Removal Options
    BSPOPTIONS      m_OptionsBSP;       // BSP Compilation Options

    PRTOPTIONS      m_OptionsPRT;       // Portal Compilation Options
    PVSOPTIONS      m_OptionsPVS;       // PVS Compilation Options

    TJROPTIONS      m_OptionsTJR;       // T-Junction Repair Options

    ILogger        *m_pLogger;          // Logging interface used to log progress etc.
    LPTSTR          m_strFileName;      // The file used for compilation
    COMPILESTATUS   m_Status;           // The current status of the compile run
    ULONG           m_CurrentLog;       // Current logging channel for messages.

    CBSPTree       *m_pBSPTree;         // Our compiled BSP Tree.
};
```

We will see later that the portal processing module has no real options that influence the way in which the portals are compiled. Therefore, the PRTOPTIONS structure contains a single Boolean which describes whether the user would like the compiler to perform the portal generation process. The structure is defined in CompilerTypes.h and is shown below.

Excerpt from CompilerTypes.h

```
typedef struct _PRTOPTIONS {            // Portal Compilation Options
    bool            Enabled;            // Process Enabled ?
} PRTOPTIONS;
```

If the Enabled Boolean is set to false in the CCompiler::m_OptionsPRT structure then the compiler will not call the CCompiler::PerformPRT method and the portal generation module will not be invoked.

The PVSOPTIONS structure has three members which will influence the way in which the PVS calculator will generate its final PVS data. The PVSOPTIONS structure is also declared in the file CompilerType.h and is shown below.

Excerpt from CompilerTypes.h

```
typedef struct _PVSOPTIONS {           // PVS Compilation Options
    bool            Enabled;           // Process Enabled ?
    bool            FullCompile;       // Perform Full PVS Compile
    unsigned char   ClipTestCount;     // Number of portal clip tests to perform
} PVSOPTIONS;
```

The ways in which these members influence the PVS calculator module are described below.

bool Enabled;

This member is no stranger to us as the options structure for each process has this member. In the case of this structure, it describes to the compiler whether PVS compilation should be invoked when compiling the data. It is possible that you might just want to compile a regular leaf tree and may not be interested in PVS calculation. When this is the case, this member can be set to false.

> **Note:** If the portal generation module has been disabled then the PVS calculator will not be invoked even if this member has been set to true. The PVS calculator absolutely needs the portal information to have been generated and stored in the BSP tree in order to perform its task. Enabling the PVS process without enabling the portal generation process will simply cause the PVS module to return prematurely as soon as it is invoked. That is, the PVS module will exit immediately when it discovers there are no portals for it to work with.

bool FullCompile;

This is a very handy option to use when you are developing your tool and do not want to wait potentially hours for your level to compile each time you wish to run your code. You will recall from the text book that the first task performed in calculating the PVS is to generate a very course visibility set for each portal based on nothing more than portal orientations to one another. A temporary list is built for each portal describing which portals could possibly have a flow between them. This is then use to perform a flood fill through the leaves of the tree from the portal currently being processed to very quickly retrieve an array of leaf visibility bits for that portal. Any bits set to zero in this 'Possible Visibility Array' represent leaves that can not possibly be seen from the portal in question. This is done for each portal so that prior to the main clipping process beginning, we have a very rough guide as to which leaves may be visible from a given portal. The main clipping process simply refines this leaf visibility information for each portal by performing anti-penumbra clipping and setting other leaves in the 'Possible Visibility Set' to zero as they are found to exist outside any valid anti-penumbra originating at the current source portal. The result at the end of the PVS process is the 'Potential Visibility Array' for each portal. This is a much refined version of the 'Possible Visibility Array' that was initially calculated at the start of the process and will typically contain much fewer leaves in its visibility set.

Having said all this, it is the calculation of the 'Potential Visibility Array' for each portal that takes so much time due to the exceptionally recursive nature of the procedure and the grotesque amount of clipping that will need to be done to the anti-penumbra planes. It is this process that makes sure that we have the tightest potential visibility set possible. However, this process takes hours to complete on complex data sets and you certainly don't always need to have a full PVS compile performed when testing your application or level geometry. Imagine for example that your artist had just added a new asset to the scene and wanted to see it being rendered in-game. The entire scene would have to be

compiled again forcing the development team to wait several hours before the new level was compiled and able to be loaded into the PVS aware game render engine.

Often, at the development time we are not nearly so picky when testing things such as new assets or new light placement within the scene that our game is actually running with the most optimal PVS data set and would gladly trade off the hours of compile time for a PVS data set that compiles in seconds even if the resulting PVS set generated halved the frame rate of the application. After all, you can save the full-blown PVS compile for when the game is about to burned and shipped.

The calculation of the 'Possible Visibility Array' for each portal is compiled just prior to the main clipping process to aid in the speed up of that process. This array can be thought of as a very over generous visibility set for each portal. As mentioned, the only thing taken into consideration when calculating this array for each portal is the orientations of the portals with respect to one another. No occlusion is considered. However, this data is still in PVS format and can be used as the PVS data instead of calculating the main data set via the core clipping procedure. It takes seconds/minutes to compile instead of hours and is ideal for performing a quick PVS build in order to test some other assets in your game engine. Therefore, if this option is not set to true, a full compile will not be performed and instead, the PVS data calculated will contain the leaf visibility information returned from the simple flood fill for each portal. The main anti-penumbra clipping procedure will not have been invoked to further refine this set. If this option is set to true, the full blown calculator will be invoked and a tight potential visibility set will be laboriously calculated.

unsigned char ClipTestCount;
In the text book we examine how when performing the anti-penumbra clipping process, we could further refine the amount of geometry that made it into the anti-penumbra's volume by building it four times. This would allow us to trim the size of the source and generation portals that got passed into the next recursion by making sure we have the tightest clip planes possible.

In the first step the anti-penumbra planes are built from the source portals vertices to the target portal edges and the generator portal is clipped to it. In the second step we would then reverse the order by building an anti-penumbra from each vertex in the target portal to each edge in the source portal. Once again the generator portal would be clipped to these planes. We showed in the accompanying text book that it was entirely possible for tighter planes to be generated from target to source instead of from source to target and vice versa. Therefore, we build an anti-penumbra in both directions to make sure we clip the maximum possible from the generator portal and reduce its size as much as possible for the next recursion. Obviously, if the generator portal does not survive the any of the two clipping stages described above, the portal is considered not to be visible from the current source portal and we do not recur through it into the neighbor leaf.

In the third test we build an anti-penumbra from what is left of the generator portal and the target portal to create an anti-penumbra with which we can clip the source portal too. We also reverse the plane order and clip the source portal to the anti-penumbra planes generated from the target to the generator portal in a 4^{th} clip test. Once again, if at any point the source portal is entirely clipped away it means that the generator portal can not see it and therefore, no line of sight can possibly exist from the source portal through the generator portal. The temporarily clipped source portal is also passed into the next recursion

with the clipped generator portal so that as we step through the process for a given source portal, the source, target and generator portals becomes smaller and smaller allowing us to generate smaller and tighter anti-penumbras in future recursions and hopefully reject more generator leaves from being recurred into and added to the source portal visibility set.

So we have seen that if all these clipping operations are to be performed, we essentially have to build four anti-penumbras and clip four portals to those anti-penumbras for each generator portal that we visit during the core recursive clipping process. As this clipping is obviously a laborious process to perform each time, the number of these clips that we perform can greatly influence the speed of PVS calculation. When generating the commercial data set it is recommended that you activate all four clipping stages to get the tightest possible PVS data set generated. However, during development tests and debug runs you can perform fewer clip tests. This will speed up PVS compile time at the cost of a more generous PVS in the typical case.

While having an option that allows us to toggle the number of clips performed from between 1 to 4 may seem like a trivial speed up option, it is not the case. Each anti-penumbra test performed means first constructing the anti-penumbra. This involves two loops that iterate through each vertex in the source portal and each edge in the target portal. A plane in constructed for each combination and the source and target portals are classified against it to determine if it is a separating plane. Two more loops enter the fray here as we have to test each vertex in each of the portals against the plane to determine its separation status. Only if the plane has the source and target portal in opposite half spaces will the plane be added to the anti-penumbras clip list. So as we can see, just the generation of the anti-penumbra generated four nested loops. Then of course, we have to loop through each anti-penumbra plane clipping the generator portal to each one which can involve memory allocations and de-allocations when the portal gets clipped. That is an awful lot of work to perform four times for each generator portal that we visit when calculating the visibility set for each source portal.

The ClipTestCount option of this structure can be set from 1 to 4 to determine how many of these clips we would like to perform at each generator portal. Performing only one clip will generate the PVS data array much faster but will typically have a larger number of leaves flagged as visible in each leaf’s potential visibility set.

So we have seen that these two new CCompiler member structures contain compilation options for the portal generation process and the PVS process. Although we will set the compile options for each process in the CCompiler constructor, the options for each process can also be set by the application via the CCompiler::SetOptions function. We will look at the modified code to this method in a moment.

Let us now examine the changes to the CCompiler source code staring with the constructor.

Constructor - CCompiler

The constructor of CCompiler is used to set up the default compile options for each of its modules. The compile options for every module can be altered and retrieved by the application once the CCompiler object has been created via its SetOptions and GetOptions methods respectively.

We saw in the previous lab project how the default options were configured for the hidden surface removal, BSP compile and T-Junction repair modules in this constructor. Now we have added code to also set the default compile options for the portal generation and PVS calculator modules.

```
CCompiler::CCompiler()
{
    // Set up default HSR options
    m_OptionsHSR.Enabled            = true;

    // Set up default BSP options
    m_OptionsBSP.Enabled            = true;
    m_OptionsBSP.TreeType           = BSP_TYPE_SPLIT;
    m_OptionsBSP.SplitHeuristic     = 3.0f;
    m_OptionsBSP.SplitterSample     = 60;
    m_OptionsBSP.RemoveBackLeaves   = true;
    m_OptionsBSP.AddBoundingPolys   = false;

    // Set up default Portal Compile Options
    m_OptionsPRT.Enabled            = true;

    // Set up default PVS Options
    m_OptionsPVS.Enabled            = true;
    m_OptionsPVS.FullCompile        = true;
    m_OptionsPVS.ClipTestCount      = 2;

    // Set up default TJR Options
    m_OptionsTJR.Enabled            = true;

    // Reset Vars
    m_strFileName = NULL;
    m_pBSPTree    = NULL;
    m_pLogger     = NULL;
    m_Status      = CS_IDLE;

}
```

As you can see, the hidden surface removal module has a single compiler option which dictates whether it should be invoked or not. By default, all modules are enabled. As mentioned though, the application can change these settings via CCompiler methods prior to calling the CCompiler::CompileScene method.

The default parameters for the BSP tree build are also unchanged. We enable the process and specify that we would like to build a tree in which the resulting polygons are split/clipped to the leaf nodes in which they reside. We set the splitter choosing heuristic to 3.0 so that we weight the reduction of splits as three times more important than tree balance during splitter selection. We also set the splitter sample to 60 so that in order to speed up BSP tree compile, only the first 60 polygons in the list that make it into each node are tested as split plane candidates. We also specify that we would like any geometry that makes it into back leaves (such as illegal geometry fragments causes by floating polygon rounding errors during the clipping process) to be deleted so that accurate solid/empty space information can be maintained. By default, we also specify that we would not like the BSP compiler to seal our level by surrounding it in an inward facing cube prior to being compiled.

The portal generation options structure has only a single Boolean member describing whether or not this process should be enabled. As mentioned, this is set to true because all modules are enabled by default. The same is true for the T Junction removal options structure.

By default we also enable the PVS calculator and set it to perform a full compile (instead of a quick portal flood) to generate its PVS data. We also set the number of clips to perform at each generator portal to 2 by default. The minimum is one and the maximum is four

SetOptions - CCompiler

The CCompiler::SetOptions function is also not a new function but has now been modified to allow the application to set the compilation options of the two new processes. You will recall that this function accepted as its first parameter the numerical ID of the process which is to have its properties set. The numerical IDs are defined in the file Common.h. We have now added two more numerical defines called PROCESS_PRT and PROCESS_PVS which are used to signify the portal generation module and the PVS calculation modules respectively. Shown below is our current list of numerical defines.

Excerpt from Common.h

```
#define PROCESS_HSR         0   // Hidden Surface Removal
#define PROCESS_BSP         2   // Binary Space Partition
#define PROCESS_PRT         3   // Portals
#define PROCESS_PVS         4   // Potential Visibility Set
#define PROCESS_TJR         5   // T-Junction Repair
```

The second parameter to the CCompiler::SetOptions function is a void pointer which the application can use to pass the relevant options structure for the process it wishes to alter the compilation parameters for. Here is the modified version of the function.

```
void CCompiler::SetOptions( UINT Process, const LPVOID Options )
{
    switch (Process)
    {
        case PROCESS_HSR:
            m_OptionsHSR = *((HSROPTIONS*)Options);
            break;

        case PROCESS_BSP:
            m_OptionsBSP = *((BSPOPTIONS*)Options);
            break;

        case PROCESS_PRT:
            m_OptionsPRT = *((PRTOPTIONS*)Options);
            break;

        case PROCESS_PVS:
            m_OptionsPVS = *((PVSOPTIONS*)Options);
            break;

        case PROCESS_TJR:
            m_OptionsTJR = *((TJROPTIONS*)Options);
            break;

    } // End Switch
```

```
}
```

As you can see, two more case statements have been added to cast the void pointer to either a PRTOPTIONS structure or a PVSOPTIONS structure based on the passed process ID. In each case we copy the contents of the passed structure into the relevant member structure to set the compile options for the passed process. For example, the application could set the options for the PVS process to compile only a 1 clip anti-penumbra PVS by using the following code.

```
CCompiler Compiler;
CompilerSetFile("SomeExampleFile.iwf")

PVSOPTIONS pvsOptions;
pvsOptions.Enabled            =     true;
pvsOptions.FullCompile        =     true;
pvsOptions.ClipTestCount      =     1;

Compiler.SetOptions( PROCESS_PVS , (void*) &pvsOptions );

… Set other process options here …

Compiler.CompileScene ();
```

This is just a simple example but shows how an application using the compiler can configure the compile options of the various processes prior to calling the CompileScene method.

GetOptions - CCompiler

As one might expect, the CCompiler class also exposes a member function to allow the application to fetch the compiler options for a given process. The function takes two parameters with the first being the numerical index of the process the application would like to retrieve the compile time options for. The second parameter is a void pointer to the options structure for the applicable process that will be cast to the correct type inside the function and filled with the compiler settings for that process as shown below.

```
void CCompiler::GetOptions( UINT Process, LPVOID Options ) const
{
    switch (Process)
    {
        case PROCESS_HSR:
            *((HSROPTIONS*)Options) = m_OptionsHSR;
            break;

        case PROCESS_BSP:
            *((BSPOPTIONS*)Options) = m_OptionsBSP;
            break;

        case PROCESS_PRT:
            *((PRTOPTIONS*)Options) = m_OptionsPRT;
            break;

        case PROCESS_PVS:
            *((PVSOPTIONS*)Options) = m_OptionsPVS;
```

```
            break;

        case PROCESS_TJR:
            *((TJROPTIONS*)Options) = m_OptionsTJR;
            break;

    } // End Switch
}
```

Once again, this is not a new method to us but has had two new cases added to the switch statement that allow us to retrieve the compiler options for the portal generation and PVS generation modules.

CompileScene - CCompiler

As we discussed in the previous lesson, it is the CCompiler::CompileScene method that glues the various processes together into a geometry compilation pipeline. In the previous lesson, we saw that this method was responsible for instantiating a CFileIWF object and using it to import the IWF information into its internal mesh, material, texture and entity arrays. This data is then copied from the CFileIWF data vectors into the compiler's own vectors where data that is not related to the BSP compile process (such as entities and materials for example) can be stored and then written back out to the resulting compiled IWF file. None of this is new and is shown below.

```
bool CCompiler::CompileScene( )
{
    CFileIWF IWFFile;

    // Validate Data
    if (!m_strFileName) return false;

    // Retrieve the filename portion only of the string
    LPTSTR FileName = NULL;
    FileName = _tcsrchr( m_strFileName, _T('\\') );
    if (!FileName) FileName = _tcsrchr( m_strFileName, _T('/') );
    if (!FileName) FileName = m_strFileName;
    if (FileName[0] == _T('\\') || FileName[0] == _T('/')) FileName++;

    try
    {
        // We Are starting the process
        m_Status = CS_INPROGRESS;

        // Load the specified file
        IWFFile.Load( m_strFileName );

        // Obtain ownership of the objects loaded
        m_vpMeshList     = IWFFile.m_vpMeshList;
        m_vpMaterialList = IWFFile.m_vpMaterialList;
        m_vpTextureList  = IWFFile.m_vpTextureList;
        m_vpEntityList   = IWFFile.m_vpEntityList;
        m_vpShaderList   = IWFFile.m_vpShaderList;

        // Clear out the IWF's object vectors (don't destroy)
        IWFFile.m_vpMeshList.clear();
        IWFFile.m_vpMaterialList.clear();
        IWFFile.m_vpTextureList.clear();
        IWFFile.m_vpEntityList.clear();
        IWFFile.m_vpShaderList.clear();
```

```
        // Write load success
        if ( m_pLogger )
        {
            m_pLogger->LogWrite( LOG_GENERAL,
                                 0,
                                 true,
                                 _T("Successfully loaded geometry from file '%s'"),
                                 FileName );

        } // End if Logger

    } // End try Block

    catch (HRESULT & e)
    {
        // Write Load Failure
        if ( m_pLogger )
        {
            m_pLogger->LogWrite( LOG_GENERAL,
                         LOGF_ERROR,
                         true,
                        _T("Failed to load geometry from file '%s' with error code '0x%x'"),
                        FileName, e );

        } // End if Logger

        IWFFile.ClearObjects();
        Release();
        return false;

    } // End Catch Block
    catch (...)
    {
        // Write Load Failure
        if ( m_pLogger )
        {
            m_pLogger->LogWrite( LOG_GENERAL,
                                 LOGF_ERROR,
                                 true,
                                 _T("Failed to load geometry from file '%s'"),
                                 FileName );

        } // End if Logger

        IWFFile.ClearObjects();
        Release();
        return false;

    } // End Catch Block
```

At this point the CFileIWF file data has all been copied into the compiler's internal vectors so the CFileIWF data objects can be released as they are no longer needed.

Now we will start the actual compilation process by invoking the various modules one at a time and passing the results of each module onto the next in the chain. As we saw in the previous lesson, the hidden surface removal module is invoked first to remove any illegal geometry and then the BSP leaf tree compiler is invoked to compile the BSP tree. In the previous lesson, the next and final step prior to saving the compiled data out to disk was to perform T-Junction repair on the final compiled polygon

data. However, we now have to processes that must be inserted after the BSP compile process and before the T-Junction repair process. That is, after the BSP tree has been compiled we will then invoke the portal generator to generate the portals for the compiled geometry. These portals will be stored in the BSP tree. The next module to be invoked will be the PVS calculator which will use the portals stored in the tree to generate the final compressed PVS for the BSP tree. This final data will also be stored in the BSP tree in the form of a single compressed data array. Each leaf in the tree will also contain a numerical index into this master array describing where in the array its PVS data begins.

Providing a logging object has been assigned to the CCompiler class we first output to the general channel that the compile process is about to begin. The first parameter to the LogWrite method specifies that this message should be output to the general channel and the second parameter describes this message as being a normal status message so that the default ink color is used for the text (only when being used with a GUI logger). The third parameter instructs the logger that this is the start of a new message so that prior to being printed the logger inserts a line feed to move the text output cursor to the start of a new line.

```
    // Write Log Info
    if ( m_pLogger )
    {
        m_pLogger->LogWrite(LOG_GENERAL,
                            0,
                            true,
                            _T("Beginning compilation run \t\t\t- ") );

    } // End if Logger
```

In the next section we step through each possible module that can be performed and test its options structure to test that its **Enabled** Boolean is set to true. If it is then this means the application would like the compiler to perform that process (assuming the compiler has not been placed into a state where the user has cancelled the compile). As you can see, we first call the CCompiler::PerformHSR function which will invoke the hidden surface removal module and instruct it to removal illegal geometry from the compiler's data set. The second process to be performed is the BSP compiler which is activated via a call to the CCompiler::PerformBSP method. Both of these methods were discussed in the previous lesson.

```
    // Start compiling by removing all hidden surfaces
    m_CurrentLog = LOG_HSR;
    if ( m_OptionsHSR.Enabled && m_Status != CS_CANCELLED) PerformHSR();

    // Build the BSP Tree if requested
    m_CurrentLog = LOG_BSP;
    if ( m_OptionsBSP.Enabled && m_Status != CS_CANCELLED) PerformBSP();
```

Out of the final three modules that are activated (shown below), the first two are new to this application and show two new methods of CCompiler which will be used to invoke the portal generation processor and the PVS calculator modules respectively. The third and final process to be activated is the T-Junction repair module via a call to the CCompiler::PerformTJR method.

```
    // Build the portals if requested
```

```
    m_CurrentLog = LOG_PRT;
    if ( m_OptionsPRT.Enabled && m_Status != CS_CANCELLED) PerformPRT();

    // Build the PVS if requested
    m_CurrentLog = LOG_PVS;
    if ( m_OptionsPVS.Enabled && m_Status != CS_CANCELLED) PerformPVS();

    // Repair any T-Juncs if requested
    m_CurrentLog = LOG_TJR;
    if ( m_OptionsTJR.Enabled && m_Status != CS_CANCELLED) PerformTJR();

    // Clean up if required
    if ( m_Status == CS_CANCELLED ) Release();

    // Processing Run Completed
    m_Status = CS_IDLE;

    // Write end of compilation message (We use warning just to make it blue ;)
    if ( m_pLogger ) m_pLogger->LogWrite( LOG_GENERAL,
                                          LOGF_WARNING | LOGF_ITALIC,
                                          false,
                                          _T("Success") );

    // Success!
    return true;
}
```

As you can see, when the T-Junction removal method returns, the level data will have been compiled and all that is left to do is output the success message (providing the compiler was not cancelled mid way through the chain of events).

The two new sections of code are highlighted in bold above and show the calls to the PerformPRT and PerformPVS methods. These are simple methods that invoke the new modules we will develop in this work book. The code to the PerformPRT method is discussed next.

PerformPRT - CCompiler

The CCompiler::PerformPRT method is called by the CCompiler::CompileScene method after the BSP tree has been compiled. Its task is to initialize and invoke the portal generation module. Although we have not yet discussed the code to the CProcessPRT class (the portal generation module), we can see in the following code how the module is initialized and used. You will notice that this module shares the same interface methods as the other modules making the way in which the compiler interacts with each module consistent for the most part. Each module for example has methods that allow us to set its options, set the logging class to be used and to pass a pointer to the parent CCompiler object that is invoking the module. The ProcessPRT module is only used during the portal generation process and once its Process method has returned, the portal information will all be stored in the BSP tree. Therefore, the CProcessPRT object can be instantiated on the stack as shown in the following code.

```
bool CCompiler::PerformPRT()
{
    // One time compile process
    CProcessPRT ProcessPRT;

    // Set our process options
    ProcessPRT.SetOptions( m_OptionsPRT );
```

```
    ProcessPRT.SetLogger( m_pLogger );
    ProcessPRT.SetParent( this );
```

Now that we have allowed the CProcessPRT object to store a pointer to the logger class our application is using, we will now write some information to the logger stating that the portal generation module is about to start. We clear the logger's channel that has been reserved for portal generation output (LOG_PRT) and output some copyright information and information instructing the user that the portal compilation process is about to begin.

```
    // Write Log Information
    if ( m_pLogger )
    {
        m_pLogger->Clear( LOG_PRT );
        m_pLogger->LogWrite( LOG_PRT,
                             LOGF_WARNING | LOGF_BOLD  ,
                             false,
                              _T("\r\nPortal Processor v1.0.0\r\n"));

        m_pLogger->LogWrite( LOG_PRT,
                             LOGF_WARNING | LOGF_ITALIC,
                             false,
                             _T("Copyright © 2005 GameInstitute.com.
                                 All Rights Reserved.\r\n"));

        m_pLogger->LogWrite( LOG_PRT,
                             0,
                             true,
                             _T("Beginning portal compilation process."));

    } // End if Logger Available
```

As the CProcessPRT object will need access to the BSP tree that it is to generate portals for, its 'Process' method accepts a pointer to a BSP tree as its only parameter. It is this function that is the top level function for the entire portal generation process. That is, when the CProcessPRT::Process function returns, every portal will have been created and will be stored in the BSP tree's portal array. The leaves of the BSP tree will also contain portal indices describing which portals they contain and every portal will contain a two element leaf array describing the indices of the leaves in which they reside.

Here is the remainder of the function that calls the 'Process' method to generate the portals and finally outputs a completion method prior to returning.

```
    // Compile the Portal set
    ProcessPRT.Process( m_pBSPTree );

    // Write Log Information
    if ( m_pLogger )
    {
        if ( m_Status != CS_CANCELLED )
            m_pLogger->LogWrite( LOG_PRT,
                                 0,
                                 true,
                                 _T("Portal compilation completed successfully."));
        else
            m_pLogger->LogWrite( LOG_PRT, 0, true, _T("Portal compilation cancelled."));
```

```
    } // End if Logger Available

    // Success!!
    return true;
}
```

If the process was cancelled for some reason during the portal compile then a cancellation message is output to the portal process logging channel instead.

PerformPVS - CCompiler

This method is almost a duplicate of the previously discussed function with the exception that it instantiates and invokes the CProcessPVS module. We will look at the code to the CProcessPVS class later in the lesson but for now just know that its Process method will build the master compressed PVS data array for the PBS tree.

A CPerformPVS object is instantiated on the stack and the PVS options structure is passed into its SetOptions method. We also inform the module of the logging object we are using and pass a pointer to the CCompiler object that is invoking the module. We then clear the PVS logging channel and output copyright information about the PVS module to that channel.

```
bool CCompiler::PerformPVS()
{
    // One time compile process
    CProcessPVS ProcessPVS;

    // Set our processor options
    ProcessPVS.SetOptions( m_OptionsPVS );
    ProcessPVS.SetLogger( m_pLogger );
    ProcessPVS.SetParent( this );

    // Write Log Information
    if ( m_pLogger )
    {
        m_pLogger->Clear( LOG_PVS );
        m_pLogger->LogWrite( LOG_PVS,
                             LOGF_WARNING | LOGF_BOLD,
                             false,
                             _T("\r\nPVS Processor v1.0.0\r\n"));

        m_pLogger->LogWrite( LOG_PVS,
                             LOGF_WARNING | LOGF_ITALIC,
                             false,
                             _T("Copyright © 2005 GameInstitute.com.
                                 All Rights Reserved.\r\n"));

        m_pLogger->LogWrite( LOG_PVS,
                             0,
                             true,
                             _T("Beginning visibility determination process."));

    } // End if Logger Available
```

After informing the user that the PVS calculator is beginning its process, we call the CProcessPVS::Process method to invoke the top level PVS processing method. When this function returns, the passed BSP tree will have had the master PVS data array stored within it and each leaf will contain and index into this master array describing where its visibility information begins.

```
    // Begin the PVS Process
    ProcessPVS.Process( m_pBSPTree );

    // Write Log Information
    if ( m_pLogger )
    {
        if ( m_Status != CS_CANCELLED )
            m_pLogger->LogWrite( LOG_PVS,
                                 0,
                                 true,
                                 _T("Visibility determination completed successfully."));
        else
            m_pLogger->LogWrite( LOG_PVS,
                                   0,
                                   true,
                                   _T("Visibility determination cancelled."));

    } // End if Logger Available

    // Success!!
    return true;

}
```

As you can see, after the CProcessPVS::Process method returns, we test the status of the compiler and output either a completion message or a cancellation message to the PVS logging channel depending on the outcome.

We have now discussed all the code changes to the CCompiler class and as we have seen, the modular design of the compiler itself makes adding future modules extremely easy. Of course, most of this work book will be dedicated to examining the code to these two new modules (CProcessPRT and CProcessPVS) but before we do, we must look at other classes and structures that will need to be changed to accommodate the storage of the information these two modules will provide our tree.

In the next section we will examine the changes to the CPolygon class and will examine a new CPolygon derived class called CBSPortal. The CBSPPortal object will be used by the CProcessPRT and CBSPTree objects to generate and store the portals of the tree respectively. As discussed in the accompanying text book, a portal is simply a polygon with some additional information packaged with it (such as which leaves in the BSP tree they reside in).

The CPolygon Class - Updated

When discussing the generation of portals in the accompanying text book, we learned that the first step in generating a portal is to create a large initial polygon on the plane of the node (currently having a portal generated for it) that is large enough to at least fill the root node’s bounding box along that plane. It was this initial portal that was passed into the BSP tree and clipped to the nodes of the tree so that any

portal fragments that existed in solid space were clipped away. The result of this clipping process was a portal that described the exact shape and size of the ‘doorway’ between two leaves.

Generating an initial portal on the node plane that was large enough to fill the root node’s bounding box was discussed in detail in the text book and requires two inputs, the plane on which the polygon/portal should be constructed an a bounding box describing how large it should be on the plane. As it is pretty useful in other situations to build a polygon on a certain plane that we know will fill some bounding box, we have decided to build this functionality straight into the CPolygon class so that all derived classes (including CBSPPortal) expose it. The modified CPolygon declaration is shown below with the new method highlighted in bold.

Excerpt from CompilerTypes.h

```
class CPolygon
{
public:
        // Constructors & Destructors
                  CPolygon( );
         virtual ~CPolygon( );

        // Public Variables for This Class
        CVertex              *Vertices;             // Polygon vertices
        unsigned long   VertexCount;                // Vertices in this poly

        // Public Functions for This Class
        long             AddVertices( unsigned long nVertexCount = 1 );
        long             InsertVertex( unsigned long nVertexPos );
        void             ReleaseVertices();

        // Public Virtual Functions for This Class
        virtual HRESULT Split( const CPlane3& Plane,
                               CPolygon * FrontSplit,
                               CPolygon * BackSplit,
                               bool bReturnNoSplit = false );

       virtual bool    GenerateFromPlane( const CPlane3& Plane,
                                          const CBounds3& Bounds );

};
```

The GenerateFromPlane method accepts two parameters. The first is the plane on which the polygon should generate its vertices and the second parameter describes a bounding box which the polygon should at least fill (it may be bigger). As the CBSPPortal class used by the portal generator is derived from this class it too will expose this method. This means, the portal generator can simply call this function to generate the initial portal on the node plane by passing in the node that is currently being processed and the bounding box of the root node. This portal can then be passed down the tree and clipped at solid leaves.

GenerateFromPlane - CPolygon

As discussed in the text book, generating a polygon on a plane of a specific size involves first projecting the center of the bounding box onto the node plane to calculate the center of the polygon we are creating. Projecting the center of the bounding box onto the plane is a simple matter of classifying the bounding box center position against the plane to get the distance to the plane from the center point along the plane normal. We can then move the bounding box center point along the plane normal to position it on the plane.

Figure 17.1 shows the center of the bounding box labeled CB and shows how moving it along the plane normal by the distance from CB to the plane creates the point CP. CP is the new center point of our polygon and the point from which the four vertices of the portal quad will be placed relative too.

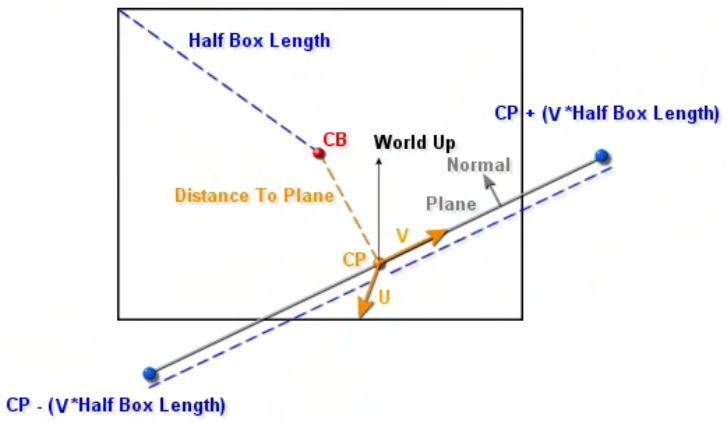


Figure 17.1

After CP has been calculated we have to generate the tangent and bi-normal vectors of the plane shown as vectors U and V in figure 17.1.

Generating the U and V vectors is simple with the cross product at our disposal. We first find any vector which is not identical to the plane normal. This is important because by crossing this vector with the normal we will get vector U, a vector that is perpendicular to the plane normal and thus tangent to the plane. If the vector we choose to cross with the normal is identical to the normal the two input vectors to the cross product will be the same and the resulting vector is undefined.

In figure 17.1 the world up vector is used but any vector can be used as long as it is not the same as the normal vector. In our code we test the world X, Y and Z axis vectors and choose the one that is least aligned with the plane normal. This assures that our cross product will not have any epsilon issues if the two input vectors are nearly equivalent. Once vector U is generated we can simply cross it with the plane normal to get vector V. At this point, these vectors should be unit length.

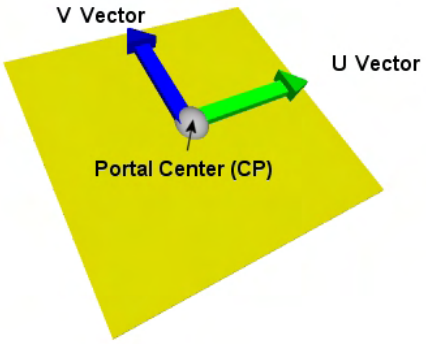

Figure 17.2

Next we get the half length vector of the bounding box by subtracting from the maximum box extent vector, the center position of the box. We then retrieve the length of this resulting half vector. Once we have the length we can use this to scale the U and V tangent vectors so that they can be used in combination with the polygon center point to describe the four corner vertex positions if the polygon. These four vertices are then generated and stored in the polygons vertex array.

> **Note:** It is clear that as this method generates the vertices of the polygon, it should only be called for CPolygon's (and derived objects) which currently contain no vertex data. For example,

```
CPolygon Poly;
Poly.GenerateFromPlane ( SomePlane , SomeBox);
```

The code to this method is fairly short and is shown below. We first calculate the center of the polygon by calculating the distance from the bounding box center point to the plane and then moving the point along the reverse plane normal to locate a point on the plane (CP).

```
bool CPolygon::GenerateFromPlane( const CPlane3& Plane, const CBounds3& Bounds )
{
        CVector3 CB, CP, U, V, A;

        // Calculate BBOX Centre Point
        CB = Bounds.GetCentre();

        // Calculate the Distance from the centre of the bounding box to the plane
        float DistanceToPlane = CB.DistanceToPlane( Plane );

        // Calculate Centre of Plane
        CP = CB + (Plane.Normal * -DistanceToPlane );
```

Next we need to generate the tangent vector and in order to do this we need a vector to cross with the plane normal which must not be identical to the plane normal. The vector A is calculated by analyzing the plane normal components and generating an axis aligned vector that is least aligned to the normal.

```
        // Calculate Major Axis Vector
        A = CVector3(0.0f,0.0f,0.0f);

         if( fabs(Plane.Normal.y) > fabs(Plane.Normal.z) ) {
              if( fabs(Plane.Normal.z)  < fabs(Plane.Normal.x) ) A.z = 1; else A.x = 1;
        } else {
              if (fabs(Plane.Normal.y) <= fabs(Plane.Normal.x) ) A.y = 1; else A.x = 1;
    } // End if
```

We then cross vector A with the plane normal to generate vector U and then cross the normal with vector U to generate vector V. These vectors are then both normalized.

```
        // Generate U and V vectors
        U = A.Cross(Plane.Normal);
        V = U.Cross(Plane.Normal);
        U.Normalize(); V.Normalize();
```

In the next step we calculate the length of the vector from the center of the bounding box to the box corner which describes the furthest the edges of the box could ever be from the polygon. We then scale the unit tangent vectors by this amount.

```
        float Length = (Bounds.Max - CB).Length();

        // Scale the UV Vectors up by half the BBOX Length
        U *= Length; V *= Length;
```

With these two vectors and the polygon center point we can now combine them to generate the position vectors of the four vertices of the quad polygon we wish to create on this plane which are stored in a temporary 3D vector array called P in the following code.

```
        CVector3 P[4];
        P[0] = CP + U - V; // Bottom Right
        P[1] = CP + U + V; // Top Right
        P[2] = CP - U + V; // Top Left
        P[3] = CP - U - V; // Bottom Left
```

With these corner positions computed we then allocate space in the polygon's vertex array to store these four vertices and then copy them into the vertices one by one. The normal of each vertex is assigned the normal of the plane.

```
        // Allocate new vertices
        if (AddVertices( 4 ) < 0) return false;

        // Place vertices in poly
        for ( int i = 0; i < 4; i++)
        {
             Vertices[i] = CVertex(P[i]);
             Vertices[i].Normal = Plane.Normal;
         } // Next vertex

    // Success!
    return true;
}
```

If you are feeling a little rusty on this procedure, please refer back to the accompanying text book where we describe this process in more detail. This completes our coverage of the modified CPolygon object. As you can see, we simply added a new member function.

The CBSPPortal Class

The portal generation module will need a structure with which it can use to represent portal data within the BSP tree. Although a portal is just a polygon (geometrically speaking), we can not use CPolygon to represent them as we need to package additional information with each portal. Such information includes storing the indices of leaves in which the portal is found to reside and the number of leaves in which the portal resides. As discussed in the text book, each valid portal will always reside in exactly two leaves so this leaf count member would be used during portal generation to delete any portal fragments that are found not to exist in two. The portal must also store information about the node in the tree on whose plane it has been created. This is also important information to have during the portal generation process as it allows us to identify the two leaves under that node which are the valid leaves in which the portal should reside. If the portal is found to pop out in a leaf which is above the portals owner node, it is a rogue fragment and can be discarded.

> **Note**: It is vitally important that you have read the accompanying text book before progressing through this work book. Portal and PVS generation is a complex subject and theory of these processes will not be rehashed again in this work book. In short, if you have not studied the text book you find you understand very little of the discussions that follow.

The process that clips the portal to the BSP tree will at some point through the process will have split the initial portal in a list of portal fragments. As these fragments must be grouped together and passed

through the tree also, the portal structure will also have a **NextPortal** member that will allow us to string multiple CBSPPortal structures together in a linked list.

The CBSPPortal class is declared in CBSPTree.h and is shown below. Notice that it is derived from CPolygon so we do not have the reinvent the wheel with respect to its vertex management and member functions. This means the CBSPPortal will also expose the 'CreateFromPlane' member previously discussed which will be used by the portal generator to build the initial portal quad on the node plane.

Excerpt from CBSPTree.h

```
class CBSPPortal : public CPolygon
{
public:

    // Constructors / Destructors for this Class
    CBSPPortal( );

   // Public Variables for This Class
    CBSPPortal     *NextPortal;         // Linked List Next Portal Item
    unsigned char   LeafCount;          // In how many leaves this portal resides
    unsigned long   OwnerNode;          // Node that created this portal
    unsigned long   LeafOwner[2];       // Front / Back Leaf Owner Array

   // Virtual Public Functions for This Class
   virtual HRESULT Split( const CPlane3& Plane,
                          CBSPPortal * FrontSplit,
                          CBSPPortal * BackSplit );

};
```

Notice that we have added four new members to those inherited from CPolygon which allow us to store the indices of the leaves in which the portal is eventually found to reside and the node the node on which the portal was generated. Notice however that we also implement a new Split function that accepts CBSPPortal pointers. Do not worry! We do not have to implement a polygon splitting function all over again. As you will see in a moment, the Split function simple calls the base class's Split function and then copies the extra portal information into the two resulting front and back splits. Let us list those member variables and describe their purpose.

unsigned long OwnerNode;
As we know, all the nodes of the BSP tree are stored in its master node array. We also know that an initial portal will need to be generated on every node that does not have solid space behind it. This portal will then be passed down the tree and any portions of the portal that exist in solid space will be clipped away. This member contains the index of the node in the tree's node array whose plane this portal was created on. This is used during portal generation to make sure that when a portal ends up in a leaf, it is a leaf that is below the owner node in the tree. If this is not the case then this is a rogue fragment and can be deleted.

unsigned long LeafOwner[2];
Every valid portal will always exist in exactly two leaves as a portal by its very nature is a polygon that represents a door way between leaves and as such, has a leaf on either of its sides. Each valid portal will contain the indices of the two leaves in which it resides in this array. Therefore, this array tells us the two leaves for which this portal forms a doorway.

unsigned char LeafCount;
This member is used during portal generation to keep track of how many leaf indices we have currently added to the above array. This member will start of at zero when the initial portal is first fed into the root node of the tree and will be incremented each time the portal pops out in a leaf. This will never be higher that 2 as a portal can only ever possibly exist in two leaves. However, that does not mean that the initial portal will not end up in many valid portals being created which all exist in a different set of leaves throughout the level. Remember, when a split plane is chosen for BSP creation, the entire geometry set beneath that node in the tree is split. That split may have caused multiple convex leaves to be created across the entire level and therefore, therefore, multiple portals may exist on this node plane to bridge the gaps between those pairs of leaves.

CBSPPortal *NextPortal;
As we showed in the text book, the portal/BSP tree clipping process will require keeping track of al the fragments that a portal gets split into via linked lists. This member allows us to storing multiple CBSPPortal fragments together into a linked list so that we can pass the entire list down the tree by simply passing a pointer to the head of the list through the recursive process.

Constructor - CBSPPortal

The constructor of CBSPPortal simply initializes the portals members to their invalid default values. Each element in the LeafOwner array is set to zero and so is the leaf count. The NextPortal member is set to NULL and the owner node index is set to -1.

```
CBSPPortal::CBSPPortal()
{
    // Initialise any class specific items
    LeafOwner[0]    = 0;
    LeafOwner[1]    = 0;
    NextPortal      = NULL;
    LeafCount       = 0;
    OwnerNode       = -1;
}
```

When the portal object is first created we can see that it is not a valid portal. The portal generation process, after creating a new CBSPPortal object will first construct its geometry via a call to its (inherited) GenerateFromPlane method. This will build the polygon on the chosen node plane and will fill the CBSPPortal with geometry representing a large quad on the node plane. This CBSPPortal will then be passed down and clipped to the BSP tree where the above members will eventually get assigned their final values.

Split - CBSPPortal

Every time a portal is split during the portal generation process, we must not only split the geometry into two child portals but must also carry over the information recorded in the parent portal into the two children. It is vitally important that the journey of the parent is inherited by the children before the parent is deleted for the portal generation process to work. For example, if it has already been

determined that the parent portal was found to exist in leaf 10, we know that both the children will also exist in leaf 10 assuming they are not found to exist in solid space further down the tree and are deleted. Therefore, we must make sure that this information is carried over into the split fragments.

As you can see in the code that follows, the CBSPortal::Split method simply wraps a call to the CPolygon::Split method which additional code to copy the portal information over into the two child splits.

```
HRESULT CBSPPortal::Split( const CPlane3& Plane,
                                CBSPPortal * FrontSplit,
                                CBSPPortal * BackSplit)
{
    // Call base class implementation
    HRESULT ErrCode = CPolygon::Split( Plane, FrontSplit, BackSplit );
    if (FAILED(ErrCode)) return ErrCode;

    // Copy remaining values
    if (FrontSplit)
    {
        FrontSplit->LeafCount    = LeafCount;
        FrontSplit->OwnerNode    = OwnerNode;
        FrontSplit->LeafOwner[0] = LeafOwner[0];
        FrontSplit->LeafOwner[1] = LeafOwner[1];

    } // End If

    if (BackSplit)
    {
        BackSplit->LeafCount     = LeafCount;
        BackSplit->OwnerNode     = OwnerNode;
        BackSplit->LeafOwner[0]  = LeafOwner[0];
        BackSplit->LeafOwner[1]  = LeafOwner[1];
    } // End If

    // Success
    return BC_OK;
}
```

Notice that we can pass FrontSplit and BackSplit into the CPolygon::Split method even though they are of type CBSPPortal because CBSPPortal is derived from CPolygon.

The CBSPTree Class - Updated

The CBSPTree class will have to be slightly updated in this lab project so that it can now accommodate the portal and PVS information that it must now also store. The BSP tree will now maintain a vector of all the valid CBSPPortals that were generated via the portal generation process. That is, once the portal generation module has found a valid two leaf portal, it will add its pointer the tree's master portal array.

The CBSPTree class will also need to have some mechanism of storing the final PVS data array that will be generated by the PVS module. As discussed in the text book, the PVS data whether compressed or uncompressed will be represented as a byte array and therefore, the BSP tree will now have an unsigned char pointer that points to this block of data. It will also need a member variable to the store the size of the PVS data block and a Boolean specifying whether the data has been compressed. The compression

technique used is called ‘zero run length encoding’ which compresses runs of zero bytes up to 255 bytes in length into two bytes. This compression technique is discussed in the text book and lecture.

The CBSPTree class is declared in the file, CBSPTree.h. We will not show the whole class declaration here as it is getting rather large and we have only added four new members. Therefore, below we show just the members that have been added in this lab project to facilitate the storage of the portal and PVS data that will be generated by the CProcessPRT and CProcessPVS modules respectively.

Excerpt from CBSPTree.h

```
class CBSPTree
{
public:

    // Public Variables for This Class.
    UCHAR          *m_pPVSData;             // PVS Data set (array)
    unsigned long   m_lPVSDataSize;         // Size of the PVS data set
    bool            m_bPVSCompressed;       // Is the PVS data compressed

private:
    // Private Functions for This Class.
    vectorBSPPortal m_vpPortals;            // Portals built by the CProcessPRT compiler.
};
```

These new member variables are described below.

UCHAR *m_pPVSData;
After the PVS calculation module has generated a PVS for every leaf in the tree and merged them together into a single array, this pointer will be assigned to point at that master PVS data block. This is the PVS data that will be saved out to file and utilized by the run time component.

This member pointer is assigned to the PVS data by the CProcessPVS module via a call to a new CBSPTree member function called SetPVSData. This function will be passed a UCHAR pointer to the PVS data, the size of the PVS data array and a Boolean describing whether the data is in compressed format. We will look at the code to the SetPVSData method in a moment.

unsigned long m_lPVSDataSize;
This member will be assigned its value via the CBSPTree::SetPVSData method which will be invoked by the CProcessPVS module after the PVS has been calculated. It will describe the size of the UCHAR array of PVS data stored in the above member.

bool m_bPVSCompressed;
This member will be assigned a value of true or false by the CBSPTree::SetPVSData method which is invoked from the CProcessPVS module. It describes whether the PVS data array is in compressed (ZRLE) format or whether it has been stored as an uncompressed bit set. Obviously, if compiler options have been set such that the data is not compressed, the run time component will need to know this so that it iterates through the PVS data at render time in the correct manner.

vectorBSPPortal m_vpPortals;
This is an STL vector that will be used to store pointers to all the valid CBSPPortal structures generated by the portal generation module. The CBSPTree interface also exposes a SetPortal method which the

portal generation module can use to store a portal to this vector once it has been validated as being valid two leaf portal. The portals in this array will all be two way portals which will later be used by the CProcessPVS module to clone a set of one way portals for PVS calculation.

Because we now have an array (vector) of portals stored in the BSP tree, methods will need to be added that allow us to reserve space in this vector every time we wish to add new portals to the tree. Methods will also be needed to allow us to retrieve the number of portals in this vector and as mentioned, a method will be added to allow another modules to place portal pointers in this vector. Furthermore, the CBSPTree object will also have a function that a calling module can use to allocate the memory for a new CBSPPortal. Let us have a look at these new methods now which will give us an idea of the functions that will be called by the portal generation module, to allocate a new portal, add it to the tree's portal array and retrieve information about that portal.

IncreasePortalCount - CBSPTree

This method is called by the CProcessPRT module every time it wishes to add space for a new CBSPPortal pointer to the end of the BSP tree's portal array. So that the vector is not being continually resized for every valid portal that we find and add to the tree, we use a resizing threshold which should not be new to you. The array resize threshold is set to 100 by default and is assigned the definition BSP_ARRAY_THRESHOLD. Here is the code to the function that allows us to make sure there is at least enough room at the end of the BSP tree's portal array to add a new portal pointer.

```
bool CBSPTree::IncreasePortalCount()
{
    try
    {
        // Resize the vector if we need to
        if (m_vpPortals.size() >= (m_vpPortals.capacity() - 1))
        {
            m_vpPortals.reserve( m_vpPortals.size() + BSP_ARRAY_THRESHOLD );

        } // End If

        // Push back a NULL pointer (will already be allocated on storage)
        m_vpPortals.push_back( NULL );

    } // Try vector ops

    // Catch Failures
    catch (...)
    {
        return false;

    } // End Catch

    // Success
    return true;
}
```

The first thing we do in the above code is fetch the size of the vector. This tells us how many portal pointers are currently stored in that vector. We compare this against the capacity of the vector which describes how many portals can be stored in that vector before it is considered full. As the purpose of this function is to assure that the capacity is at least 1 greater than the current size so that there is room

to add another portal pointer, a compare between the two is performed. If the size of the vector is greater or equal to the capacity then it means the vector is full and we must resize it. However, instead of simply resizing the vector by 1 to make room for the a new portal, we resize by our threshold value which by default will resize the vector making room for 100 more portal pointers. Why do we do this? Because array resizes are expensive and we do not want to be performing one for every single portal that we add. This way, we make sure that we only cause a resize every 100 portals even if that means at the end of the process we have a little unused capacity in the vector.

You can see that if the capacity is full we reserve more space so that the vector is large enough to contain its current data (size) plus the 100 (BSP_ARRAY_THRESHOLD) new elements. Notice how we push a NULL pointer on the back of the array which forces the size of array to be increased by 1. You will see why this is necessary in a moment as.

GetPortalCount - CBSPTree

This simple function allows a calling module to inquire about how many portals are currently contained in the BSP tree's portal array. It simply returns the size of the vector.

```
unsigned long   GetPortalCount( ) const { return m_vpPortals.size(); }
```

To understand how this might be needed, imagine that we have a CBSPPortal called pMyPortal that we would like to add to the BSP tree's portal array after finding that it is a valid portal. We would first fetch the current portal count of the array as this will also describe the index of the portal we wish to add to the end like so.

```
// Get the current number of portals stored in the tree's array
int PortalIndex = pTree->GetPortalCount();

// The capacity of the array is such that there is enough room to store new portal
pTree->IncreasePortalCount();

// Store the portal at the end of the array
pTree->SetPortal ( PortalIndex , pMyPortal);
```

You will see later that this is exactly the steps taken by the portal generation module each time it wishes to add a new portal to the BSP trees portal array.

AllocBSPPortal - CBSPTree

This function should be used by all modules that wish to allocate a new CBSPPortal. In keeping with our previous strategy we are placing all memory allocation responsibility on the BSP tree object via a series of AllocBSP…method, for all objects that are defined in its header file. This method simply allocates a new CBSPPortal structure and returns it to the caller.

```
CBSPPortal * CBSPTree::AllocBSPPortal( )
{
    CBSPPortal * NewPortal = NULL;
```

```
    try
    {
        // Allocate new portal
        NewPortal = new CBSPPortal;

        // Note : VC++ new does not throw an exception on failure (easily ;)
        if (!NewPortal) throw std::bad_alloc();

    } // End Try

    catch (...) { return NULL; }

    // Success!
    return NewPortal;
}
```

Note that this function does not add the allocated portal to the portal array in any way. It is simply a helper function that wraps the allocation and handles the throwing of an exception if an error occurs.

SetPortal - CBSPTree

When discussing the GetPortalCount method a moment ago, we showed some example code that demonstrated how to add a new portal to the end of the tree's portal array. This protocol involved fetching the current portal count, increasing the size of the portal array by 1 and then setting the portal at the specified position. Here we see the code to the SetPortal function that is used to store the portal pointer in the BSP tree's portal array at the specified position.

The function takes two parameters. The first in the array index where the caller would like the portal to be stored in the array and the second is a pointer to the CBSPPortal structure that is to be stored in the array.

```
void CBSPTree::SetPortal ( unsigned long Index, CBSPPortal * pPortal )
{
  if (Index < m_vpPortals.size()) m_vpPortals[Index] = pPortal;
}
```

Providing that the passed index is within the current size of the array, the value of that array element is replaced with the passed pointer. You might be wondering why the passed index is compared against the size of the vector and not the capacity. To be safe, we only allow the SetPointer method to assign values to elements that are within the current size of the array even if the array has a much larger capacity. As we know that we will always be adding portals to this array one at a time and in order, this just introduces a safety net that would stop us storing portals in non-linear addresses within the array. However, this now clearly demonstrates why in the IncreasePortalCount method we pushed a NULL on the back of the array and forced the size of the array to be increased by one. Were we not to do this we would not be able to use SetPortal to add a new portal to the end of the array. By adding a NULL to the back of the list initially, we create this portal position in the array first and then fill it later when we call the SetPortal method.

GetPortal - CBSPTree

For completeness, whenever there is a Set function there is usually a Get function that performs the reverse operation. The CBSPTree::GetPortal method accepts a single parameter describing the location of the element within the BSP tree's portal array for which the caller would like to fetch the portal pointer. This is fetched from the array/vector and returned to the caller.

```
CBSPPortal* CBSPTree::GetPortal( unsigned long Index ) const
{
   return (Index < m_vpPortals.size()) ? m_vpPortals[Index] : NULL;
}
```

If the passed index is outside the range of the current number of portals stored in the array (<size), NULL is returned.

SetPVSData - CBSPTree

This new member function will be called by the CProcessPVS module to store the compiled PVS data and accompanying information in the BSP tree. The first parameter to this function is where the unsigned char array of PVS data for the entire tree will be passed. The second parameter will describe the number of bytes in this array and the third parameter will describe whether compression was enabled for the CProcessPVS module. This information will be copied and stored in the tree's member variables.

The first thing the function does is delete any PVS data that the tree may already be pointing to with its m_pPVSData pointer as this will now be used to allocate a new block to contain a copy of the passed PVS data. A new byte array is allocated of the correct size (described by the second parameter) and is pointed to by the tree's m_pPVSData pointer.

```
HRESULT CBSPTree::SetPVSData( UCHAR PVSData[], unsigned long PVSSize, bool PVSCompressed )
{
    // Release any previous data
    if (m_pPVSData) delete[] m_pPVSData;

    try
    {
        // Allocate the PVS Set
        m_pPVSData = new UCHAR[ PVSSize ];
        if (!m_pPVSData) throw std::bad_alloc(); // VC++ Compat

        // Copy over the data
        memcpy( m_pPVSData, PVSData, PVSSize );

    } // End Try Block

    catch ( std::bad_alloc )
    {
        return BCERR_OUTOFMEMORY;

    } // End Catch Block

    // Store Values
    m_lPVSDataSize      = PVSSize;
```

```
    m_bPVSCompressed    = PVSCompressed;

    // Success
    return BC_OK;
}
```

After the new array has been allocated the PVS data is copied over from the passed array into the tree's m_pPVSData array. We also copy over the size and compression status of the data into the m_lPVSDataSize and m_bPVSCompressed member variables.

After this function has been called by the CProcessPVS module, the BSP tree will contain all relevant PVS information. This new BSP tree information will also be written out to file when the scene is saved.

That covers all the changes to the CBSPTree class so we will now look at some minor modifications that have been made to the CBSPLeaf class.

The CBSPLeaf Class - Updated

With the introduction of the portal generation and PVS calculation process in this lab project, two new member variables will be added to our leaf structure. Each leaf will now need to store a ULONG array of indices into the tree's portal array describing the portals in that array that reside in that leaf. You will recall from the accompanying text book that in addition to each portal storing the indices of the leaves in which it belongs, each leaf will store the indices of the portals (which index in to the BSP tree's portal array/vector) that reside in that leaf. We also discussed in the text book how because of the fact that the PVS data for every leaf will be combined into a single PVS data block when stored in the BSP tree (as we have seen), each leaf will need to store the index of the BYTE in the tree's m_pPVSData array where its PVS data set begins. Here is the updated class declaration for CBSPLeaf contained in the file, CBSPTree.h

Excerpt from CBSPTree.h

```
class CBSPLeaf
{
public:

    // Constructors & Destructors
             CBSPLeaf( );
    virtual ~CBSPLeaf( );

    // Public Functions for This Class
    bool            BuildFaceIndices( CBSPFace * pFaceList );
    bool            AddPortal( unsigned long PortalIndex );

    // Public Variables for This Class
    std::vector<long>   FaceIndices;    // Indices to faces in this leaf

    std::vector<long>   PortalIndices;  // Indices to portals in this leaf
    unsigned long       PVSIndex;       // Index into the master PVS array

    CBounds3            Bounds;         // Leaf Bounding Box
};
```

As you can see, there is also a new method called ‘AddPortal’ which is a simple helper function that allows the caller (in this application the portal generation module) to add a portal index to the leaf’s PortalIndices array. Let us have a look at those two new member variables first.

std::vector<long> PortalIndices;
This is an array/vector of portal indices describing the portals that reside in the leaf. Each element in this vector is an index into the CBSPTree::m_vpPortals vector. This array will be filled during the portal generation process.

unsigned long PVSIndex;
This single unsigned long member describes a byte offset into the CBSPTree::m_pPVSData where the leaf’s visibility bits begin. This is calculated and stored in each leaf during the PVS calculation process.

Constructor - CBSPLeaf

The leaf constructor now simply sets the PVSIndex of the leaf to -1 initially indicating that either no PVS data exists for the tree or that it is has not yet been calculated.

```
CBSPLeaf::CBSPLeaf()
{
    // Initialise anything we need
    PVSIndex        = -1;
}
```

AddPortal - CBSPLeaf

The CBSPLeaf::AddPortal method is called to add a portal index to the leaf’s PortalIndices array. This method is called during the portal generation process when a portal is found to exist in a leaf.

The function uses the same BSP_ARRAY_THRESHOLD strategy to minimize the number of array capacity resizes that must be performed during the portal generation process. As you can see in the following code, if the vector size reaches the vector capacity then the capacity of the vector is resized to make room for N more indices (were N is the current resize threshold). The passed portal index is then added to the end of the array.

```
bool CBSPLeaf::AddPortal( unsigned long PortalIndex )
{
    try
    {
        // Resize the vector if we need to
        if (PortalIndices.size() >= (PortalIndices.capacity() - 1))
        {
            PortalIndices.reserve( PortalIndices.size() + BSP_ARRAY_THRESHOLD );
        } // End If

        // Finally add this portal index to the list
```

```
        PortalIndices.push_back( PortalIndex );

    } // End Try Block

    catch (...)
    {
        // Clean up and bail
        PortalIndices.clear();
        return false;
    } // End Catch

    // Success
    return true;
}
```

We have finally covered all the changes to the BSP tree and the CCompiler class and are now ready to start looking at the source code to the CProcessPRT class. This is the module whose ‘Process’ function is used to generate the portals for the BSP tree.

The Portal Generator Module

The portal generation module is the first of the two new modules we will introduce in this lab project. It is vitally important that you have read the accompanying text book and especially the section that pertains to portal generation before continuing with this section. The portal generation code is highly recursive and hard to follow if you have not achieved a grasp of the theory. The theory will not be explained in this work book and it is assumed that you have at least a basic understanding of the portal generation algorithm we are using when viewing this section.

As we have discussed, the portal generation module is contained in a class called CProcessPRT. That is, this module contains all the functions that CCompiler will call to generate the portals for the BSP tree. We saw earlier, that the portal generation process is invoked from a function in CCompiler called PerformPRT which is called from CCompiler::CompileScene should portal generation be enabled for the current compile. The PerformPRT method calls a handful member functions of the CProcessPRT object that are common to all our modules. These include such trivial tasks as informing the module of the BSP tree that is being used, the logger object that error/status reports should be sent to and informing the module of the parent CCompiler object that is invoking the process. This information is all stored inside the CProcessPRT module prior to the CProcessPRT::Process method being called. This same strategy is common across all the modules. That is, for each module, we set up some of its member variables prior to calling its Process method. It is the Process method of each module that kick starts the actual process. In the case of the CProcessPRT module, it is the Process method that will generate all the portals for the tree. On function return, all portals will have been compiled and stored in the BSP tree’s portal array. All leaves in the tree will contain an array of portal indices that describe the portals that were found to reside in those leaves. Finally, each portal will contain a 2 element array of leaf indices describing the two leaves that each portal forms the doorway between. We will now examine the code to this module.

The CProcessPRT Class

The CProcessPRT class declaration is contained in the file ProcessPRT.h and is also shown below. The public interface of this class should be instantly familiar from other modules. It comprises of four methods that are exposed by other modules. The SetOptions, SetLogger and SetParent methods are common to all modules and allow the module to be configured prior to the Process method being invoked. The options structure, logging object pointer and CCompiler parent pointer passed into these methods are all stored in private members variables (you can see that they are inline functions). The private member variables are also the same as the other modules with the exception that a PRTOPTIONS structure is used to contain the portal compilation options.

Excerpt from ProcessPRT.h

```
class CProcessPRT
{
public:
    // Constructors & Destructors for This Class.
             CProcessPRT();
    virtual ~CProcessPRT();

    // Public Functions for This Class.
    HRESULT         Process( CBSPTree * pTree );
    void            SetOptions( const PRTOPTIONS& Options ) { m_OptionSet = Options; }
    void            SetLogger ( ILogger * pLogger )         { m_pLogger = pLogger; }
    void            SetParent ( CCompiler * pParent )       { m_pParent = pParent; }

private:
    // Private Functions for This Class.
    CBSPPortal     *ClipPortal          ( unsigned long Node, CBSPPortal * pPortal );
    bool            FindLeaf            ( unsigned long Leaf, unsigned long Node );
    unsigned long   ClassifyLeaf        ( unsigned long Leaf, unsigned long Node );
    HRESULT         AddPortals          ( CBSPPortal * PortalList );

    // Private Variables for This Class.
    PRTOPTIONS      m_OptionSet;        // The option set for portal Compilation.
    ILogger        *m_pLogger;          // Logging interface used to log progress etc.
    CCompiler      *m_pParent;          // Parent Compiler Pointer
    CBSPTree       *m_pTree;            // The tree used to compile the portal set.

};
```

The Process method is also no stranger to us and is the method that all modules expose to actually carry out their task. This class also has four private member functions which will be called by the public Process method to carry out its task of generating the portals and storing them in the tree.

Process - CProcessPRT

This method invoked by CCompiler to perform the portal generation. With the help of four of the class's private methods, this function is responsible for the entire process tasked to this module. That is, when this function has completed, the two way portals will all have been generated and stored in the BSP tree's portal array. Each portal in this array will also contain the indices of the two leaves in which they reside and each leaf in the BSP tree will contain an array of portal that live in that leaf.

Note: Recall from text book that while a single portal can never exist in more than two leaves, a single leaf may have many portals that reside within it.

The function takes a single parameter when called from the CCompiler object. It is passed a pointer to the BSP tree which is to have its portals generated. The passed BSP tree pointer is copied into the module's member variable (m_pTree) so that we have access to the BSP tree throughout all its functions. We then output information to the logging object via its LogWrite function displaying the message that portal compilation is about to commence. We also set a rewind marker and progress range within the logger so that every time the progress indicator is updated, we can return to the cursor position set by the rewind marker and overwrite the old progress value with the current one in the loggers output window. The initial progress value is set to zero and the range of the progress indicator is set to the number of nodes in the tree. Therefore, each time we process a node and (potentially) generate a portal for it, we can increase the current progress and have the logging object return to the rewind marker (the cursor position in the output channel where the first digit of the progress percentage will be displayed) and will update the current progress percentage value.

```
HRESULT CProcessPRT::Process( CBSPTree * pTree )
{
    HRESULT      ErrCode;
    CBounds3     PortalBounds;
    CBSPPortal * InitialPortal = NULL;
    CBSPNode   * CurrentNode   = NULL;
    CBSPNode   * RootNode      = NULL;
    CPlane3    * NodePlane     = NULL;
    CBSPPortal * PortalList    = NULL;

    // Validate values
    if (!pTree) return BCERR_INVALIDPARAMS;

    // Store tree for compilation
    m_pTree = pTree;

    try
    {
        // ************************
        // * Write Log Information *
        // ************************
        if ( m_pLogger )
        {
            m_pLogger->LogWrite( LOG_PRT,
                                 0,
                                 true,
                                 _T("Compiling scene portal information \t\t- " ) );

            m_pLogger->SetRewindMarker( LOG_PRT );
            m_pLogger->LogWrite( LOG_PRT, 0, false, _T("0%%" ) );
            m_pLogger->SetProgressRange( pTree->GetNodeCount() );
            m_pLogger->SetProgressValue( 0 );
        }
        // ************************
        // *    End of Logging     *
        // ************************
```

In the next section of the code we first test that we can retrieve the root node (node index 0) from the node array and if not then we return error (safety incase we are trying to compile portal data for a BSP

tree object that has not yet compiled its data). We fetch the root node because its bounding box will be used to create the initial portal on each node plane. We then loop through each node in the node array.

Let us now examine the contents of this node loop.

```
        // Store required values ready for use.
        if (!(RootNode = m_pTree->GetNode(0))) throw BCERR_BSP_INVALIDTREEDATA;

        // Create a portal for each node
        for (unsigned long i = 0; i < pTree->GetNodeCount(); i++)
        {
            // Update progress
            if ( m_pParent && !m_pParent->TestCompilerState()) return BC_CANCELLED;
            if ( m_pLogger ) m_pLogger->UpdateProgress( );
```

The first thing we do inside this loop is test that the parent compiler has not been put into a cancelled state by the user. If so, we simple return BC_CANCELLED because the user has obviously aborted the process mid compile. Provided this is not the case however, you can see that we instruct the logging object to update its progress as we are about to process another node.

In the next section of code we fetch the current node structure we are processing from the BSP tree's node array. We store a pointer to this node structure in the local node pointer **CurrentNode**. We then fetch from this structure the index of the node plane stored at that node so that we can fetch the node's plane from the BSP tree's plane array and store its pointer in the local variable **NodePlane.**

```
            // Store required values ready for use.
            if (!(CurrentNode = m_pTree->GetNode(i))) throw BCERR_BSP_INVALIDTREEDATA;

            if (!(NodePlane   = m_pTree->GetPlane(CurrentNode->Plane)))
                                                    throw BCERR_BSP_INVALIDTREEDATA;
```

Now that we have the node structure and the plane structure of the node we are currently processing, let us first test whether a portal could possibly exist on this node. As we know, a portal can only exist on a node plane if that node has **not** got solid space behind it. If it has then this node does not have leaves in both its half spaces and therefore, no portal generated on this node could ever bridge two leaves. When this is the case we simply skip processing this node any further and continue on to the next iteration of the loop and the next node waiting to be processed.

```
            // Skip any that have solid space behind them
            if ( CurrentNode->Back == BSP_SOLID_LEAF ) continue;
```

If we get this far without skipping to the next iteration then it means the current node we are processing has leaves on both sides and it stands a very good chance of generating a real portals. Of course, we do not know this for sure yet, but we certainly know that we will have to create a new portal on the node plane that is as large as the root node's bounding box and will have to send this portal down the tree clipping away any fragments that exist in solid space. If anything survives, then we do have a portal or multiple portal fragments that can be added to the BSP tree's portal array.

The first step is to allocate a new CBSPPortal structure using the CBSPTree::AllocBSPPortal function which we described earlier. This portal will be initially empty but we want it to represent a quad that is

located in the current node's plane and is large enough to fill the root node's bounding box. Fortunately, we have already written the CPolygon::GenerateFromPlane method that will construct such a portal given the node plane and the root nodes bounding box. Therefore, in the next section of code, you can see that after we allocate a new portal structure and retrieve the root node's bounding box, we then pass this information into the GenerateFromPlane method to generate the initial portal on that plane. We also store in the portal the index of the node on which it was initially generated in its OwnerNode member.

```
            // Allocate a new initial portal for clipping
            if (!(InitialPortal = CBSPTree::AllocBSPPortal())) throw BCERR_OUTOFMEMORY;

            // Initial Portal should fill root node
            PortalBounds = RootNode->Bounds;

            // Generate the portal polygon for the current node
            InitialPortal->GenerateFromPlane( *NodePlane, PortalBounds );
            InitialPortal->OwnerNode = i;
```

At this point we are ready to drop that initial portal in at the root node of the tree and clip it to the solid space of the tree as it makes its way down to the leaf nodes. The ClipPortal method is used for this. It is a recursive function that will call itself repeatedly until either the initial portal has been completely clipped away (in which case PortalList will be assign NULL on function return) or until it has correctly calculated the valid portal fragments in which case, they will be returned in a linked list. PortalList will point to the head of this valid portal list on function return. As the first parameter to the ClipPortal method we pass in the index of the node we would like to start clipping from which will be the root node (node zero). As the second parameter we pass our initial portal that is to be passed through the tree and clipped.

```
            // Clip the portal and obtain a list of all fragments
            PortalList = ClipPortal(0, InitialPortal );

            // Clear the initial portal value, we no longer own this
            InitialPortal = NULL;
```

Notice in the above code how when the ClipPortal method returns, we simply set the InitialPortal pointer to NULL instead of releasing it. That is because this portal will have been clipped and deleted by the ClipPortal method as it is passed through the tree and split into child fragments. As soon as we pass the initial portal into the ClipPortal method it is the responsibility of the ClipPortal method to clean up its memory when it gets split.

At this point, if PortalList is not NULL then it contains a list of one or more valid portals that have been generated on the current node plane. If this is the case these portals should be added to the BSP tree's portal array. The CProcessPRT::AddPortals method is invoked to perform this task. Contrary to the way we normally do things, we will look at the simple AddPortals method prior to examining the ClipPortal code. This will show us how the portal information returned from ClipPortal gets added to the tree and the leaves of that tree first.

```
            // Add any valid fragments to the final portal list
            if (PortalList)
            {
                if (FAILED(ErrCode = AddPortals( PortalList ))) throw ErrCode;
            } // End If PortalList
```

```
        } // Next Node

    } // End Try

    catch ( HRESULT& Error )
    {
        // If we dropped here, something failed
        if ( InitialPortal )     delete InitialPortal;
        if ( m_pLogger )         m_pLogger->ProgressFailure( LOG_PRT );
        return Error;

    } // End Catch

    // Success
    if ( m_pLogger ) m_pLogger->ProgressSuccess( LOG_PRT );
    return BC_OK;

}
```

We can see that after the AddPortals method has been called we see the closing brace to the node loop such that at the bottom of the function, every portal in the level will have been created and added to the tree's portal list. Before returning success, we output to the logging object that the mission has been a success. When the function returns, the portal generation process is over and all portals have been created and stored in the tree.

AddPortals - CProcessPRT

The AddPortals method is called from the Process method to add a list of valid portals returned from the ClipPortal method for a given node to the BSP tree's node array. The function is passed a CBSPPortal pointer that points to the head of this list. First we set up a loop to iterate through every portal in the list. The Iterator local pointer is used to step through the elements in the list.

```
HRESULT CProcessPRT::AddPortals( CBSPPortal * PortalList )
{
    unsigned long PortalIndex = 0;
    CBSPPortal  * Iterator;
    CBSPLeaf * Leaf = NULL;

    // Validate
    if (!PortalList) return BCERR_INVALIDPARAMS;

    // Iterate through the list, obtaining valid portals
    Iterator = PortalList;
    while ( Iterator != NULL )
    {
```

Inside this loop we first fetch the current portal count from the BSP tree as this will tell us the location within the BSP tree's master portal array where the next portal should be placed (at the end of the currently stored portals).

```
        // Store new portal index
        PortalIndex = m_pTree->GetPortalCount();
```

As every portal will at this point store in its LeafOwner array the indices of the two leaves in which it was found to reside during the ClipPortal function, we next loop through each of these elements and store the index of this portal (in the BSP tree's portal array) in the PortalIndices array of each leaf.

```
        // Add this portal to each leaf
        for ( int i = 0; i < 2; i++ )
        {
            Leaf = m_pTree->GetLeaf( Iterator->LeafOwner[i] );
            if (!Leaf) return BCERR_BSP_INVALIDTREEDATA;
            Leaf->AddPortal( PortalIndex );

        } // Next Leaf
```

As you can see in the above code, in each iteration of the loop we fetch the leaf index from the portal's LeafOwner array and then use that to retrieve the relevant leaf structure from the tree. Once we have a pointer to the leaf in which this portal should have its index stored, we then call the CBSPLeaf::AddPortal method (which we looked at earlier) which will add the passed index to the leaf's PortalIndices array. Remember that although we have not yet added the current portal being processed in the passed list to the BSP tree's portal array, PortalIndex describes the location of where it will be stored as this describes the current number of portals in the list prior to this portal being added.

With the portal index now stored in the two leaves in which it was found to reside, we next instruct the BSP tree to make sure there is enough space in its portal array to add this new portal pointer.

```
        // We are adding a new portal
        m_pTree->IncreasePortalCount();
```

We then finish processing the current portal by using the CBSPTree::SetPortal method to store the current portal's pointer at that index in the tree's master portal array.

```
        // Set the portal
        m_pTree->SetPortal( PortalIndex, Iterator );
```

We then assign the current portal's NextPortal member to Iterator so that in the next iteration of the loop, if NextPortal is not NULL, Iterator will point to the next portal in the passed list to be added to the tree's portal array.

```
        // Move onto next portal
        Iterator = Iterator->NextPortal;

    } // End While

    return BC_OK;
}
```

When this function returns, every portal in the passed list will have been added to the BSP tree's portal array and the leaves in which these portals reside will have had the portal indices added to their PortalIndices array.

ClipPortal - CProcessPRT

As discussed in the accompanying text book, the ClipPortal method really is the portal generation engine. It is the function that is called from the Process method and passed an initial portal that is to be clipped to the tree. When the function is first called it will visit the root node and will then recursively call itself until the portal has either been complete deleted, or until it has a list of valid portal fragments to return. Valid portals are fragments of the initial portal passed in the root that ended up in empty space and were found to reside in two leaves. This is a rather huge function which was explained in detail in the text book. As this version of the function is almost identical we will make our way through it quite quickly so that you can see the version of the function that is used by our compiler.

The function is passed a node index (which will be the root node the first time it is called from the Process method) and a portal. The first time this function is called this portal will be the initial portal that was created on the node inside the Process method, for nodes further down the tree, this portal may be a fragment of that initial portal.

```
CBSPPortal * CProcessPRT::ClipPortal( unsigned long Node, CBSPPortal * pPortal )
{
    // 52 Bytes including Parameter list (based on __thiscall declaration)
    CBSPPortal   * PortalList     = NULL, *FrontPortalList = NULL;
    CBSPPortal   * BackPortalList = NULL, *Iterator        = NULL;
    CBSPPortal   * FrontSplit     = NULL, *BackSplit       = NULL;
    CBSPNode     * CurrentNode    = NULL;
    CPlane3      * CurrentPlane   = NULL;
    unsigned long  OwnerPos, LeafIndex;

    // Validate Requirements
    if (!pPortal || !m_pTree) throw BCERR_INVALIDPARAMS;

    // Store node for quick access
    if (!(CurrentNode  = m_pTree->GetNode( Node ))) throw BCERR_BSP_INVALIDTREEDATA;
    if (!(CurrentPlane = m_pTree->GetPlane(CurrentNode->Plane)))
                                                    throw BCERR_BSP_INVALIDTREEDATA;
```

As we can see in the above section of code, we first use the passed node index to fetch the node structure from the BSP tree. This is the node that we are currently visiting with the passed portal/fragment. We then use the node's Plane index to fetch the node's plane structure from the BSP tree's master plane array.

The rest of the function is essentially just a switch statement which deals with the result of classifying the portal against the plane. The following code classifies the vertices of the polygon against the node plane. We use the CPlane3::ClassifyPoly function for this task. The function will return either CLASSIFY_FRONT, CLASSIFY_BACK, CLASSIFY_ONPLANE or CLASSIFY_SPANNING.

```
    // Classify the portal against this nodes plane
     switch (CurrentPlane->ClassifyPoly(      pPortal->Vertices,
                                              pPortal->VertexCount,
                                              sizeof(CVertex))    )
    {
```

The front and back cases are small and simple to deal with but the spanning and on plane cases are considerably more complex. We will look at the CLASSIFY_ONPLANE case first.

```
        case CLASSIFY_ONPLANE:

            // The Portal has to be sent down Both sides of the tree and tracked.
            // Send it down front first but DO NOT delete any bits that end up in solid
            // space, just ignore them.
            if (CurrentNode->Front < 0 )
            {
                        // The Front is a Leaf, determine which side of the node it fell
                LeafIndex   = abs(CurrentNode->Front + 1);
                OwnerPos    = ClassifyLeaf( LeafIndex, pPortal->OwnerNode );

                // Found the leaf below?
                if ( OwnerPos != NO_OWNER)
                {
                    // This portal is added straight to the front list
                    pPortal->LeafOwner[OwnerPos] = LeafIndex;
                    pPortal->NextPortal          = NULL;
                    FrontPortalList              = pPortal;
                    pPortal->LeafCount++;

                } // End if leaf found
                else
                {
                    delete pPortal;
                    return NULL;

                } // End If no leaf found

            } // End if child leaf
            else
            {
                    // Send the Portal Down the Front List and get returned
                    // a list of PortalFragments that survived the Front Tree
                    FrontPortalList = ClipPortal(CurrentNode->Front, pPortal);

             } // End If child node
```

The above code shows the first section of dealing with the on plane case. When a portal is on plane we need to send that portal down the front tree so that it can be clipped to the front tree of the node. This will return a linked list of any portal fragments that survive the front tree. Each portal in this list should then be passed down and clipped to the back tree of the node. Any fragment of the portal passed into this function that survives both the front and back trees of the node can then be compiled into a linked list and returned from the function.

In the above section of code we show the portion of the on plane case that deals with sending the portal down the front of the node first. If the node's Front member contains a negative number then we know that there is a leaf to the front of this node (empty space) and as such, the portal should record the index of this leaf in the portal. This is one of the leaves the portal has been found to reside in. Therefore, when this is the case we add 1 to the node's Front value and ABS it so that we have an index into the BSP tree's leaf array of the leaf in which the portal has landed. We then call the ClassifyLeaf function which will return either NO_OWNER, FRONT_OWNER or BACK_OWNER indicating whether this leaf is located in the front or back half space of the node. If the function returns NO_OWNER then it means that the leaf the portal has landed in does not exist beneath the portal's owner node in the tree and therefore this is a rogue portal (rogue portals are discussed in the text book). When this is the case we simply delete the portal as this portal is not valid for the current node being generated. However, if

FRONT_OWNER or BACK_OWNER is returned then we store the leaf index in the portal's LeafOwner array. Notice that FRONT_OWNER and BACK_OWNER are also used as the array indexes so that the leaf that exists in the front space of a portal will always be contained in the first element of the portal's LeafOwner array and the second element will always contain the index of the leaf contained in the back half space of the node. You can also see in the above code that if the portal does land in a leaf, we increase the portal's LeafCount member to reflect the fact that we have just added a leaf index to the portal's leaf array. We also assign the FrontPortalList local variable to point at this portal which will be used in a moment. We also make sure that the portal's next pointer is set to NULL.

Finally notice at the bottom of the above code, how if a leaf does not exist down the front of this node, but a child node exists instead, the ClipPortal function is called recursively to send the portal down the front tree of the current node. This function will either return a linked list of all the fragments of this portal that survived the front tree, the head of which is assigned to the FrontPortalList local variable, or will return NULL if none of the portal survived being clipped to the front tree.

At this point, FrontPortalList either points to the single portal that made it into a leaf to the front of this node, a list of fragments that survived the portal being clipped to the front tree of the node, or NULL if either the portal made it into a leaf that was not beneath the owner node in the tree (rogue portal fragment) or if the portal was clipped to the front tree and was found to be contained completely in solid space.

In the next section of code we see that if FrontPortalList equals NULL then there is nothing more to do at this node. The portal passed into this node has been completely deleted so we return NULL.

```
            // If nothing survived return here.
            if (FrontPortalList == NULL) return NULL;
```

However, if there are portals in our front list then we know each will have to be clipped to the back tree of the node next. If the node has no back child (solid space behind it) then we simply return the front list of portal fragments.

```
            //// If the back is solid, just return the front list
            if ( CurrentNode->Back == BSP_SOLID_LEAF ) return FrontPortalList;
```

Now we will loop through each portal in the front portal list and will send each one in the list into the ClipPortal function to clip it to the front tree of the node. Each time we call the ClipPortal function to send the current front list portal being processed down the back tree, we will take the returned list of portals and add them to a larger list that is being compiled. This larger list will contain, at the end of the next section of the code, any fragments that survived both the front and back trees of the node.

```
            // Loop through each front list fragment and send it down the back branch
            pPortal = FrontPortalList;

             while ( pPortal != NULL )
             {
                CBSPPortal * NextPortal = pPortal->NextPortal;
                BackPortalList          = NULL;
```

At the head of the loop we cache the next portal in the front portal list so that when the current portal we are processing gets sent down the back tree and potentially deleted, we do not loose access to the next portal in the front portal list to be processed. The variable BackPortalList will be used to retrieve any fragments of the current front portal fragment that is sent down the back tree of the node.

> **Note**: Remember that the current portal being processed in this loop (pPortal) is a portal fragment from the front portal list that is now about to be clipped to the back tree.

First we test the Back member of the current node and if found to be negative it means an empty space leaf exists to the back of this node. Here we are adding support for empty back leaves that can occur in very special cases which will be discussed later in the series. As discussed in the text book however, a level provided for solid BSP compilation, will not ever contain populated back leaves. Still, we will add support for populated back leaves now.

As we did in the case of an immediate front leaf, if a leaf does exist to the back of this node, it means the portal has landed in this leaf. As such, we convert the node's Back member into a valid leaf index and fetch the appropriate leaf structure from the BSP tree's leaf array. We then classify this leaf against the portal's owner node to determine in which half space of the portal this leaf exists. The leaf indices are then stored in the portal depending on the outcome.

```
                // Empty leaf behind?
                if ( CurrentNode->Back < 0 )
                {
                    // The back is a Leaf, determine which side of the node it fell
                    LeafIndex   = abs(CurrentNode->Back + 1);
                    OwnerPos    = ClassifyLeaf( LeafIndex, pPortal->OwnerNode );

                    // Found the leaf below?
                    if ( OwnerPos != NO_OWNER )
                    {
                        // Attach it to the back list
                        pPortal->LeafOwner[OwnerPos] = LeafIndex;
                        pPortal->NextPortal          = BackPortalList;
                        BackPortalList               = pPortal;
                        pPortal->LeafCount++;

                    } // End if leaf found
                    else
                    {
                        // Delete the portal, but continue to the next fragment
                        delete pPortal;
                        continue;

                    } // End If no leaf found

                } // End if child leaf

                else

                {
                    // Send the Portal Down the back and get returned a list of
                    // PortalFragments that survived the Front Tree
                    BackPortalList      = ClipPortal(CurrentNode->Back, pPortal);

                } // End If child node
```

Notice that if a leaf does not exist immediately to the back of this node it means a child node must exist there instead. When this is the case we send the portal down the back of the node to clip it to the node's back tree. Any surviving fragments are returned in a linked list, the head of which is assigned to the BackPortalList pointer.

At this point, BackPortalList contains only the list of fragments for a single fragment that survived the front tree of the node and as discussed, we must collect all the BackPortalList's generated from each portal in FrontPortalList and stitch them together into a single linked list that can be returned from the function. The PortalList local variable will be used to point at the head of this combined list which will be returned from the function.

In the next section of code we can see that assuming that BackPortalList is not null, we must add them to the current list we have compiled so far. We do this by first iterating to the tail of the BackPortalList.

```
                // Anything in the back list?
                if (BackPortalList != NULL)
                {
                    // Iterate to the end to get the last item in the back list
                    Iterator = BackPortalList;

                    while ( Iterator->NextPortal != NULL) Iterator = Iterator->NextPortal;
```

At this point Iterator will point to the last element in BackPortalList. We now assign the NextPortal member of this final portal in the back portal list to point at 'PortalList' which currently points to the head of the list of portal fragments we have collected so far. What we are doing is adding the back portal list to the front of the portal list of all the fragments we have collected so far. Here is the remaining code of the on plane case.

```
                    // Attach the last fragment to the first fragment
                    // from the previous iteration.
                    Iterator->NextPortal = PortalList;

                    // Portal List now points at the current complete
                    // list of fragments collected so far
                    PortalList = BackPortalList;

                } // End if BackPortalList is not empty

                // Move on to next portal
                pPortal = NextPortal;

            } // End While Portal != NULL

            // Return the full list
            return PortalList;
```

As you can see after we have assigned the Iterator to point at PortalList (the current head of the list of all fragments we have collected so far), we the reassign PortalList to point at BackPortalList so that it now points to the complete list of fragments we have collected so far, including those contained in BackPortalList. Finally, we can see that at the bottom of main loop that iterates through each portal in FrontPortalList, we assign pPortal to point at NextPortal. Next Portal is where we stored a pointer to the

next portal in FrontPortalList that will need to be clipped to the back tree of the node in the next iteration.

Outside the loop and in the very last line of code shown above, PortalList will contain all the fragments of the portal passed into the function that survived both the front and back trees of the current node being visited. This linked list is returned from the function.

With the on plane case covered, we will next look at what happens if the portal passed into the function is found to be contained entirely in the front half space of the current node being visited.

If there is a leaf immediately attached to the front of this node then it means the portal has made it into a leaf. When this is the case we see that familiar piece of code that fetches the leaf from the BSP tree's leaf array and classifies it against the owner node of the portal. Depending on which side of the owner node's plane the leaf is found to reside, the leaf index is recorded in the appropriate position in the portals LeafOwner array and the portals leaf count is increased so that we know how many leaves this portal has been found to exist in at this point. Below we show the entire CLASSIFY_INFRONT case.

```
            case CLASSIFY_INFRONT:

             // Either send it down the front tree or add it to the portal
             // list because it has come out in Empty Space
            if (CurrentNode->Front < 0 )
            {
                // The front is a Leaf, determine which side of the node it fell
                LeafIndex   = abs(CurrentNode->Front + 1);
                OwnerPos    = ClassifyLeaf( LeafIndex, pPortal->OwnerNode );

                // Found the leaf below?
                if ( OwnerPos != NO_OWNER )
                {
                    // This is just returned straight away, it's in an empty leaf
                    pPortal->LeafOwner[OwnerPos] = LeafIndex;
                    pPortal->NextPortal          = NULL;
                    pPortal->LeafCount++;
                    return pPortal;

                } // End if leaf found
                else
                {
                    delete pPortal;
                    return NULL;

                } // End if leaf not found

            } // End if child leaf
            else
            {
                // Pass down the front
                PortalList = ClipPortal(CurrentNode->Front, pPortal);
                return PortalList;

            } // End If child node

            break;
```

Above we can see that if a leaf does not exist immediately to the front of this node it means a child node exists and as such, the portal is passed down the front tree of the node and clipped to any solid space that may exist there. The ClipPortal method will return a list of one or more fragments of this portal that survived being clipped to the front tree which are then returned from the function to the parent instance of the function.

The CLASSIFY_BEHIND case is almost the same except with a very important difference. If solid space exists to the back of the node then the portal has to be deleted and NULL returned. It is this case during the recursive process that is responsible for clipping away the parts of a portal that land in solid space.

```
            case CLASSIFY_BEHIND:

            // Test the contents of the back child
            if (CurrentNode->Back == BSP_SOLID_LEAF )
            {
                // Destroy the portal
                delete pPortal;
                return NULL;

            } // End if solid leaf
```

However, if solid space does not exist down the back of this node then two other conditions may be true. Either an empty space leaf exists down the back of this node in which case we store the leaf index in the portal in the normal way, or a child node exists down the back of the current node in which case the portal must be clipped to the back tree and the resulting fragment list returned as shown below.

```
            else

            if (CurrentNode->Back < 0 )
            {
                // The back is a Leaf, determine which side of the node it fell
                LeafIndex   = abs(CurrentNode->Back + 1);
                OwnerPos    = ClassifyLeaf( LeafIndex, pPortal->OwnerNode );

                // Found the leaf below?
                if ( OwnerPos != NO_OWNER )
                {
                    // This is just returned straight away, it's in an empty leaf
                    pPortal->LeafOwner[OwnerPos] = LeafIndex;
                    pPortal->NextPortal          = NULL;
                    pPortal->LeafCount++;
                    return pPortal;

                } // End if leaf found
                else
                {
                    delete pPortal;
                    return NULL;

                } // End if leaf not found

            } // End if child leaf
            else
            {
                // Pass down the back
```

```
                PortalList = ClipPortal(CurrentNode->Back, pPortal);
                return PortalList;

            } // End If child node

            break;
```

The final case we must deal with I this function is the case where the portal is spanning the plane. When this is the case we must split the portal into two child fragments and clip the back fragment to the back tree of the node and the front fragment to the front tree of the node. Any surviving fragments from the front split portal and the back split portal are joined together into a single linked list which is then returned from the function. We will look at this case a section at a time.

```
            case CLASSIFY_SPANNING:

            // Allocate new front fragment
            if (!(FrontSplit = CBSPTree::AllocBSPPortal())) throw BCERR_OUTOFMEMORY;

            // Allocate new back fragment
            if (!(BackSplit  = CBSPTree::AllocBSPPortal())) { delete FrontSplit;
                                                              throw BCERR_OUTOFMEMORY; }

            // Portal fragment is spanning the plane, so it must be split
            if (FAILED( pPortal->Split(*CurrentPlane, FrontSplit, BackSplit)))
            {
                delete FrontSplit; delete BackSplit;
                throw BCERR_OUTOFMEMORY;
            } // End If

            // Delete the ORIGINAL portal fragment
            delete pPortal;
            pPortal = NULL;
```

As the above code shows, because we know the portal is spanning the plane it will have to be split into two children so we first allocate two new empty CBSPPortal structures. These are then passed into the parent portal's Split method along with the plane of the current node we are visiting. When the split function returns, FrontSplit will contain the fragment of the portal that exists in the front half space of the passed plane and BackSplit will contain the fragment that exists in the back half space. The original portal (pPortal) that was passed into the function can now be deleted as it has been replaced by these two splits.

Our next task is to deal with the front split first by sending it down the front tree of the node. If a leaf exists immediately to the front of the node then the front split portal obviously exists in this leaf. When this is the case the leaf index is recorded in the portal as we have seen many times before.

```
            // There is another Front NODE ?
            if (CurrentNode->Front < 0 )
            {
                // The front is a Leaf, determine which side of the node it fell
                LeafIndex   = abs(CurrentNode->Front + 1);
                OwnerPos    = ClassifyLeaf(LeafIndex, FrontSplit->OwnerNode );

                // Found the leaf?
                if ( OwnerPos != NO_OWNER)
                {
```

```
                FrontSplit->LeafOwner[OwnerPos] = LeafIndex;
                FrontSplit->NextPortal          = NULL;
                FrontPortalList                 = FrontSplit;
                FrontSplit->LeafCount++;

            } // End if leaf found
            else
            {
                delete FrontSplit;

            } // End If no leaf found

        } // End if child leaf
        else
        {
                FrontPortalList = ClipPortal(CurrentNode->Front, FrontSplit);

        } // End If child node
```

Notice in the **else** case however that if a child node exists here instead, the front split portal is clipped to the front tree of the node with any surviving fragments being assigned to the FrontPortalList local variable. Notice that even if the portal makes it into the leaf, we also assign FrontPortalList to point at it so that regardless of whether a node or a leaf exists to the front of this node, we know that FrontPortalList will point to one or more portals that have survived the front tree of the node at this point.

With the front split being clipped to the front tree dealt with, we will now send the back split portal down the back tree of the node. If there is solid space behind this node then the back split has landed in solid space and is therefore simply deleted. Alternatively, if a leaf exists to the back of this node we see that familiar code that classifies the leaf against the node and stores the leaf index in the appropriate location in the portals LeafOwner array.

```
        // There is another back NODE ?
        if ( CurrentNode->Back == BSP_SOLID_LEAF )
        {
            // We ended up in solid space
            delete BackSplit;

        } // End if solid leaf
        else if (CurrentNode->Back < 0 )
        {
            // The back is a Leaf, determine which side of the node it fell
            LeafIndex   = abs(CurrentNode->Back + 1);
            OwnerPos    = ClassifyLeaf(LeafIndex, BackSplit->OwnerNode );

            // Found the leaf?
            if ( OwnerPos != NO_OWNER)
            {
                BackSplit->LeafOwner[OwnerPos] = LeafIndex;
                BackSplit->NextPortal          = NULL;
                BackPortalList                 = BackSplit;
                BackSplit->LeafCount++;

            } // End if leaf found
            else
            {
                delete BackSplit;
```

```
            } // End If no leaf found

        } // End if child leaf
```

Finally, if a child node exists to the back of this node instead of a leaf, we clip the back split portal to the back tree of the node using the BackPortalList local pointer to point to any surviving fragments on function return.

```
    else
        {
            BackPortalList = ClipPortal(CurrentNode->Back, BackSplit);

        } // End If child node
```

Notice that even in the case where the portal makes it into a back leaf, we assign BackPortalList to point at the portal so regardless of whether or not it landed in a leaf or was clipped to the back of the tree, BackPortalList will contain any fragments of the back split portal that survived the back node of the tree.

At this point we have FrontPortalList and BackPortalList which can potentially contain the fragments of the front split portal and the back split portal that survived being sent down the front and back of the node respectively. Our final step is two join these two portal lists together into a single list before returning this combined list from the function.

The following code shows that if there are portals in FrontPortalList then we iterate through the list to get a pointer to the last portal in that list. If BackPortalList isn't NULL then we assign the NextPortal member of that last portal in FrontPortalList to point to the first portal in the back portal list which is then returned from the function.

```
        // Find the End of the front list and attach it to Back List
        if (FrontPortalList != NULL)
        {
                // There is something in the front list
                Iterator = FrontPortalList;

                while (Iterator->NextPortal != NULL) Iterator = Iterator->NextPortal;

                if (BackPortalList != NULL) Iterator->NextPortal = BackPortalList;
                    return FrontPortalList;

        } // End if front list
```

If there are no portals in the front portal list then alternatively we just return either the back portal list or NULL if no portals exist in this the back portal list either as shown below.

```
        else
        {
            // There is nothing in the front list simply return the back list
            if (BackPortalList != NULL) return BackPortalList;
            return NULL;

        } // End if no front list
```

```
            // If we got here, we are fresh out of portal fragments so simply return NULL.
            return NULL;

    } // End switch

    return NULL;
}
```

The ClipPortal method is certainly an intimidating function on first appearance although, examining the various cases in isolation has shown that this is really just a special case CSG function. Most of the code that seems to make the function look overly complex is actually trivial linked list manipulation and management code. This function is the core of the portal generation process. As we have seen, it is called by the CProcessPRT::ClipPortal method for each initial portal that is created on a node plane.

Whenever a portal is found to exist in a leaf in the above code, we record the index of that leaf in the portal. Whether the leaf index is stored in the first element of the portals LeafOwner array or the second depends on whether the leaf exists in the front or back half space of the node respectively. To make this determination the ClassifyLeaf method is used. This method also takes care of identifying rogue portal fragments if the leaf can not be found down either the front or back tree of the current portals owner node. Let us have a look at the code to this function next.

ClassifyLeaf - CProcessPRT

When this function is called from ClipPortal it is passed the index of the leaf in which the portal fragment has been found to reside and is also passed the index of the portal's owner node. Recall that the owner node is the node for which the initial portal was created and sent into the first instance of the ClipPortal method.

The function first uses the passed node index to fetch the node structure from the BSP tree's node array.

```
unsigned long CProcessPRT::ClassifyLeaf( unsigned long Leaf, unsigned long Node )
{
    CBSPNode * CurrentNode = NULL;

    // Validate Requirements
    if (!m_pTree) throw BCERR_INVALIDPARAMS;
    if (!(CurrentNode = m_pTree->GetNode( Node ))) throw BCERR_BSP_INVALIDTREEDATA;
```

If the node has a negative number in its Front member then it means a leaf exists down the front of the node. In this case we convert it to a valid leaf index and perform an equality test with the passed leaf index. If they are equal then we have located the passed leaf as being attached immediately to the front of the node. This means the leaf we are looking for is in the front half space of the portal so we return FRONT_OWNER.

```
    // Check to see if the front is this leaf
    if ( CurrentNode->Front < 0 )
    {
        if ( abs(CurrentNode->Front + 1) == Leaf ) return FRONT_OWNER;
    }
```

If the node's Front member is non negative then it contains the index of the front child node. When this is the case we use the CProcessPRT::FindLeaf function (discussed in a moment) to traverse the front tree of the node looking for the leaf. If the function returns true then the leaf was located down the front tree of the node so we can also return FRONT_OWNER. If the function did not return true then we were unable to locate the leaf in the front tree so we will have to search the back tree of the node instead.

```
    else
    {
        if (FindLeaf( Leaf, CurrentNode->Front )) return FRONT_OWNER;
    } // End If
```

Provided that the node's Back member is non negative it means a child node exists there so we should traverse down the back tree of the node searching for the leaf using the FindLeaf function once again. If the function returns true the leaf was located in the back tree which means this is the leaf that exists in the back space of the portal thus we return BACK_OWNER. If none of these cases are true then it means the portal fragment obviously landed in a leaf that is not beneath the portal's owner node in the tree and as such is obviously a rogue fragment that should be deleted. When this is the case we reach the bottom of the function where NO_OWNER is returned.

```
    if ( CurrentNode->Back >= 0 )
    {
        if (FindLeaf(Leaf, CurrentNode->Back )) return BACK_OWNER;
    } // End If

    return NO_OWNER;
}
```

When NO_OWNER is returned from this function back to the ClipPortal method, the portal fragment is deleted.

FindLeaf - CProcessPRT

This is the recursive leaf searching function that was called from the previously discussed function to search for a given leaf down a given sub-tree. As we saw in the previous function, the first parameter to this function is where the index of the leaf we wish to search for should be passed. The second parameter is where the index of the node we would like to start searching from should be passed. As we saw in the previous function, this is the back or front child of the portal's owner node for which the leaf search is being performed.

The function first uses the passed node index to fetch the relevant node structure from the tree's node array.

```
bool CProcessPRT::FindLeaf( unsigned long Leaf, unsigned long Node )
{
    CBSPNode * CurrentNode = NULL;

    // Validate Requirements
    if (!m_pTree) throw BCERR_INVALIDPARAMS;
    if (!(CurrentNode = m_pTree->GetNode( Node ))) throw BCERR_BSP_INVALIDTREEDATA;
```

If a leaf exists down the front of this node then we test to see if that leaf has the same index as the leaf we are searching for. If so, we have found our leaf so we return true.

```
    // Check to see if the front is this leaf
    if ( CurrentNode->Front < 0 )
    {
        if ( abs(CurrentNode->Front + 1) == Leaf ) return true;
    }
```

If a leaf does not exist down the front of the current node we are visiting but a child node exists there instead, we will recur down the front tree of this node searching for the leaf.

```
    else
    {
        if (FindLeaf( Leaf, CurrentNode->Front )) return true;
    } // End If
```

If we get this far then it means the leaf could not be found down the front tree of the current node so we will search the back tree of the current node instead and return true if it is located.

```
    // Iterate down the back if it's a node
    if ( CurrentNode->Back >= 0 )
    {
        if (FindLeaf( Leaf, CurrentNode->Back )) return true;
    } // End If

    return false;
}
```

If we reach the bottom of the function without returning true then it means the leaf could not be found down the front and back tree of the current node so we return false.

Portal Generation Conclusion

This completes our coverage of the portal generation module and as we have seen, it is implemented via a handful of functions. We have also seen that all our CCompiler object had to do was invoke the CProcessPRT::Process method to populate the BSP with portal data.

We are at the mid-way point in this lab project having implemented one of the two modules necessary to add potential visibility set calculation to our compiler application. In the next section we will discuss the implementation of the CProcessPVS class which uses the portal data now present in the tree to perform the final calculation of the PVS data. It should be noted that the portal generation module must be enabled for the PVS calculation module to work. As the PVS calculation module can not possibly perform its task with our portal data being present in the tree, the module will terminate immediately if no portal data is found to be present in the BSP tree.

The PVS Calculator

It is crucial that you have read the PVS section in the accompanying text book before continuing with this section of the work book. In this section we will not re-cover the theory of PVS calculation and anti-penumbra generation and clipping. It is assumed you have read and understood the text book and are now interested in seeing how this technique pertains to this particular application and our application structures and classes.

Our PVS calculator is contained in the module CProcessPVS. It is this module's Process method which is called from CCompiler post portal generation. The PVS calculation module itself has all its data and structures contained in the project source files ProcessPVS.h and ProcessPVS.cpp.

In ProcessPVS.h we have a compiler define named PVS_COMPRESSDATA which can be set to zero or one to control whether the resulting PVS data should be zero run length encoded by the PVS generation module prior to being stored in the BSP tree.

```
#define PVS_COMPRESSDATA        1       // 1 = ZRLE Compress, 0 = Don't Compress
```

By default we set this to 1 and it is unlikely that you will want to change this. PVS data sets for complex levels can be quite large if no compression is used and while memory is fairly abundant on today's end user systems, we do not want to waste it considering the typical huge number of other resources that may have to be stored. Also, we discussed in the text book how zero run length encoding our data actually helps speed up the rendering of a given leaf's PVS by allowing us to skip past entire runs of non-visible leaves with a single byte increment of the PVS data pointer.

Before we examine the code to the CProcessPVS module, there are several support structures used by this process that we must first discuss. For example, we know that the two-way portals stored in the BSP tree will have to be duplicated into a number of one way portal structures that have added member variables that pertain to the PVS calculation process. We also discussed in the text book how in order to reduce memory allocation and fragmentation during the recursive clipping process, each of these portals will have the ability to share its underlying geometry with other portals.

The CPVSPortal Class

The CPVSPortal class is the object that will be used to store the one way portals used by the PVS calculation module. For each original two-way portal stored in the BSP tree at the end of the portal generation process, two CPVSPortal objects will be created. Each of the two one-way portals will share and represent the same geometry of the two-way portal from which they were cloned but each will point into an opposing half space. In the text book we had a section devoted to the need for us having a strict portal flow during the PVS clipping process and that is what these one-way portals provide us.

Each one-way portal which is temporarily generated for the PVS calculation module stores much more additional information than a normal two-way portal it was cloned from. We have to store in that portal the index of its neighbor leaf. The neighbor leaf is the leaf in which the one-way portal does not reside but has its normal facing into. That is to say, a one-way portal's visibility flows out from its owner leaf

into the neighbor leaf. We will also need to store in the one-way portal the visibility bit sets that are being compiled for that portal. Recall from the text book, that the PVS for the tree is actually generated by first calculating the PVS of each portal. Therefore, each of these portals will need to have a member where we can store its PVS. Each leaf's PVS is then calculated by simply accumulating the visibility information of each portal that resides within that leaf.

The CPVSPortal structure is shown below followed by a description of its members.

Excerpt from CPVSPortal.h

```
class CPVSPortal
{
public:
    // Constructors / Destructors for this Class
              CPVSPortal( );
    virtual ~CPVSPortal( );

    // Public Variables for This Class
    UCHAR             Status;               // The compilation status of this portal
    UCHAR             Side;                 // Which direction does this portal point
    long              Plane;                // The plane on which this portal lies
    long              NeighbourLeaf;        // The leaf into which this portal points
    long              PossibleVisCount;     // The size of the PossibleVis array
    UCHAR            *PossibleVis;          // "Possible" visibility information
    UCHAR            *ActualVis;            // "Actual" visibility information
    bool              OwnsPoints;           // Does this own the points ??
    CPortalPoints    *Points;               // The vertices making up this portal

};
```

UCHAR Status;

This member is used to store the current status of the portal. This allows us to determine whether this portal has had its PVS calculated yet, whether it is still waiting to have its PVS calculated or whether it is currently in the process of having its visibility information calculated. During the calculation of the PVS, each portal can be set to one of the following #defines from the file CProcessPVS.h

Excerpt from CProcessPVS.h

```
#define PS_NOTPROCESSED     0       // Portal has not yet been processed
#define PS_PROCESSING       1       // Portal is currently being processed
#define PS_PROCESSED        2       // Portal has been processed
```

These status flags are used in a number of places. Firstly, as the PVS calculation process is one of essentially looping through each portal and calculating its PVS, we need to know which portals have been processed already so that we do not try and calculate its PVS more than one. Now this would not be necessary if we were to simply loop through the array of one-portals and calculate the PVS for each one in that order however, as discussed in the text book, the PVS calculator can be speeded up slightly by processing less complex portals first. That is, portals which have a lower 'Possible Visibility Count'. The possible visibility count is calculated prior to the core clipping process and describes the number of leaves that had the potential to be visible as determined by a simple flood fill. By choosing portals with the lowest possible visibility count first and which have not yet be processed (obviously), we have a situation where during the main clipping process, the calculation time of visibility information for more complex portals can be reduced by using the PVS already calculated for each of the lesser complex

portals it can see. There will only ever be one CPVSPortal with a status of PS_PROCESSING at any one time during the PVS calculation procedure.

long Plane;
In this member we will store the index of the plane in the BSP tree's plane array on which the portal was created. This is the index of the owner node of the two way portal from which this portal was cloned. As two one-way portals will be generated from a single two-way portal, both of these portals will share the same plane index. It might seem strange that these two one-way portals would share the same plane when they face into opposing half spaces of that plane but we will see that it is precisely for this reason the 'Side' member of this structure (discussed next) is used.

The plane is stored in the one-way portal because it will be needed for clipping. For example, we discussed in the text book how if during the core clipping process the generator portal is found to span the source portal's plane, the generator portal should be clipped to that plane such that any fragment of the generator portal that lay in the back space of that plane is discarded. This helps narrow the anti-penumbra and is also more vital than a simple optimization. If this was not done then when we recur through that generator portal such that it becomes the target portal in the next recursion, the anti-penumbra generated could become twisted or inverted causing erroneous clipping and endless recursive loops to be formed.

The problem one might see at the moment is that both the one-way portals duplicated from a single two-way portal share the same plane while the portals themselves are pointing into opposing half spaces of that plane. Therefore, this would only work correctly for the one-way portal that shares the same front space with the plane. For the other one-way portal, clipping the generator portal to its plane would actually remove the section of the generator portal that is in the front space of the portal instead of in its back space. This would obviously be completely incorrect which is why the 'Side' member (discussed next) is used. The Side member tells the PVS processing module on which side of the plane the portal's normal is assumed to be pointing into. If the Side member indicates that the one-way portal is actually pointing into the opposing half space of its stored plane, then the plane is flipped temporarily on the fly prior to the clip being performed such that in both cases, we always remove the section of the generator portal that is in the back space of the portal.

UCHAR Side;
As discussed above, this member is used to indicate whether the portal is pointing into the same front space as its stored node plane. If this member is set to FRONT_OWNER then it is and any generator portals can be clipped against this plane without any problems. As polygon clipping functions typically remove the polygon fragment that lay in the back space of the plane, this is correct and the fragment of the generator portal that lay in the back space of the portal will be discarded. If this member is set to BACK_OWNER then it means the stored node plane is actually facing into the opposing half space to that of the plane normal and as such, the plane direction will need to be flipped prior to the clip.

long NeighbourLeaf;
This member stores the index of the leaf that the portal flows into. As discussed in the text book, portal visibility flow happens from a source leaf, through the back of its contained portals and into their neighbor leaves. This stores the neighbor leaf of the portal; the leaf that you will arrive in if you step through the back of the portal from its owner leaf.

UCHAR *PossibleVis;

To optimize the core clipping process as much as possible, prior to the main anti-penumbra clipping processor being invoked, a very approximate PVS will be calculated using a simple flood fill technique controlled by the rules of one-way portal flow. This process will be very quick to perform and will generate a leaf visibility bit set for each portal. Any bits set to zero in this bit set represent leaves that could not possibly ever be visible from the portal and as such, we know during the core clipping process not to visit these leaves unnecessarily and perform wasteful expensive clipping operations to essentially arrive at a non visible result.

After the portal flow procedure has been perform for this portal (prior to the core clipping procedure being invoked for this portal), this unsigned char pointer will point to an array of bytes that contain the 'Possible' visibility set for the portal. Each bit in the array will represent a leaf and as such, each byte element in this array represents the visibility information for eight leaves with respect to this portal. This visibility set will be very approximate and vastly over generous but will help optimize the core recursive clipping procedure.

> **Note**: We discussed earlier how one of the compile time options for our CProcessPVS module is the PVSOPTIONS::FullCompile Boolean. If set to false, our PVS calculator will not bother performing the core clipping procedure at all and will simply return the PVS data based into the possible visibility information stored in this byte array for each portal. That is, the PVS calculated for each leaf will be the accumulation of the PossibleVis arrays of each portal contained in that leaf. While this will generate an very over generous PVS with very approximate visibility, it will compile extremely quickly which might be useful during development time when you wish to test the compiler but not wait hours for the compiler to calculate the actual potential visibility set.

long PossibleVisCount;

This member will be calculated during the initial flood of this portal and the calculation of its PossibleVis array. It will describe the number of possibly visible leaves. That is, the number of bits in the PossibleVis array that have been set to 1. As discussed a moment ago, to speed up compilation we will wish to calculate the PVS for the least complex portals first. This member describes the portals complexity and therefore, describes the order in which it should be chosen for full PVS calculation. The lower this number, the earlier in the process this portal will be chosen to have its PVS calculated.

UCHAR *ActualVis;

The job of the core clipping process of this module is to take the PossibleVis array of a portal and refine it using anti-penumbra clipping to generate the tightest potential visibility set possible. The resulting (actual) PVS for the portal will be stored in this array. That is, after this portal has been processed, the ActualVis array will contain the 'real' visibility information for this portal and the visibility information that will ultimately contribute to its owner leaf's PVS at the end of the process.

CPortalPoints *Points;

This member is of a type we have not yet discussed. The CPortalPoints structure is a specialized structure derived from CPolygon and as such is actually used to store the geometry of the portal itself. We can think of the CPortalPoints class as being a CPolygon object with a few extra member variables that pertain to the PVS clipping process.

bool OwnsPoints;
To save memory, we try to maximize the re-use of geometry among the portals. For example, we know that when we generate two one-way portals from a two-way portal that it would be a waste to allocate two CPortalPoints objects for each one-way portal. These polygons and their geometry will essentially be exactly the same as each other and will contain the exact same vertex data. Therefore, we can allocate one CPortalPoints structure (remember this is just a CPolygon derived object) and can have both one-way portals point at it. Therefore, in order to make sure that when each one-way portal is deleted we do not try and delete this shared CPortalPoints structure twice, only one of the one-way portals will have its OwnsPoints set to true. This will be assumed to be the portal that owns the structure and the one that will take care of releasing it when it is deleted. When the other one-way portal is deleted, which has this member set to false, it will not attempt to delete the CPortalPoints structure that it references as it knows that another object will handle its clean up.

Let us now have a look at the methods of this one way portal class for which there is only a constructor and a destructor.

Constructor - CPVSPortal

The constructor simply initializes all members to zero, NULL or false and sets the status of this portal to its default state of PS_NOTPROCESSED. That is, this portal has not yet had its PVS data (ActualVis array) calculated.

```
CPVSPortal::CPVSPortal()
{
    // Initialise any class specific items
    Status              = PS_NOTPROCESSED;
    Plane               = -1;
    NeighbourLeaf       = -1;
    PossibleVisCount    = 0;
    PossibleVis         = NULL;
    ActualVis           = NULL;
    Points              = NULL;
    OwnsPoints          = false;
}
```

Destructor - CPVSPortal

The destructor is simple also but sheds some light on the OwnsPoints member that we discussed a moment ago.

The portal contains three possible memory allocations that it may be responsible for releasing. If its ActualVis and PossibleVis arrays have been allocated then they will need to be deleted. Also, if this portal is the owner of the CPortalPoints object that it references then it should deleted that too.

```
CPVSPortal::~CPVSPortal()
{
    // Clean up after ourselves
    if (ActualVis && PossibleVis != ActualVis) delete []ActualVis;
    if (PossibleVis) delete []PossibleVis;
    if (Points && OwnsPoints ) delete Points;

    // Empty pointers
    PossibleVis = NULL;
    ActualVis   = NULL;
    Points      = NULL;
}
```

As you can see in the above code, we only release the CPortalPoints object if the portal's OwnsPoints Boolean is set to true.

Let us now look at the CPortalPoints object which is derived from CPolygon and contains the actual geometry of the portal referenced by this CPVSPortal object.

The CPortalPoints Class

The CPortalPoints class essentially encapsulates a portal polygon. It is derived from CPolygon and as such inherits its geometry members and methods. This class adds some of its own members and implements its own versions of the Split and Clip functions. Once again, do not worry we do not have to write polygon splitting and clipping functions all over again. These functions are simple wrappers around their base class counterparts that facilitate the copying of the extra data into the child polygons resulting from the split/clip.

This class is declared in CProcessPRT.h and is shown below. It will be followed by a discussion of its members and an examination of its member functions.

```
class CPortalPoints : public CPolygon
{
public:

    // Constructors / Destructors for this Class
             CPortalPoints( );
             CPortalPoints( const CPolygon * pPolygon, bool Duplicate = false );
    virtual ~CPortalPoints( );

    // Public Functions for This Class
    CPortalPoints *     Clip( const CPlane3& Plane, bool KeepOnPlane );
    virtual HRESULT     Split( const CPlane3& Plane,
                               CPortalPoints * FrontSplit,
                               CPortalPoints * BackSplit);

    // Public Variables for This Class
    bool                OwnsVertices;           // Do we own the vertices stored here ?
    CPVSPortal         *OwnerPortal;            // Pointer to this points parent portal ;)
};
```

As you can see, we have added only two member variables to that of those inherited from CPolygon.

bool OwnsVertices;
This member is analogous to the OwnsPoints member of the CPVSPortal structure. It allows multiple CPortalPoints structures to share the same underlying vertex data. For example, when two CPVSPortals are first created (from a given two-way portal) we have seen that one CPortalPoints structure is created which is shared by both. Furthermore, as the geometry of this portal is identical to that of the two-way portal stored in the tree, we can simply assign its vertex pointer to the vertex array stored in the two-way portal in the BSP tree. That is, for each one-way portal that we initially create, its CPortalPoints structure will not have allocated its own vertex data but will point to the vertex array of the CBSPPortal from which it was cloned.

This may all sound a little over cautious but it is quite necessary for both the compiler's performance and addressing memory footprint issues. For example, we know that if portal gets clipped then we will have to allocate a new set of vertex data for the child split fragments. There is nothing we can do about that. However, there may be many times during the process where a generator portal does not get clipped at all and as such, we can happily use the vertex data that was originally created for the CBSPPortal version of the portal.

This Boolean lets the CPortalPoints destructor know whether or not the vertex array store here is owed by (was allocated for) this portal specifically (such as if this polygon was the result of a clip operation) or if its vertex pointer is assigned to the vertex array of another object in which case the memory should not be released. As discussed, when each one-way portal is created, each of their CPortalPoints objects will not contain there own vertex data but alias the vertex data stored in the portals of the BSP tree.

CPVSPortal *OwnerPortal;
This member is used to point at the CPVSPortal that owns this object and will be responsible for its clean up. For each pair of one-way portals that we generate, only one of them will own the CPortalPoints structure that they both alias (phew, that is a lot to keep track of).

Constructor - CPortalPoints

There are two constructors for this class. The default constructor simply sets the owner portal pointer to NULL and sets the OwnsVertices Boolean to false by default as shown below.

```
CPortalPoints::CPortalPoints()
{
    // Initialise any class specific items
    OwnsVertices = false;
    OwnerPortal  = NULL;
}
```

The second constructor is a copy constructor that can be used to create and populate a new CPortalPoints object from the data stored in a passed CPolygon object.

The first parameter to the copy constructor is a pointer to the CPolygon we would like this object to copy or alias the vertex data of. The second parameter is a Boolean which specifies whether we would

like this object to allocate its own vertex array and copy the vertex data over from the passed CPolygon, or whether we would like to simply alias the vertex data by assigning the vertex data pointer to point at the vertex array of the passed CPolygon. In the later case, the CPortalPoints object will not own the vertex data and should no delete it within its destructor. We inform the destructor of whether or not the vertex data of this object should be released during object deletion by setting the OwnsVertices member to true or false respectively.

Here is the code:

```
CPortalPoints::CPortalPoints( const CPolygon * pPolygon, bool Duplicate )
{
    // Initialise any class specific items
    OwnsVertices = false;
    OwnerPortal  = NULL;
    if (!pPolygon) return;

    // Store or duplicate verts
    if ( Duplicate )
    {
        // Duplicate the vertices
        if (AddVertices( pPolygon->VertexCount ) < 0) throw BCERR_OUTOFMEMORY;
        memcpy( Vertices, pPolygon->Vertices, VertexCount * sizeof(CVertex) );
        OwnsVertices = true;

    } // End if Duplicate
    else
    {
        // Simply store a copy of the pointer info
        Vertices     = pPolygon->Vertices;
        VertexCount  = pPolygon->VertexCount;
        OwnsVertices = false;

    } // End if !Duplicate
}
```

As you can see, if the Duplicate Boolean parameter is set to true then we do indeed allocate a vertex array for this object and copy over the vertex data from the passed CPolygon. We then set the OwnsVertices member to true which will instruct the destructor to release this memory on object de-allocation. If the Boolean is set to false then we simply copy over the vertex count from the passed polygon and assign the vertex pointer to point at the passed CPolygon vertex array. We also set the OwnsVertices member to false so that we do not try to delete this vertex array on object destruction. These are not our vertices to delete.

Destructor - CPortalPoints

The destructor only deletes the vertex array of the CPortalPoints object if it owns them. That is, if the OwnsVertices Boolean is set to true.

```
CPortalPoints::~CPortalPoints()
{
    // Clean up after ourselves only if required
    if (OwnsVertices) ReleaseVertices();
```

```
    // Simply NULL our vertex values
    Vertices    = NULL;
    VertexCount = 0;
}
```

It will become more apparent why we try to share as much data as possible during the core clipping process.

Split - CPortalPoints

The CPortalPoints object implements it own polygon splitter. As with the base class version of this function it takes three parameters with the first being the split plane. The final two parameters however are now of type CPortalPoints.

As CPortalPoints is derived from CPolygon we can use the base class version of the function to perform that actual splitting of the geometry into the front and back children.

```
HRESULT CPortalPoints::Split( const CPlane3& Plane,
                                    CPortalPoints * FrontSplit,
                                    CPortalPoints * BackSplit)
{
    // Call base class implementation
    HRESULT ErrCode = CPolygon::Split( Plane, FrontSplit, BackSplit );
    if (FAILED(ErrCode)) return ErrCode;
```

As we have created two new polygons by copying over portions of vertex data from the parent polygon, each one will own its own vertices so we must set the OwnsVertices member of both the front and back split (if they exist) to true.

```
    // Copy remaining values
    if (FrontSplit)
    {
        FrontSplit->OwnsVertices = true;
    } // End If

    if (BackSplit)
    {
        BackSplit->OwnsVertices  = true;
    } // End If

    // Success
    return BC_OK;
}
```

As we have seen, this function is a simple wrapper around a call to the base class version of the function with the added logic of making sure that the child split fragments understand that they have had there own unique vertex data generated by the clipping process. This is especially true as we would not want the vertex data of the children to be deleted when the parent polygon is deleted because as we know, one of the first things we do after splitting a polygon into two children is delete the original. Our split routines (as we have seen) will always create polygon fragments that own there own vertex data.

Clip - CPortalPoints

The Clip method simply classifies the polygon represented by this object against the plane passed in as the first parameter and removes the portion of the polygon that is found to be behind the plane. The second parameter indicates whether we would like the polygon to be clipped or kept if it is found to exist on the plane itself. This will be used later during the anti-penumbra clipping process. The function returns a pointer to the new clipped polygon.

First we classify the polygon against the plane and then enter a switch statement that chooses the outcome based on the classification result. Notice at the top of the function how the NewPoints local pointer is allocated. This will be used to point to the clipped fragment and will be the pointer that is returned from the function.

```
CPortalPoints * CPortalPoints::Clip( const CPlane3& Plane, bool KeepOnPlane )
{
    CPortalPoints * NewPoints = NULL;

    try
    {
        // Classify the points
        CLASSIFYTYPE Location = Plane.ClassifyPoly( Vertices, VertexCount, sizeof(CVertex) );

        // What location ?
        switch ( Location )
        {
```

If the polygon is found to be contained in the front space of the plane then nothing is to be clipped. Therefore, we simple assign the NewPoints pointer to point at the current polygon. This means, the method will return a pointer to the CPortalPoints structure for which it was invoked. That is, the object will just return a pointer to itself.

```
            case CLASSIFY_INFRONT:
                // All were in front, simply return this
                NewPoints = this;
                break;
```

If the polygon is found to exist entirely in the back space of the clip plane then the polygon should be totally clipped away. When this is the case we return NULL indicating that none of the polygon should survive. The caller can then choose to delete the object if it so chooses.

```
            case CLASSIFY_BEHIND:
                // Nothing was in front
                NewPoints = NULL;
                break;
```

We will see later when we cover the core clipping function of the PVS calculation how we sometimes want to clip away a polygon even if it is located on the plane. For example, if the generator portal is located on the same plane as the target portal then the target portal can not possibly see through the generator portal and should be completely clipped away.

You can see below that in the on plane case, if the KeepOnPlane Boolean parameter is set to true, we just assign the NewPoints pointer to the ‘this’ pointer allowing the object to return a pointer to itself. Otherwise, we break and NULL will be returned at the bottom of the function signifying to the caller that the portal should be deleted.

```
            case CLASSIFY_ONPLANE:
                // Should we keep the onplane case ?
                if ( KeepOnPlane ) NewPoints = this;
                break;
```

Finally, if the polygon is spanning the plane, we create a new CPortalPoints object which is passed into the Split function to retrieve the front fragment. NULL is passed as the back split as we do not wish to retrieve the back fragment of the polygon as this is the fragment that should be discarded.

```
            case CLASSIFY_SPANNING:

                // Allocate a new set of points
                NewPoints = new CPortalPoints;
                if (!NewPoints) throw std::bad_alloc();

                // Clip the current portal points
                if ( FAILED(Split( Plane, NewPoints, NULL ))) throw BCERR_OUTOFMEMORY;
                break;

        } // End Switch

    } // End try block

    catch (...)
    {
        return NULL;

    } // End catch block

    // Success!!
    return NewPoints;
}
```

The CProcessPVS Class

With the initial support structures covered, we will now look at the code to the CProcessPVS module. It is declared in ProcessPVS.h and is shown below. First four public methods of the object's interface should be familiar as they form the method set common to all our modules. They include the Process method that is called by CCompiler to invoke the PVS calculator module and the methods to set the modules Logger, parent and options. There are also two additional public methods called 'GetPVSPortalCount' and 'GetPVSPortal' which can be used to fetch the one-way portal information stored in the module. There are also many private functions which are used by the Process method to accomplish its task which we will examine in a moment.

```
class CProcessPVS
{
public:
    // Constructors & Destructors for This Class.
             CProcessPVS();
    virtual ~CProcessPVS();

    // Public Functions for This Class.
    HRESULT         Process( CBSPTree * pTree );
    void            SetOptions( const PVSOPTIONS& Options ) { m_OptionSet = Options; }
    void            SetLogger ( ILogger * pLogger )         { m_pLogger = pLogger; }
    void            SetParent ( CCompiler * pParent )       { m_pParent = pParent; }

    unsigned long   GetPVSPortalCount( ) const
                               { return (unsigned long)m_vpPVSPortals.size(); }

    CPVSPortal     *GetPVSPortal( unsigned long Index ) const
                               { return (Index < m_vpPVSPortals.size()) ?
                                         m_vpPVSPortals[Index] : NULL; }

private:
    // Private Functions for This Class.
    HRESULT         GeneratePVSPortals( );
    HRESULT         InitialPortalVis( );
    HRESULT         CalcPortalVis( );
    void            PortalFlood( CPVSPortal * SourcePortal,
                                 unsigned char PortalVis[],
                                 unsigned long Leaf );

    HRESULT         ExportPVS( CBSPTree * pTree );

    void            GetPortalPlane( const CPVSPortal * pPortal, CPlane3& Plane );

    ULONG           CompressLeafSet ( UCHAR MasterPVS[],
                                      const UCHAR VisArray[],
                                      ULONG WritePos);

    ULONG           GetNextPortal();

    HRESULT         RecursePVS( ULONG Leaf, CPVSPortal * SourcePortal, PVSDATA & PrevData );

    CPortalPoints * ClipToAntiPenumbra( CPortalPoints * Source,
                                        CPortalPoints * Target,
                                        CPortalPoints * Generator,
                                        bool ReverseClip );

    // Private Static Functions for This Class.
```

```
    static CPortalPoints *  AllocPortalPoints( const CPolygon * pPolygon, bool Duplicate );
    static bool             GetPVSBit( UCHAR VisArray[], ULONG DestLeaf );
    static void             SetPVSBit( UCHAR VisArray[], ULONG DestLeaf, bool Value = true );
    static void             FreePortalPoints( CPortalPoints * pPoints );

    // Private Variables for This Class.
    PVSOPTIONS      m_OptionSet;        // The option set for PVS Compilation.
    ILogger        *m_pLogger;          // Logging interface used to log progress etc.
    CCompiler      *m_pParent;          // Parent Compiler Pointer

    CBSPTree       *m_pTree;            // The tree used to compile the PVS.
    ULONG           m_PVSBytesPerSet;   // Number of Bytes required to
                                        // describe a single leaf's visibility
    vectorPVSPortal m_vpPVSPortals;     // Vector storage of pointers to CPVSPortal objects
};
```

We will first examine the member variables of this object before examining each of its methods.

PVSOPTIONS m_OptionSet;
This member holds the compilation options for the PVS module and is set by CCompiler via the CProcessPVS::SetOptions method. We looked at this structure earlier and saw that it contained members to instruct the module to either do a full or fast compile (where fast simply use the PossibleVis array and does not perform the anti-penumbra clipping procedure) and describes the number of anti-penumbra clip tests (1 to 4) that should be carried out for each Source/Generator portal combination encountered during the recursive clipping procedure.

ILogger *m_pLogger;
This member will point to the logging object whose interface will be used by this module to output status reports and compilation errors or warnings. This is set by the CCompiler object prior to the Process function being called via the CporcessPVS::SetLogger method.

CCompiler *m_pParent;
This member is set by the CCompiler object via the CProcessPVS::SetParent method. It stores a pointer to the CCompiler object that invoked it.

CBSPTree *m_pTree;
This member points to the BSP tree that is having its PVS data calculated and that contains the portal information generated by the previously discussed module. This pointer is set by CCompiler via the parameter to the CProcessPVS::Process method.

ULONG m_PVSBytesPerSet;
This member will be calculated by this module at the start of the Process method and will contain the number of bytes needed to store the visibility information for a single leaf. As each byte contains 8 bits a single byte will contain the information for 8 leaves.

vectorPVSPortal m_vpPVSPortals;
This is an STL vector will store CPVSPortal structures. It is in this vector that the pointers of all the one-way portals generated by this module will be stored.

Constructor - CProcessPVS

The constructor of this module simply initializes all members to zero or NULL.

```
CProcessPVS::CProcessPVS()
{
    // Reset / Clear all required values
    m_PVSBytesPerSet    = 0;
    m_pLogger           = NULL;
    m_pTree             = NULL;
    m_pParent           = NULL;
}
```

Destructor - CProcessPVS

The destructor of this object must release the one-way portals (CPVSPortal structures) that it allocated to complete its task and must also empty the vector that contained these pointers.

```
CProcessPVS::~CProcessPVS()
{
    ULONG i;

    // Clean up after ourselves
    for ( i = 0; i < GetPVSPortalCount(); i++ ) if ( GetPVSPortal(i) )
                                                    delete GetPVSPortal(i);

    // Clear Vectors
    m_vpPVSPortals.clear();
}
```

AllocPortalPoints - CProcessPVS

There will be many times throughout the PVS calculation process that we will need to allocate new CPortalPoints object. In keeping with the allocation strategy we have used for other modules, this function can be used to allocate a new object of this type. The function simply wraps the allocation call.

The function takes two parameters. The first is a pointer to the CPolygon object (or derived object) that has the geometry we would like this new CPortalPoints object to represent and the second parameter is a Boolean that specifies whether we would like the CPortalPoints structure to copy the polygon data into its own vertex array or simply alias it. These parameters are simply passed into the CPortalPoints copy constructor which we have already covered.

```
CPortalPoints * CProcessPVS::AllocPortalPoints( const CPolygon * pPolygon, bool Duplicate )
{
    CPortalPoints * NewPoints = NULL;

    try
    {
        // Attempt to allocate a new set of points
```

```
        NewPoints = new CPortalPoints( pPolygon, Duplicate );
        if (!NewPoints) throw std::bad_alloc();

    } // End try block

    catch (HRESULT)
    {
        // Constructor throws HRESULT
        if (NewPoints) delete NewPoints;
        return NULL;

    } // End Catch

    catch ( std::bad_alloc )
    {
        // Failed to allocate
        return NULL;

    } // End Catch

    // Success!!
    return NewPoints;
}
```

FreePortalPoints - CProcessPVS

This module also has a method that can be used to free a CPortalPoints structure. It takes a single parameter, a pointer to the CPortalPoints structure that is to be released.

```
void CProcessPVS::FreePortalPoints( CPortalPoints * pPoints )
{
    // Validate Parameters
    if (!pPoints) return;

    // We are only allowed to delete NON-Owned point sets
    if ( pPoints->OwnerPortal == NULL ) delete pPoints;
}
```

Notice that this method will only physically delete the CPortalPoints object if it is not owned by a parent portal. If it is owned by a portal then the portal should be responsible for its clean up inside the portals destructor.

SetPVSBit - CProcessPVS

There will be several times throughout the PVS compilation procedure when we will need to set or clear a bit in a given portal's visibility bit set (be that its ActualVis array or its PossibleVis array). This method is a utility method that allows us to pass a bit set, a leaf whose visibility bit is to be altered in that set and a Boolean describing whether that leaf's bit should be set or cleared in the passed bit set. The function wraps calculating the bit that needs to be set in the passed bit array and setting that bit accordingly.

```
void CProcessPVS::SetPVSBit( UCHAR VisArray[], ULONG DestLeaf, bool Value /* = true */ )
{
    // Set / remove bit depending on the value
    if ( Value == true )
    {
        VisArray[ DestLeaf >> 3 ] |=  (1 << ( DestLeaf & 7 ));
    }
    else
    {
        VisArray[ DestLeaf >> 3 ] &= ~(1 << ( DestLeaf & 7 ));

    } // End if Value
}
```

The bit shifting logic is explained in the text book so refer back if you are feeling a little rusty. Recall that DestLeaf>>3 just divides it by eight which tells us the byte in which this leaf's visibility bit resides. By ANDing the leaf index with 7 (binary 00000111) we also get the bit within that byte that needs to be set (0 through 7). Therefore, we can shift a value of one by this amount to create a byte that has only that bit set (or unset) and then OR it with the byte in the bit set to toggle that leaf's bit on or off.

GetPVSBit - CProcessPVS

We also have a function that uses the same bit shifting logic to retrieve the visibility status of a leaf in the passed bit set.

```
bool CProcessPVS::GetPVSBit( UCHAR VisArray[], ULONG DestLeaf )
{
    return (VisArray[ DestLeaf >> 3 ] & (1 << ( DestLeaf & 7))) != 0;
}
```

With these utility functions out of the way, let us now look at the function that makes it all happen. The CProcessPVS::Process method.

Process - CProcessPVS

This function is the parent function of the PVS calculation process that calls the various sub-processes in order to calculate the final PVS for the passed BSP tree. We will look at the code a section at a time.

The first thing we do in this function is test that the passed tree has portal data generated for it. If this is not the case we return immediately as we can not possibly calculate PVS data for this tree. Otherwise, we copy the passed BSP tree pointer into the module's member variable.

```
HRESULT CProcessPVS::Process( CBSPTree * pTree )
{
    HRESULT hRet;

    // Validate values
    if (!pTree) return BCERR_INVALIDPARAMS;

    // Validate Input Data
    if ( pTree->GetPortalCount() == 0 ) return BCERR_BSP_INVALIDTREEDATA;
```

```
    // Store tree for compilation
    m_pTree = pTree;
```

The next thing we do is calculate the module's m_PVSBytesPerSet member such that it describes the number of bytes needed to hold the visibility bit set for a single leaf. As discussed in the text book, although there are 8 bits per byte with each bit representing a leaf's visibility, we can not just divide the total leaf count of the tree by 8 to calculate this size. If we did it would erroneously calculate the number of bytes to be allocated to store a 9 leaf tree as 9/8 = 1 (integer math). As we know, we would actually need two bytes to represent this information with the first 8 leaves having their bits in byte one and the 9^{th} leaf with its bit in the first position in byte 2. Therefore, to cope with the integer truncation we add 7 to the leaf count first and then divide this by 8. Therefore, if we had a 9 leaf tree, the number of bytes we would need to represent a bit for each leaf would be (9+7)/8 = 16/8=2.

```
    // Calculate Number Of Bytes needed to store each leafs
    // vis array in BIT form (i.e 8 leafs vis per byte uncompressed)
    m_PVSBytesPerSet = (pTree->GetLeafCount() + 7) / 8;
```

For reasons that will become clear in the core clipping process we also wish to pad this size to the nearest four byte boundary. This will allow us to access the visibility byte arrays using a long pointer and iterate through 4 bytes (32 leaves) at a time. For example, imagine that we allocated three bytes and then tried to write to the first byte with a four-byte pointer (long *). In this case, we would accidentally write to the fourth byte, overstepping the bounds of the array and writing to invalid memory. Therefore, if we need 22 bytes, we will allocate 24 bytes instead; the two bytes at the end will serve as padding only and will never be used by us.

```
    // 32 bit align the bytes per set to allow for our early out long conversion
    m_PVSBytesPerSet = (m_PVSBytesPerSet * 3 + 3) & 0xFFFFFFFC;
```

This m_PVSBytesPerSet member now describes the size that we will need to allocate each portal's PossibleVis and ActualVis arrays later in the process. These arrays will be padded with extra unused bytes at the end of the array if necessary to make sure we can access the array four bytes at a time without overflowing the array. The remainder of the function calls four member functions and clearly shows the four sub-process involved in generating the PVS data for the tree.

First we call the GeneratePVSPortals method. This is the method that will fetch each two-way portal from the tree and will generate two one-way CPVSPortal structures from it. It is the CPVSPortals that will be used by the PVS calculator to control flow visibility as we recur through the level.

```
    // Retrieve all of our one way portals
    hRet = GeneratePVSPortals();
    if ( FAILED( hRet ) ) return hRet;
    if ( m_pParent->GetCompileStatus() == CS_CANCELLED ) return BC_CANCELLED;
```

After the above function returns, this object's m_vpPVSPortals vector will be filled with all the one-way portals needed to perform PVS calculation. Because of their one-way nature, there will be twice as many CPVSPortals in this array as there are CBSPPortals stored in the BSP tree.

With the one-way portals generated, next we call the InitialPortalVis function. It is this function that will perform the initial flood fill through the level and calculate the PossibleVis array for each portal. You will recall that the PossibleVis array stored in each portal is a very approximate leaf visibility array for that portal which will be used to speed up the core clipping process when the portal's ActualVis array is calculated.

```
    // Calculate initial portal visibility
    hRet = InitialPortalVis();
    if ( FAILED( hRet ) ) return hRet;
    if ( m_pParent->GetCompileStatus() == CS_CANCELLED ) return BC_CANCELLED;
```

When the above function returns each CPVSPortal will contain its PossibleVis array of approximate leaf visibility information. Next we enter the core clipping process with a call to CalcPortalVis. This function is the function that will calculate the ActualVis array for each portal. That is, the function that will generate the leaf visibility information for each portal, the portals' PVS.

```
    // Perform actual full PVS calculation
    hRet = CalcPortalVis();
    if ( FAILED( hRet ) ) return hRet;
    if ( m_pParent->GetCompileStatus() == CS_CANCELLED ) return BC_CANCELLED;
```

At this point in the function the PVS for each portal will have been calculated so we next call the ExportPVS method. This method will use the portal PVS's to calculate the PVS for each leaf in the tree. Recall that a leaf's PVS is simply the accumulation of the PVS's of each portal residing in that leaf. After the PVS for each leaf has been calculated this information will be compressed and stored in the BSP tree in a single byte array. The leaves of the tree will also have their PVSIndex members pointing to the correct location in this array describing the starting location of the leaf's visibility information within the final PVS data block.

```
    // Export the visibility set to the final BSP Tree master array
    hRet = ExportPVS( pTree );
    if ( FAILED( hRet ) ) return hRet;
    if ( m_pParent->GetCompileStatus() == CS_CANCELLED ) return BC_CANCELLED;

    // Success
    return BC_OK;
}
```

After the ExportPVS method returns, all that is left to do is return from the function as the PVS information has been calculated, optionally compressed using zero run length encoding and stored in the BSP tree. Our module at this point has completed its task and can return program flow back to CCompiler.

> **Note:** Recall that after the PVS module has returned after completing its process, CCompiler will then activate the T-junction repair module as a final step before saving the BSP tree out to disk in the form of an IWF file.

We will now cover the methods called from the above function in order and get a real understanding of where and when everything happens throughout the PVS calculation process. The first function to be called is the GeneratePVSPortals method so we will examine the code to this function first.

GeneratePVSPortals - CProcessPVS

This method has a very simple task. It has to loop through each CBSPPortal (two-way portal) stored in the BSP tree and generate two CPVSPortals (one-way portals) for it. Each one-way portal will have a different neighbor leaf selected from the two leaves in which the two-way portal resides. This will dictate the direction in which the one-way portals are assumed to facing.

The first section of the code fetches the number of portals stored in the BSP tree. We then set up a loop to allocate twice this many CPVSPortals and store their pointers in the CProcessPVS::m_vpPVSPortals vector.

```
HRESULT CProcessPVS::GeneratePVSPortals( )
{
    ULONG i, p, PortalCount = m_pTree->GetPortalCount();

    // Allocate enough PVS portals to store one-way copies.
    try
    {
        m_vpPVSPortals.resize( PortalCount * 2 );
        for ( i = 0; i < PortalCount * 2; i++ )
        {
            // Allocate a new portal
            m_vpPVSPortals[i] = new CPVSPortal;
            if (!m_vpPVSPortals[i]) throw std::bad_alloc();

        } // Next Portal

    } // Try vector ops

    // Catch Failures
    catch (...)
    {
        return BCERR_OUTOFMEMORY;

    } // End Catch
```

At this point we have allocated the correct number of one-way portals and have their pointers stored in the module's one-way portal vector. However, these portals are still un-initialized as we have not yet populated them with geometry.

In the next step we will loop through each of the portals we just calculated two at a time. We process the one-way portals in pairs in the following loop as each pair of one-way portals is a child (to use the term very loosely) of a single one-way portal in the BSP tree. So you can see that we set up the following loop to step through the one-way portal list two portals at a time. Heee is the first section of the loop code.

```
    // Loop through each portal, creating the duplicate points
    for ( i = 0, p = 0; i < PortalCount; i++, p+=2 )
    {
        // Retrieve BSP Portal for easy access
        CBSPPortal * pBSPPortal = m_pTree->GetPortal(i);
```

```
        CPortalPoints *pp = AllocPortalPoints( pBSPPortal, false );
        if ( !pp ) return BCERR_OUTOFMEMORY;
```

Inside the loop we fetch a pointer to the original two-way portal from the BSP tree whose geometry we are going to copy/alias using the pair of one-way portals we are currently processing. pBSPPortal points to the original portal in the BSP tree which we will use to set up two one-way portals. We then allocate a new CPortalPoints object. Remember, this is the polygon that will be stored in the two CPVSPortals we are about to populate.

Notice how we clone the CPortalPoints object from the BSP portal. Although we are creating two one way portals, we only need to create one CPortalPoints objects as each one-way portal will share the same physical polygon data. Only one of the CPVSPortals we are about to populate will actually own the CPortalPoints structure and will be responsible for deleting it within its destructor. The other CPVSPortal object will simply reference it.

Another important point to notice is how we also pass false into the copy constructor so that the CPortalPoints object does not have its own array of vertex data allocated, but simply aliases the vertex array stored in the original BSP portal. Therefore, we will create two CPVSPortal structures that share the same CCPortalPoints object and that CPortalPoints object will share its vertex data with the original BSP portal. It is clear then that the two CPVSPortals we are about to populate share the same vertex data, the vertex data in the original BSP polygon.

Here is the remainder of the loop (and the function) that sets up each CPVSPortal which we discuss beneath it.

```
        // Create link information for front facing portal
        m_vpPVSPortals[p]->Points        = pp;
        m_vpPVSPortals[p]->Side          = FRONT_OWNER;
        m_vpPVSPortals[p]->Status        = PS_NOTPROCESSED;
        m_vpPVSPortals[p]->Plane         = m_pTree->GetNode( pBSPPortal->OwnerNode )->Plane;
        m_vpPVSPortals[p]->NeighbourLeaf = pBSPPortal->LeafOwner[ FRONT_OWNER ];
        m_vpPVSPortals[p]->OwnsPoints    = true;

        // Store owner portal information (used later)
        pp->OwnerPortal = m_vpPVSPortals[p];

        // Create link information for back facing portal
        m_vpPVSPortals[p + 1]->Points   = pp;
        m_vpPVSPortals[p + 1]->Side     = BACK_OWNER;
        m_vpPVSPortals[p + 1]->Status   = PS_NOTPROCESSED;
        m_vpPVSPortals[p + 1]->Plane    = m_pTree->GetNode( pBSPPortal->OwnerNode )->Plane;

        m_vpPVSPortals[p + 1]->NeighbourLeaf = pBSPPortal->LeafOwner[ BACK_OWNER ];
        m_vpPVSPortals[p + 1]->OwnsPoints    = false;

    } // Next Portal

    // Success!!
    return BC_OK;
}
```

Notice how each one-way portal we populate points to the same CPortalPoints structure but only the first portal we create has its OwnsPoints Boolean set to true. The first one-way portal is therefore the owner of the polygon itself and is responsible for the cleanup of that polygon in its destructor.

Notice also that because we know that the BSP portal has the index of the leaf in its front space stored in element zero (FRONT_OWNER) in its LeafOwner array and the leaf that is located in its back space located in element 1 (BACK_OWNER) in the portal's LeafOwner array, we can easily set up portals that correctly point into the relevant neighbor leaves. For example, the first portal we set up is assigned the Side value of front owner which means we intend this portal to be the one that faces in the same direction as the owner node's plane. When this is the case we know that its neighbor leaf (the leaf its normal should point into should a normal actually exist) is in the front space of the node plane and as such, we assign to its NeighborLeaf member the leaf index stored in the BSP portal's LeafOwner array at element FRONT_OWNER. Notice that we simply flip this logic to set up the 2nd one-way portal so that its side is set to BACK_OWNER. This means its normal is assumed to flow into the back space of the leaf and thus, it faces in the opposite direction to that of the original node plane.

Finally, notice how we also store the plane of the portal's owner node (the portals plane) in the CPVSPortals. As discussed earlier, although the portals are supposed to be facing in opposing directions we store the same clip plane in both. The Side member will instruct the core clipping process to flip the plane orientation of the back facing portal prior to clipping anything against it. This may seem a little unclear at the moment which is why we will jump ahead temporarily and look at a function that will be used later during the main clipping process, the GetPortalPlane function.

GetPortalPlane - CProcessPVS

This function is used by the PVS calculator when it wishes to retrieve the plane of a CPVSPortal object. This is often required when generator portals need to be clipped against the plane of the source portal and vice versa. As our clip functions will always remove portions of a polygon/portal that lay in the back space of a clip plane, and considering that the two one-way way portals that exist on the same plane and were duplicated from the same two way polygon both store the same plane, it is obvious that just using this clip plane for the back facing portal (Side = BACK_OWNER) would cause errors. That is, as the plane normal is facing into the opposite half space as the portal, clipping anything away that lies behind this plane would actually clip away anything that lay in the front half space of the portal causing obvious PVS errors. To fix this problem the GetPortalPlane method is used to retrieve the plane of a portal. If the portal whose plane is being retrieved has its side set to BACK_OWNER, then the plane orientation is flipped prior to it being returned. This will make sure that the returned plane always faces into the same front space as the portal flows.

```
void CProcessPVS::GetPortalPlane( const CPVSPortal * pPortal, CPlane3& Plane )
{

    // Store plane information
    Plane = *m_pTree->GetPlane( pPortal->Plane );

    // Swap sides if necessary
    if ( pPortal->Side == BACK_OWNER )
    {
        Plane.Normal   = -Plane.Normal;
```

```
        Plane.Distance = -Plane.Distance;

    } // End if Swap Sides
}
```

InitialPortalVis - CProcessPVS

After the one-way portal array has been created, the Process method next calls the InitialPortalVis method. It is this method that performs the flood fill through the leaves of the tree and constructs a very crude visibility array (PossibleVis) for each portal. As we have discussed, this array will be used to optimize the main PVS calculation procedure (the anti-penumbra clipping process).

The function first sends some information to the PVS logging channel specifying that the initial portal flow is about to be calculated and the progress range of the logger is set to the total number of portals in the one-way portal array. Once we have processed each portal in this array and calculated its PossibleVis array, we will have completed the initial portal flow procedure.

```
HRESULT CProcessPVS::InitialPortalVis()
{
    CPortalPoints  *pp;
    ULONG           p1, p2, i;
    CPlane3         Plane1, Plane2;
    UCHAR          *PortalVis = NULL;
    CPVSPortal     *pPortal1, *pPortal2;

    // *************************
    // * Write Log Information *
    // *************************
    if ( m_pLogger )
    {
        m_pLogger->LogWrite( LOG_PVS,
                             0,
                             true,
                             _T("Calculating initial PVS portal flow \t\t- " ) );

        m_pLogger->SetRewindMarker( LOG_PVS );
        m_pLogger->LogWrite( LOG_PVS, 0, false, _T("0%%" ) );
        m_pLogger->SetProgressRange( GetPVSPortalCount() );
        m_pLogger->SetProgressValue( 0 );
    }
    // ************************
    // *    End of Logging    *
    // ************************
```

The rest of the function is essentially just a loop through each portal that performs a flood fill and is comprised of two different stages.

In the first stage we calculate which portals in the level could conceivably have portal flow with the current portal being processed. This allows us to compile a temporary byte array large enough to store a byte for each portal. Each byte in this array is set to either 1 or 0 depending on whether that portal can be seen from the current portal being processed. Portals that have their bytes set to zero in this array will essentially stop the flood for this portal. Once we have this portal visibility array compiled for the current portal being processed, it will be passed into a recursive flood filling function and used to

calculate the PossibleVis array for the current portal. Remember, the PossibleVis array of the portal is a bit set containing the 'possible' leaf visibility array of the portal. That is, which leaves in the tree have the potential to be visible during the anti-penumbra clipping process.

So, the first thing we must construct inside the loop that iterates through each portal, is the array of bytes that describes which portals can be seen by the current portal being processed.

We loop through each of the other portals and perform two tests on it to determine whether its corresponding byte in the array should be set to zero or one for the current source portal.

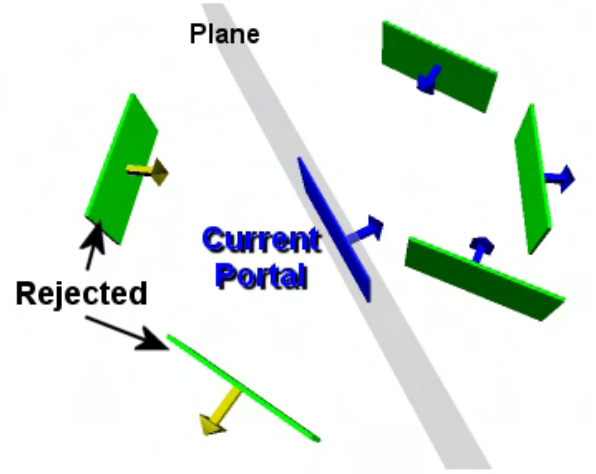

Figure 17.3

Firstly, as portal flow passes through the back of a portal out into its neighbor leaf, we know that any portals that are located behind the plane of the current portal being processed can not possibly be visible to the current portal as shown in figure 17.3. We can see that in the initial test we find two portals located behind the current portal's plane. This means visibility flow can not exist out of the front of the current portal and through the back of these two portals. That is, the current portal can only see into its front space and therefore can not possible see through portals in its back space. As such, the two portals in the example would have their bytes set to zero in the current portals array.

As flow can only exist out of the front of one portal and through the back of another, we can also see that for portals in the front space of the current portal which face towards the current portal no flow can exist also.

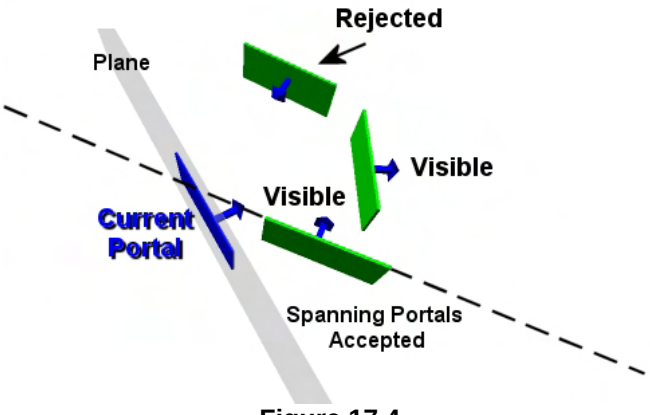

Figure 17.4

In figure 17.4 we can see that in this second test another portal is also rejected by the visibility test because its faces into the opposing half space to the current portal. That is, the text portal and the current portal are facing each other.

We can see that the middle portal on the right hand side of the diagram is not rejected from the visibility test because it faces into the same half space as the current portal. Therefore, we can clearly see that the back side of this portal is clearly visible from the current portal and as such, portal flow can happen between these two portals. The bottom portal of the three test portals is also accepted even though its plane spans the current portal. We will have to sort this problem out later in the main recursive process and clip such portals to each others plane, but for now it is accepted as at least some of the current portal lay in the test portals back space and can see through the back of that portal. Therefore, portal flow does occur between these portals to some degree.

Let is now see the code that performs these tests and compiles the temporary portal/portal visibility buffer. This should obviously be large enough to store a byte for each portal.

```
    try
    {
        // Allocate temporary visibility buffer
        if ( !(PortalVis = new UCHAR[ GetPVSPortalCount() ])) throw std::bad_alloc();

        // Loop through the portal array allocating and checking
        // portal visibility against every other portal
        for ( p1 = 0; p1 < GetPVSPortalCount(); p1++)
        {
            // Update progress
            if (!m_pParent->TestCompilerState()) break;
            if ( m_pLogger ) m_pLogger->UpdateProgress( );

            // Retrieve first portal for easy access
            pPortal1 = GetPVSPortal( p1 );

            // Retrieve portal's plane
            GetPortalPlane( pPortal1, Plane1 );

            // Allocate memory for portal visibility info
            if (!(pPortal1->PossibleVis = new UCHAR[m_PVSBytesPerSet]))
                  throw std::bad_alloc();

            ZeroMemory( pPortal1->PossibleVis, m_PVSBytesPerSet );

            // Clear temporary buffer
            ZeroMemory( PortalVis, GetPVSPortalCount() );
```

Starting at the top of the above section of code we can see that we allocate the byte array that will be temporarily used by each portal we process to contain its portal/portal visibility information. We allocate it large enough to store a byte for each one-way portal.

We then set up a loop to iterate through each portal and compute its possible visibility. After updating the logger's progress we fetch the pointer to the portal that is to be process p1. We then fetch the portals plane using the GetPortalPlane method. Recall from earlier that this function will take care of returning a plane which always faces into the portals neighbor leaf. As this portal (pPortal1) is about to have its PossibleVis array calculated we allocate this array next. Notice that it is allocated to m_PVSBytesPerSet in size. The value of this variable was calculated at the beginning of the Process method and contains how many bytes (including 4 byte alignment padding) we must allocate to have an array where we can represent a single visibility bit for each leaf in the tree. We then zero this array initially so that all leaves are considered invisible to this portal by default. We also zero the PortalVis buffer which is the buffer we will use temporarily in this loop to calculate the portal/portal visibility information (byte for each portal).

Now that we have all the information for the current portal that we are processing, we will set up a loop to iterate through all the other portals in the scene and will perform the two visibility tests illustrated in figures 17.3 and 17.4. At the head of this inner loop we obviously skip the tests if the test portal is equal to the current portal being processed. If this is not the case however, then we fetch a pointer to the test portal and its plane.

```
            // For this portal, loop through all other portals
            for ( p2 = 0; p2 < GetPVSPortalCount(); p2++)
            {
                // Don't test against self
                if (p2 == p1) continue;

                // Retrieve second portal for easy access
                pPortal2 = GetPVSPortal( p2 );

                // Retrieve portal's plane
                GetPortalPlane( pPortal2, Plane2 );
```

For the first test we loop though each of the test portals vertices and classify their positions against the plane of the current portal. If any vertex is found to exist in the front space of the current portal then some portal flow may exist so we break. If we do not break from the loop prematurely however, then it means we must have found that the test portal is contained completely in the back space of the current portal's plane. When this is the case the loop variable 'i' will equal the vertex count of the test portal on loop exit which we can test and skip any further processing if this is the case. That is, if the test portal is found to be in the back space of the current portal then it can not possibly be visible and no portal flow can exist between them so we skip any further tests and never set its byte to one in the PortalVis array.

```
                // Test to see if any of p2's points are in front of p1's plane
                pp = pPortal2->Points;
                for ( i = 0; i < pp->VertexCount; i++)
                {
                   if ( Plane1.ClassifyPoint( pp->Vertices[i] ) == CLASSIFY_INFRONT ) break;

                } // Next Portal Vertex

                // If the loop reached the end, there were no points in front so continue
                if ( i == pp->VertexCount ) continue;
```

If we get this far then it means the test portal (or a fragment of it) must be located in front of the current portal. Our next test is to see if the portals are facing into each other because if this is the case, no portal flow can exist between them also.

As the portals do not contain normals we perform this test by classifying each vertex in the current portal against the plane of the test portal. If portal flow exists between these portals then some of the vertices of the current portal must be located in the back space of the test portal. As soon as we find a vertex that is contained in the back space of the test portal we break from the loop.

```
                // Test to see if any of p1's portal points are Behind p2's plane.
                pp = pPortal1->Points;

                for ( i = 0; i < pp->VertexCount; i++)
                {
                    if ( Plane2.ClassifyPoint( pp->Vertices[i] ) == CLASSIFY_BEHIND ) break;

                } // Next Portal Vertex

                // If the loop reached the end, there were no points in front so continue
                if ( i == pp->VertexCount ) continue;
```

If the loop does not exit prematurely then it means the current portal is in the front space of the test portal and therefore, these portals must be facing each other. When this is the case, loop variable ‘i’ will be equal to the current portal’s vertex count so we can perform this comparison and skip this portal if this is the case. That is, the back of the test portal is not visible to the current portal so no portal flow can exist between them.

If the test portal passes both these tests then it means portal flow does exist between the current portal and the test portal so we set the test portal’s byte to 1 in the PortalVis buffer.

```
                // Fill out the temporary portal visibility array
                PortalVis[p2] = 1;

            } // Next Portal 2
```

After the above inner loop has completed, PortalVis will contain a byte set to 1 for every portal that is potentially visible from the current portal. All we have to do now is perform the flood fill using this information.

```
            // Now flood through all the portals which are visible
            // from the source portal through into the neighbour leaf
            // and flag any leaves which are visible (the leaves which
            // remain set to 0 can never possibly be seen from this portal)
            pPortal1->PossibleVisCount = 0;
            PortalFlood( pPortal1, PortalVis, pPortal1->NeighbourLeaf );

        } // Next Portal
```

As you can see, before performing the flood fill we set the current portals PossibleVisCount to zero as we have not yet found any leaves to be visible, this is what the PortalFlood method will determine. We then call the PortalFlood function (which we will discuss next) to perform the flood. We pass in the current portal which is to have its PossibleVis array calculated, the PortalVis buffer which describes where the flood is blocked by non-visible portals and as the third parameter we pass in the neighbor leaf index of the current portal. It is in this leaf the portal flood will begin. When the outer portal loop exits, every portal will have had a chance to be the current portal and will have had its PossibleVis array calculated using the PortalFlood function.

Before we continue we next test that the compiler has not had a notification to cancel the compilation and if it has received such a notification we return. (Remember that the compiler is running in its own thread).

```
        // If we're cancelled, clean up and return
        if ( m_pParent->GetCompileStatus() == CS_CANCELLED )
        {
            if ( PortalVis) delete[]PortalVis;
            return BC_CANCELLED;

        } // End if Cancelled.

    } // End Try Block

    // Catch Bad Allocations
```

```
    catch ( std::bad_alloc )
    {
        // Clean up and return (Failure)
        if (PortalVis) delete []PortalVis;
        if ( m_pLogger ) m_pLogger->ProgressFailure( LOG_PVS );
        return BCERR_OUTOFMEMORY;

    } // End Catch Block
```

At the bottom of the function we delete the temporary portal/portal visibility buffer and inform the logger that the process has been a success before returning from the function.

```
    // Clean up
    if (PortalVis) delete []PortalVis;

    // Success!!
    if ( m_pLogger ) m_pLogger->ProgressSuccess( LOG_PVS );
    return BC_OK;
}
```

As was evident from look at the above code, a call is made to the PortalFlood function for each portal it processes to generate that portals 'possible' visibility set. Let us have a look at that function next.

PortalFlood - CProcessPVS

This recursive function is passed a source portal which needs to have its PossibleVis array populated with leaf visibility information. It is also passed a byte array describing, for the passed portal, which other portals in the level are visible. As the third parameter the neighbor leaf of the portal is passed. This is the leaf that is located immediately in front of the passed portal and is the leaf at which the flood fill for the portal will begin. This function will start from the neighbor leaf and will recursively flood out through its portals into neighboring leaves. The flood stops in any given direction when we enter an area where its portals are no longer considered visible from the passed source portal. That is, when we reach a portal that has its corresponding byte in the PortalVis buffer set to zero.

For each leaf we recur into via a portal we set its visibility bit in the source portals PossibleVis array to 1. Figure 17.5 demonstrates this process.

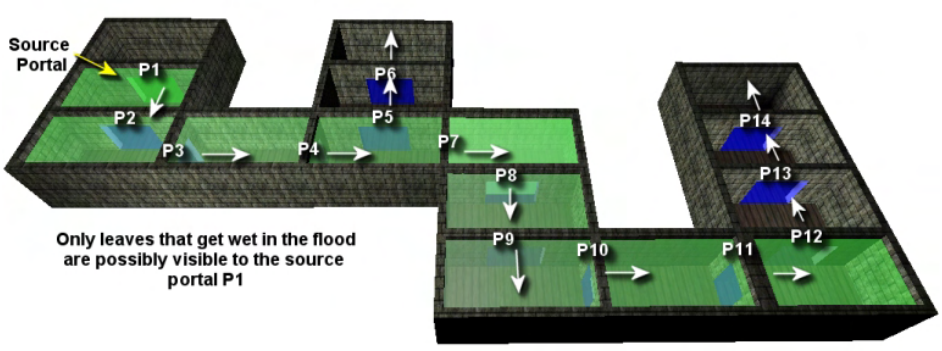

Figure 17.5

We can see that the flood starts in the neighbor leaf of portal P1 and flows through every portal for which portal flow exists and marks that portal's neighbor leaf as visible. The pattern repeats until we run out of visible portals to flood through. You can see in figure 17.5 that we do not flood through portals P5 or P2 as these portals were found to have no portal flow with the source portal (P1) in the previous method. That is, we only flow through a portal and mark its neighbor leaf as visible if its corresponding

byte in the passed PortalVis array is set to 1. In figure 17.5 the leaves that are highlighted green were marked as possibly visible by this flood filling process.

In the first section of the function we use the passed neighbor leaf index to fetch the leaf structure from the BSP tree's leaf array. As this is the leaf we are currently visiting it means the flood has made it into this leaf and therefore this leaf must be visible from the portal in question. However, because we do not wish to ever get stuck in a recursive loop we must make sure that we have not visited this leaf before in the flood so that we do not flow through its portals again. You can see that we use the GetPVSBit method to fetch the visibility bit in the portals PossibleVis array for the current leaf and if it is already set to 1, it means we have already visited this leaf before and have marked it as visible. When this is the case we simply return. If this is not the case however, we use the SetPVSBit method to mark the current leaf as visible in the portals PossibleVis array.

```
void CProcessPVS::PortalFlood( CPVSPortal * SourcePortal,
                               unsigned char PortalVis[],
                               unsigned long Leaf )
{
    CBSPLeaf * pLeaf = m_pTree->GetLeaf( Leaf );

    // Test the source portals 'Possible Visibility' list
    // to see if this leaf has already been set.
    if ( GetPVSBit( SourcePortal->PossibleVis, Leaf ) ) return;

    // Set the possible visibility bit for this leaf
    SetPVSBit( SourcePortal->PossibleVis, Leaf );

    // Increase portals 'Complexity' level
    SourcePortal->PossibleVisCount++;
```

Notice in the above code that after we have marked the leaf as visible to the portal we increment the portal's PossibleVisCount so that when the flood is complete, this member will contain all the visible leaves that were found. That is, the number of leaves that got wet by the flood fill. As described earlier, this PossibleVisCount member will be used as a measure of the portal's potential complexity and will be used by the core clipping process to determine which portal should have its PVS calculated next. Portals with a smaller PossibleVisCount will be selected for PVS calculation first.

Now that we have identified that the current leaf is visible it is now time to loop through all the portals stored in that leaf. If the portal is visible to the current source portal we will recur through that portal into its neighbor leaf. Otherwise we will skip the portal. Here is the remainder of the function code.

```
    // Loop through all portals in this leaf (remember the portal numbering
    // in the leaves match up with the originals, not our PVS portals )
    for ( ULONG i = 0; i < pLeaf->PortalIndices.size(); i++)
    {
        // Find correct portal index (the one IN this leaf (not Neighbouring))
        ULONG PortalIndex = pLeaf->PortalIndices[ i ] * 2;
        if ( GetPVSPortal( PortalIndex )->NeighbourLeaf == Leaf ) PortalIndex++;

        // If we can't pass through this portal then continue to next portal
        if ( !PortalVis[ PortalIndex ] ) continue;

        // Flood fill out through this portal
        PortalFlood( SourcePortal, PortalVis, GetPVSPortal( PortalIndex )->NeighbourLeaf );
```

```
    } // Next Leaf Portal
}
```

Notice that because we are accessing the portal information from the leaf of the BSP tree which stores one two-way portal instead of a pair of one-way portals, we need to multiply the leaf's portal index by 2 to get the index into the one-way portal array of the first in the pair of one-way portals that were generated for it. If the first one-way portal in the pair has a neighbor leaf equal to the leaf we are already in then this is obviously the one-way portal that points back into this leaf. This is obviously not the one-way portal that flows out of the neighbor leaf and therefore, the portal we are after must be the second in the pair so we increment the leaf index so that it addresses the correct one-way portal. Next we test to make sure this portal is visible by testing its corresponding byte in the PortalVis array, and if it is visible, the function calls itself to recur into the neighbor leaf of this portal.

We have now covered two of the processes that are invoked from the main Process method of this module. At this point, program flow will have been returned back to the Process method and not only will the one-way portals have been created and stored, each of these portals will contain a PossibleVis array describing a very approximate leaf PVS for that portal. The next method invoked from the Process method is the CalcPortalVis function. This is the function that is the doorway to the core PVS calculation process and the function that kick starts the anti-penumbra clipping function that ultimately calculates the ActualVis array (the real PVS) for each portal.

The CalcPortalVis - CProcessPVS

Before we look at the CalcPortalVis method we must look at a structure that will be used to pass data from one recursion of the function to the next when performing the recursive clipping process. Because we will need to recur through the RecursePVS function many times (covered in a moment), it will be helpful to have a data structure where we can pass information from the previous recursion to the next. For example, when the RecursePVS function calls itself, the current generator portal needs to be passed into the next recursion as the target portal. We also need to be able to access the source portal at all times, regardless of what instance of the function we are in, so that we can set its visibility bits for each visible leaf we encounter. The structure is shown below.

Excerpt from CProcessPVS.h

```
typedef struct _PVSDATA                 // Structure to hold pvs processing data
{
        CPortalPoints   *SourcePoints;   // Current source portals points
        CPortalPoints   *TargetPoints;   // Current target portals points
        CPlane3          TargetPlane;    // The target's plane
        UCHAR           *VisBits;        // Visible Bits being calculated
} PVSDATA;
```

This structure is the transport mechanism with which to pass data about the generator portal that was selected in a previous iteration of the recursive function onto the next recursion. Since the previous generator portal becomes the target portal in the next recursion and is used to build a new anti-penumbra, this allows us to find a generator portal, fill out the information about it in one of these structures, and then pass on this structure to the next recursion so that we can access and use it as the

target portal during anti-penumbra generation. Let is discuss what the four members will be used for by the core PVS calculation process.

CPortalPoints *SourcePoints;
As we discuss in the text book, during the recursive clipping process the source portal will be the portal that is currently having is PVS calculated (ActualVis array populated). As we step recursively through generator portal after generator portal into new neighbor leaves, we need access to the source portals polygon data so that it can be used to create the anti-penumbra with the target portal at each step. When the RecursePVS function is first called, this will be a pointer to the source portal's polygon data.

However, we also discussed in the text book how at each step we build anti-penumbras between not only the source and target portals (allowing us to cull/clip generator portals) but also between the generator portal and the target portal which is used to clip a temporary copy of the source portal's polygon. By clipping the source portal and the generator portal at each step as small as possible, we assure that in the next recursive step a smaller anti-penumbra will be built allowing us to cull more generator portals from having to be visited. During the recursive process, this member will contain a copy of the source portal in its currently clipped state. That is, when at a given step in the process the source portal is clipped to the anti-penumbra and a new smaller source portal polygon is generated, that polygon is stored in this member so that it can be passed into the next recursion as the source portal geometry.

This is always a temporary copy of the source portal polygon from the first point it gets clipped. That is, although we set this to the CPortalPoints member of the source portal at the start of the process, we never want to clip or delete the original source portal as this will be needed for the calculation of other portals later in the process. Our hope is that as we step from leaf to leaf, the portal stored in this member will become smaller and smaller due to the ongoing clipping in each recursion until it generates a very small anti-penumbra in which no generator portals are contained and stopping the portal flow along that given path.

CPortalPoints *TargetPoints;
This member will be used to pass the geometry of the generator portal that has been stepped though in one recursion onto the next recursion where it will become the target portal and used to build the anti-penumbra planes.

As was the case with the source portal transport mechanism described above, a generator portal selected in one recursion of the function will be clipped to the current anti-penumbra in an attempt to make that generator as small as possible (or cull it completely) for the next recursion. The clipped copy of the generator portal is then stored in this member variable and passed into the next recursion of the function where it will be used as the target portal. By making both the source and target portals smaller and smaller with each generator portal that we step through, we will get a tighter and more accurate PVS calculated and raise the chances of being able to abort a from given path of portals earlier.

When the RecursePVS method is first called, this will be set to NULL as no target portal will have yet been selected. This allows us to identify the special case in the RecursePVS function where we have entered it for the very first time and we do yet have two portals with which to construct an anti-penumbra. In this first special case, no anti-penumbra clipping is performed. A generator portal is

simply selected and stored in the TargetPoints member. We then recur through that portal into its neighbor leaf where we enter the clipping process proper.

CPlane3 TargetPlane;
This will be used to store the plane of the target portal when input into the RecursePVS function. That is, this will be the plane of the generator portal that was selected in the previous recursion and the plane of the portal polygon stored in the TargetPoints member. As discussed in the accompanying text book, we will need this as we will need to clip the generator portal to the target portal's plane to make sure that a spanning case does not occur that could corrupt the anti-penumbra in the next recursion. The source portal will also be clipped to the generator portal's plane so all spanning case are eliminated. Remember, the only portion of the generator portal that should be visible is the portion that is contained in the front space of the source/target portal and vice versa.

The first time the RecursePVS function is called this will be set to the plane of the source portal. As we described above, the first call is a special case where a target portal has not yet been selected. This will allow us to make sure that the generator portal we selected (which will become the first target portal in the next recursion) will be clipped to the plane of the source portal as once again, the only portion of the target portal that should be visible to the source portal is the section that is contained in the source portal's front space.

UCHAR *VisBits;
This array will be used to accumulate and pass into the current recursion all leaves that can possibly be seen by the source portal given the current combination of portals we have stepped through up to this point. This allows us to very efficiently determine if there are any leaves to process down this path which might be visible to the source portal and if not, we can terminate this path of flow immediately. We know for example that at the start of the process each portal will have a bitset (PossibleVis) describing which leaves may be visible. However, we also know that this set can be refined by ANDing the bitsets of all portals we have stepped through up until this point. For example, imagine that in a 10 leaf level the PossibleVis array of the source portal has the following leaf bits set to 1.

Source Portal Vis - 1111100000

We can see at the start that only the first five leaves of the level could possibly be visible to the source portal as this was determined by the portal flood we performed earlier. Let us also assume that we next choose a target portal with which to build the anti-penumbra which had the following PossibleVis array calculated for it during the portal flood.

Target Portal Vis - 1110011100

We can see that the source portal has the possibility of being able to see into leaves 1 through 5 whilst the target portal has the possibility of seeing into leaves 1 through 3 and 6 through 8. Therefore, when we build an anti-penumbra between these two portals we are actually asking the question, "How much can we see from the source portal through the target portal" which at an approximate level can be determined by ANDing the visibility sets

Current Vis - 1111100000 + 1110011100 = 1110000000

As you can see, before we even perform any clipping we can tell that there can only possibly be 3 leaves that we need to visit and can be seen through the combination of portals we are currently looking through, leaves 1 through 3. It doesn't stop there though.

For example, imagine that we next choose a generator portal that has the following PossibleVis array

Generator Vis - 0011111111

When we combine its visibility set with the current visibility information we have collected so far we get:-

Current Vis - 111000000
AND
Generator Vis - 001111111

New Current Vis - 001000000

As you can see, this tells us that there is only one leaf we are interested in visiting at this point in the process. That is, there is only one leaf that is visible from the source portal when looking through the target and generator portals. This process is ongoing. As we step from recursion to recursion we combine the possible visibility sets of each portal we step through so we can very quickly determine whether there are any leaves to visit down this current path of portals through which we have traveled. This allows us to bail from the path early instead of having to perform the anti-penumbra clipping for generator portals which we have already determined have neighbor leaves that could not possibly be visible through the combination of portals we have traveled to get to this point.

The VisBits member of this structure allows us to pass this combined bitset into the next recursion where it will be combined with the next generator portals PossbleVis array and so on. That is, it inputs into the RecursePVS function a bitset that describes what leaves could possibly be visible given the portals we have traveled through to that point. When the RecursePVS function is first called, this will point to the source portal's PossibleVis array as we have not yet selected any target portals. For all future recursions this will contain the combination (the bitwise ANDing) of the source portals PossiblVis array with the PossibleVis arrays of all the portals we have walked through to get to the current leaf.

With this structure explained we can now look at the code to the CalcPortalVis function a section at a time and see how this structure is initially setup and passed into the first instance of the RecursePVS function.

In the first section of the code we test the compiler options for this module. If the option has not be set to enable a full PVS compile then it means the user does not wish us to perform the core time consuming anti-penumbra clipping tests at all and as such we should just use the PossibleVis arrays calculated for each portal in the portal flood fill as the actual PVS for each portal and return.

```
HRESULT CProcessPVS::CalcPortalVis()
{
    ULONG   i;
    HRESULT hRet;
    PVSDATA PVSData;

    // If we want to perform a quick vis (not at all accurate) we can
    // simply use the possible vis bits array as our pvs bytes.
     if ( !m_OptionSet.FullCompile )
     {
        for ( i = 0; i < GetPVSPortalCount(); i++ )
        {
            CPVSPortal * pPortal = GetPVSPortal( i );
             pPortal->ActualVis = pPortal->PossibleVis;

        } // Next Portal

        // We are finished here
        return BC_OK;

    } // End if !FullCompile
```

As you can see in the above code, if a full compile is not required we just loop through each portal and copy its PossibleVis array into its ActualVis array. As we know, the ActualVis array is where our compiler will expect the real PVS data of the portal to exist after the core clipping process has been performed. As we do not wish to perform this core clipping process we simply copy over the PossibleVis arrays into the ActualVis arrays of each portal so that the bitset is stored in the portal where the PVS exporter will expect to find it. We then return because our job is already done.

> **Note**: This option is not to be used for commercial output. The PVS set generated using such an option will be extremely over generous and run time application performance will suffer. This option is really for the developers of the project to perform a very quick compile to test the various assets of their game without having to wait long periods for PVS calculation every time they update the geometry of their level.

Now it is time to start the core PVS calculation process and as such we output to the logging device that PVS calculation is about to being. As the PVS process is essentially one of just looping through each portal and calculating its ActualVis array (that made it sound deceptively easy) we set the range of the logger to the portal count so that it can be increased with each portal we process.

```
    // *************************
    // * Write Log Information *
    // *************************
    if ( m_pLogger )
    {
        m_pLogger->LogWrite( LOG_PVS, 0, true, _T("Full PVS compile progress \t\t\t- " ) );
        m_pLogger->SetRewindMarker( LOG_PVS );
        m_pLogger->LogWrite( LOG_PVS, 0, false, _T("0%%" ) );
        m_pLogger->SetProgressRange( GetPVSPortalCount() );
        m_pLogger->SetProgressValue( 0 );
    }
    // ************************
    // *    End of Logging     *
    // ************************
```

Next we make sure that the PVSData structure that we pass into the initial call to the RecursePVS function is initialized to zero and then we set up a loop to iterate through each portal.

```
    try
    {
        // Clear out our PVSData struct
        ZeroMemory( &PVSData, sizeof(PVSDATA) );

        // Lets process those portal bad boys!! ;)
        for ( i = 0; i != -1; i = GetNextPortal() )
        {
            CPVSPortal * pPortal = GetPVSPortal( i );

            // Update Progress
            if (!m_pParent->TestCompilerState()) throw BC_CANCELLED;
            if (m_pLogger) m_pLogger->UpdateProgress();
```

Notice that we use the GetNextPortal method to choose the next portal in the list to have its PVS calculated. We will have a look at this function in a moment but as discussed earlier, we wish to process least complex portals first so this function simply returns the index of a portal that has not yet been processed and has the smallest number of visible leaves in its PossibleVis array. We then use this index to fetch the next portal to be processed (pPortal) which will become the source portal in the next call to the RecursePVS function. We also update the logger's progress as a new portal is about to have its PVS calculated.

Our next task is to populate the members of the PVSData structure that will be passed into the first recursion of the function. As explained above, we should initially set the SourcePoints member to point to the source portal's polygon geometry (its CPortalPoints structure) and should set the VisBits pointer to point at the PossibleVis array of the source portal. The Plane of the source portal is also retrieved and stored in the TargetPlane member. Although this last step seems a little strange, by storing the source portal's plane in the TargetPlane member for the first call to the RecursePVS function, it means the target portal that we do select in that function will be clipped to the source portals plane so that any spanning cases are eliminated.

```
            // Fill our our initial data structure
            PVSData.SourcePoints    = pPortal->Points;
            PVSData.VisBits         = pPortal->PossibleVis;
            GetPortalPlane( pPortal, PVSData.TargetPlane );
```

Notice that we do not set the TargetPoints member of the PVSData structure in the above section of code. This is left at NULL so that we can detect in the RecursePVS function that it is the first recur of the function and as such, no anti-penumbra has to be created. We can just choose a generator portal and recur into its neighbor leaf.

Because the current portal we are processing is about to have its ActualVis array calculated, we had better allocate the memory for it now so that it is large enough to store a bitset that represents the visibility information for each leaf and we should initially set all the bits in this array to zero so that they are all initially invisible. It will be the RecursePVS function that will set the bits to 1 in this array when it finds a leaf that is visible.

```
            // Allocate the portals actual visibility array
            pPortal->ActualVis = new UCHAR[ m_PVSBytesPerSet ];
            if (!pPortal->ActualVis) throw std::bad_alloc(); // VC++ Compat

            // Set initial visibility to off for all leaves
            ZeroMemory( pPortal->ActualVis, m_PVSBytesPerSet );
```

Now we call the RecursePVS function to calculate the PVS for this portal. We pass in the neighbor leaf index as the first parameter as this is the leaf for which the source portal first leads into and is where the recursive procedure should begin for this portal. As the second parameter we pass in the source portal itself. This will be needed by the RecursePVS function so that it can set bits to 1 in its ActualVis array each time it locates a visible leaf. As the final parameter we pass in the PVSData structure. When this function returns, the PVS for the portal will be stored in its ActualVis array so we set the status of this portal to PS_PROCESSED. This will assure that the GetNextPortal method used to select the next portal to be processed in the loop will not select this portal again.

```
            // Step in and begin processing this portal
            hRet = RecursePVS( pPortal->NeighbourLeaf, pPortal, PVSData );
            if ( FAILED( hRet ) ) throw hRet;

            // We've finished processing this portal
            pPortal->Status = PS_PROCESSED;

        } // Next Portal

    } // End Try Block
```

At this point the PVS for each portal has been calculated and is stored in their ActualVis arrays. All that is let to do is inform the logger to output success before returning from the function.

```
    // Catch all failures
    catch (std::bad_alloc)
    {
        // Failed to allocate
        if ( m_pLogger ) m_pLogger->ProgressFailure( LOG_PVS );
        return BCERR_OUTOFMEMORY;

    } // End if

    catch ( HRESULT& e )
    {
        // Arbitrary Error
        if ( m_pLogger && FAILED(e) ) m_pLogger->ProgressFailure( LOG_PVS );
        return e;

    } // End if

    // Success!!
    if ( m_pLogger ) m_pLogger->ProgressSuccess( LOG_PVS );
    return BC_OK;
}
```

Before we look at the RecursePVS function which will undoubtedly require heavy discussion, we will first examine the GetNextPortal method of this module that was used in the above code to select the next portal to have its PVS calculated.

GetNextPortal - CProcessPVS

This small function has the simple task of determining which portal in the list should have its PVS calculated next. The function loops through each portal in the list searching for the portal with the lowest PossbleVisCount that has not yet had its PVS calculated. That is, it is looking for the least complex portal in the list whose status is still PS_NOTPROCESSED. Once the portal is located, its status is set to PS_PROCESSING prior to its index being returned. This is the portal that will have its PVS calculated next and is therefore the portal that we are currently processing. The complete code is shown below.

```
ULONG CProcessPVS::GetNextPortal( )
{
    CPVSPortal * pPortal;
    long PortalIndex = -1, Min = 999999, i;

    // Loop through all portals
    for ( i = 0; i < (signed)GetPVSPortalCount(); i++ )
    {
        pPortal = GetPVSPortal(i);

             // If this portal's complexity is the lowest and it has
        // not already been processed then we could use it.
        if ( pPortal->PossibleVisCount < Min && pPortal->Status == PS_NOTPROCESSED)
        {
                    Min = pPortal->PossibleVisCount;
                    PortalIndex = i;
        } // End if Least Complex

     } // Next Portal

     // Set our status flag to currently being worked on =)
     if ( PortalIndex > -1) GetPVSPortal( PortalIndex )->Status = PS_PROCESSING;

    // Return the next portal
    return PortalIndex;
}
```

RecursePVS - CProcessPVS

We finally get to the function that contains the real meat of the process. This function calls itself recursively until the PVS set of the source portal has been calculated. The function takes three parameters. The first is the index of the leaf that we have currently stepped into which will be the neighbor leaf of the source portal the first time it is called. This leaf will be marked as visible in the source portals PVS. As we have stepped into this leaf it is obviously visible from the source portal. The second parameter is the source portal itself which is in the process of having its PVS calculated by this function. The third parameter is a PVSData structure which in the normal case will contain information about the target portal that is to be used in this function (the generator portal selected in the previous recursion) and the visibility buffer of all the portals we have stepped through so far which will be used for early-out determination.

```
HRESULT CProcessPVS::RecursePVS( ULONG Leaf, CPVSPortal * SourcePortal, PVSDATA & PrevData )
{
    ULONG           i,j;
    bool            More;
    ULONG          *Test, *Possible, *Vis;

    PVSDATA         Data;
    CPVSPortal     *GeneratorPortal;
    CPlane3         ReverseGenPlane, SourcePlane;
    CPortalPoints  *SourcePoints, *GeneratorPoints, *NewPoints;

    // Store the leaf for easy access
    CBSPLeaf * pLeaf = m_pTree->GetLeaf( Leaf );

    // Mark this leaf as visible
    SetPVSBit( SourcePortal->ActualVis, Leaf );
```

The first thing the function does is used the passed leaf index to fetch the leaf structure from the BSP tree. It then sets this leaf's bit to one in the source portal's ActualVis array. This leaf is visible from the source portal and has now been added to its PVS.

Notice in the above code that we instantiate on the stack a PVSData structure (in addition the one passed into the function as the third parameter). This new PVSData structure (imaginatively named Data) will be used to carry the generator portal information and combined visibility bitset from this function into the next recursion. That is, the Data local variable will be what we pass into the next call to the function as the third parameter and is the structure whose data we must fill out before we do so.

First, we allocate the structure a new VisBits array large enough to hold a bit for each leaf. This array will be used to store the result of combining the VisBits array passed into the function (PrevData.VisBits) with the PossibleVis array of the generator portal that we select in this function.

```
    // Allocate our current visibility buffer
    Data.VisBits = new UCHAR[ m_PVSBytesPerSet ];
    if (!Data.VisBits) throw std::bad_alloc(); // VC++ Compat
```

For ease of access, we also assign some local variables to structure members we are going to need to access frequently. We can see in the following code that the Possible local variable is used to point at the Data.VisBits array we just allocated and the Vis local variable is used to point at the PVS set (ActualVis array) of the source portal. This allows us to access these two buffers in short hand.

```
    // Store data we will be using inside the loop
    Possible    = (ULONG*)Data.VisBits;
    Vis         = (ULONG*)SourcePortal->ActualVis;
    GetPortalPlane( SourcePortal, SourcePlane );
```

Notice in the above code how we then fetch the plane of the source portal and store it in the SourcePlane local variable. Remember once again why the GetPortalPlane method is used for this task. It takes care of flipping the direction of the portal's node plane (the returned plane) if it faces into an opposing half space to the portals neighbor leaf.

The rest of the function is contained inside a loop that iterates through every portal in the current leaf and processes it for generator portal candidacy. Remember that the leaf structure in the BSP tree (which

we just retrieved above) will contain the indices of the two-way portals that reside in that leaf. As we did before, we must multiply this index by 2 so that we get the index of the first in the pair of one-way portals that were generated by that two-way portal. We then test to see if the first portal in the pair does not have a neighbor leaf equal to the leaf we are currently in because if it does, this is the one-way portal that flows into the current leaf and not out of it. When this is the case we know that the next portal in the array must be the other portal in the pair which faces out of the current leaf and into the neighbor leaf we may be interested in recurring into if this generator portal is not completely clipped away later in the function.

```
    // Check all portals for flow into other leaves
    for ( i = 0; i < pLeaf->PortalIndices.size(); i++ )
    {
        // Find correct portal index (the one IN this leaf (not Neighbouring))
        ULONG PortalIndex = pLeaf->PortalIndices[ i ] * 2;
        if ( GetPVSPortal( PortalIndex )->NeighbourLeaf == Leaf ) PortalIndex++;

        // Store the portal for easy access
        GeneratorPortal = GetPVSPortal( PortalIndex );
```

Now that we have the generator portal we can see how the PrevData.VisBits array that is passed into this function is used. This contains a leaf bitset that has been generated by ANDing all the PossibleVis arrays of the portals we have traveled through to get to this current leaf. Therefore, only leaves with their bits set to one in this array are leaves that are visible from the source portal when looking through all the portals we have stepped through to get to this leaf. Therefore, we test to see if the generator portal's neighbor leaf has its bit set to one in this bitset. If it does not, it means the leaf on the opposing side of this portal is not possibly visible from the source portal so we have no interest in processing this generator portal any further. As you can see, when this is the case we simply skip this generator portal and continue to the next iteration of the generator portal loop.

```
        // We can't possibly recurse through this portal if it's neighbour
        // leaf is set to invisible in the target portals PVS
        if ( !GetPVSBit( PrevData.VisBits, GeneratorPortal->NeighbourLeaf ) ) continue;
```

Now it is time to combine the PrevData.VisBits array with the visibility array of the generator portal so that we can store the resulting bit set in Data.VisBits (aliased via the 'Possible' pointer) and send that onto a future recursion. It is this section of code that performs the bitset accumulation we have discussed in each recursion. What we are going to do is take the visibility set we have been passed into this function (PrevData.VisBits) and further refine it by the generator portal's PossibleVis bits. But wait!!! If the generator portal has already had its PVS generated such that its status is equal to PS_PROCESSED, we can refine this bit set even further by using its ActualVis array instead of its PossibleVis array which will allow us to hopefully carve of a great many more visible leaves out of the equation. Therefore, in the next section of code we first test the status of the generator portal and if it has been processed, we assign the local Test pointer to point at its ActualVis array. If not, then Test is assigned to point at its PossibleVis array.

```
        // If the portal can't see anything we haven't already seen, skip it
        if ( GeneratorPortal->Status == PS_PROCESSED )
            Test = (ULONG*)GeneratorPortal->ActualVis;
        else
            Test = (ULONG*)GeneratorPortal->PossibleVis;
```

Now we will loop through PrevData.VisBits four bytes at a time (using a long pointer which is why we padded these visibility arrays to a 32 bit boundary) and will AND it with the visibility buffer of the generator portal 'Test'. We will store the result in 'Possible' which is a pointer to Data.VisBits which we know is the PVSData structure that will be passed into the next recur of this function. As we AND these arrays together four bytes at a time and store them in 'Possible', we will also perform a bitwise AND with the NOT of the source portals PossibleVis array (Aliased by the local Vis pointer). This allows us to quickly detect if there are any bits set in Possible which are also set in Vis and therefore means there are still leaves in Possible that might be visible from the source portal and will need to be visited. When this is the case we set the More local Boolean variable to true

```
        More = false;
        // Check to see if we have processed as much as we need to
        // this is an early out system. We check in 32 bit chunks to
        // help speed the process up a little.
        for ( j = 0; j < m_PVSBytesPerSet / sizeof(ULONG); j++ )
        {
            Possible[j] = ((ULONG*)PrevData.VisBits)[j] & Test[j];
            if ( Possible[j] & ~Vis[j] ) More = true;

        } // Next 32 bit Chunk

        // Can we see anything new ??
        if ( !More ) continue;
```

The little loop above can be a bit of a brain teaser at first but it is essentially just creating the combined VisBits array that will be sent into the next recursion and at the same time determining whether there is anything left to see by continuing down this path. Outside the loop you can see that if More is not set to true, if means there are no bits set to one in the Possible array that are also set to one in the source portal's PossibleVis array and as such, there is nothing of interested on the other side of this generator portal so there is not need to recur through it into the neighbor leaf. When this is the case we simply skip any further processing of the generator portal and continue to the next iteration of the loop.

In the next step we fetch the plane of the generator portal and store it in the Data.TargetPlane so that it can be passed to the next recursion as the target portal's clip plane. Remember, the generator portal selected in this recursion will become the next target portal when we recur through it into its neighbor leaf.

```
        // The current generator plane will become the next recursions target plane
        GetPortalPlane( GeneratorPortal, Data.TargetPlane );
```

Our next test is to make sure that the generator portal is not ON_PLANE with the target portal that has been passed into this function in the PrevData parameter. If it is, then they cannot see each other and we can skip this generator portal. For this test we are using a generator plane with a reversed normal and are comparing this normal against the normal the normal of the target portal (PrevData.TargetPlane). We do

this because we need to check that the portal we have just entered this leaf through is not on the same plane as any we are about to leave this leaf through. A target portal can not see a generator portal that is on the same plane as it and stepping through such a portal could carry us back into the leaf that we just exited in the previous recur.

```
        // We can't recurse out of a coplanar face, so check it
        ReverseGenPlane.Normal   = -Data.TargetPlane.Normal;
        ReverseGenPlane.Distance = -Data.TargetPlane.Distance;
        if ( ReverseGenPlane.Normal.FuzzyCompare( PrevData.TargetPlane.Normal, 0.001f ))
              continue;
```

Our next task is to clip the generator portal to the plane of the source portal so that any portion of the generator portal that is contained in the back space of the source portal is removed. If this operation completely clips away the generator portal we skip this generator portal as there seems to be no valid portion of it in front of the source portal.

```
        // Clip the generator portal to the source. If none remains, continue.
        GeneratorPoints = GeneratorPortal->Points->Clip( SourcePlane, false );
        if ( GeneratorPoints != GeneratorPortal->Points )
             FreePortalPoints( GeneratorPortal->Points );

        if (!GeneratorPoints) continue;
```

In this next section of code we see some special case code which is only executed the first time the RecursePVS function is called (when PrevData.TargetPoints will equal NULL). When this is the case we do not wish to perform any anti-penumbra clipping as we are really just trying to select the first target portal. As you can see, in this instance we simply copy over the source points passed into the function (PrevData.SourcePoint) into the PVSData structure that will be passed into the next recursion (Data.SourcePoints) and also copy over the generator portal into the TargetPoints member of this structure also so that it will become the target portal in the next recursion. We then call the RecursePVS function to recur into the neighbor leaf of the generator portal (which is really the first target portal in this instance) and on function return skip to the next generator portal in the leaf to be processed.

```
        // The second leaf can only be blocked if coplanar
        if ( !PrevData.TargetPoints )
        {
            Data.SourcePoints = PrevData.SourcePoints;
            Data.TargetPoints = GeneratorPoints;
            RecursePVS( GeneratorPortal->NeighbourLeaf, SourcePortal, Data );
            FreePortalPoints( GeneratorPoints );
            continue;

        } // End if Previous Points
```

Remember that the above conditional code is only executed in the first instance of the function when no previous target portals exist and need to be found.

The next thing we do is clip the generator portal to the target portal's plane. The section of the generator portal that should be visible to the source portal is that section located in the front space of the target portal and as such, can be seen when looking through the back of the target portal. If none of the generator portal survives the clip then it is not visible to the source portal and we do not have to step

through it into its neighbor leaf. When this is the case we process the generator portal no further and simply skip to the next generator portal in the loop that needs to be processed.

```
        // Clip the generator portal to the previous target. If none remains, continue.
        NewPoints = GeneratorPoints->Clip( PrevData.TargetPlane, false );
        if ( NewPoints != GeneratorPoints ) FreePortalPoints( GeneratorPoints );
        GeneratorPoints = NewPoints;
        if (!GeneratorPoints) continue;
```

The source portal should also be clipped to the generator portals plane. However, we need to make sure that the only portion of the source portal that survives is the portion that is located behind the plane of the generator portal and not in front as it usually the case with a clipping routine. The source portal should only ever be able to see through the back of a generator portal and a source portal that spans the generator portals plane clearly violates that. We need to flip our clipping operation so that is clips away any portion of the source portal that is located in the front space of the generator portal's plane. Fortunately, we already calculated a reversed generator plane above so we can re-use it here. By passing in the reversed generator plane into our clip function we will remove the section of the source portal that is in the back space of this plane, which is really the section that is in the front space of the real generator portal's plane. As you can see, we make a new copy of the source portal geometry from the source portal geometry passed into the function (PrevData.SourcePoint) which my have been clipped many times before and we then clip it to the reversed generator plane.

```
        // Make a copy of the source portals points
        SourcePoints = new CPortalPoints( PrevData.SourcePoints, true );

        // Clip the source portal
        NewPoints = SourcePoints->Clip( ReverseGenPlane, false );
        if ( NewPoints != SourcePoints ) FreePortalPoints( SourcePoints );
        SourcePoints = NewPoints;

        // If none remains, continue to the next portal
        if ( !SourcePoints ) { FreePortalPoints(  GeneratorPoints ); continue; }
```

As the above code shows, if none of the source portal survived the clip it means the source portal can see no portion of the generator portal's back face and as such no portal flow can exist. When this is the case we skip any further processing of this generator portal and continue to the next iteration of the loop where we will test the next generator portal in this leaf which needs to be tested.

At this point we know we have a source portal and a generator portal which although have been clipped to each others plane, have portal flow between them in the loosest sense. Our next task is to perform the clipping of the source and generator portals to the anti-penumbra. The ClipToAntiPenumbra function is the method that creates the anti-penumbra and performs the clipping of the passed portal to its planes. As discussed earlier, there are a possibly four anti-penumbras that we can build and clip to and how many we perform depends on the number of clip tests that have been enabled in the PVSOPTIONS structure. The clip tests are performed as shown below:-

- Clip Test 1 : Build Anti-Penumbra from **source portal** to **target portal** and clip the **generator portal** to its planes.
- Clip Test 2 : Build Anti-Penumbra from **target portal** to **source portal** and clip the **generator portal** to its planes.
- Clip Test 3 : Build Anti-Penumbra from **generator portal** to **target portal** and clip the **source portal** to its planes.
- Clip Test 4 : Build Anti-Penumbra from **target portal** to **generator portal** and clip the source portal to its planes.

After each clipping operation, if none of the portal that was clipped survived, the source and generator portals can not see each other through the target portal meaning we need process this generator portal no further and should not recur through it into the neighbor leaf. Instead, we simply continue on to the next iteration of the loop and process the next generator portal in the leaf. Here is the code that performs the four clip tests. We will look at the ClipToAntiPenumbra method next.

```
        // Lets go Clipping :)
        if ( m_OptionSet.ClipTestCount > 0 )
        {
            GeneratorPoints = ClipToAntiPenumbra( SourcePoints,
                                                  PrevData.TargetPoints,
                                                  GeneratorPoints,
                                                  false );

            if (!GeneratorPoints) { FreePortalPoints( SourcePoints ); continue; }

        } // End if 1 Clip Test

        if ( m_OptionSet.ClipTestCount > 1 )
        {
            GeneratorPoints = ClipToAntiPenumbra( PrevData.TargetPoints,
                                                  SourcePoints,
                                                  GeneratorPoints,
                                                  true );

            if (!GeneratorPoints) { FreePortalPoints( SourcePoints ); continue; }

        } // End if 2 Clip Tests

        if ( m_OptionSet.ClipTestCount > 2 )
        {
            SourcePoints = ClipToAntiPenumbra( GeneratorPoints,
                                               PrevData.TargetPoints,
                                               SourcePoints,
                                               false );

            if (!SourcePoints) { FreePortalPoints( GeneratorPoints ); continue; }

        } // End if 3 Clip Test

        if ( m_OptionSet.ClipTestCount > 3 )
        {
            SourcePoints = ClipToAntiPenumbra( PrevData.TargetPoints,
```

```
                                            GeneratorPoints,
                                            SourcePoints,
                                            true );

            if (!SourcePoints) { FreePortalPoints( GeneratorPoints ); continue; }

        } // End if 4 Clip Test
```

The first two parameters to the ClipToAntiPenumbra function are the portals between which the anti-penumbra will be created. The third parameter is where the portal that should be clipped is passed.

The fourth parameter to the function is a Boolean that describes whether the portal should be clipped to the back of the anti-penumbra planes or the front. This is necessary because the direction of the plane normals being built from source to target will be opposite to that of the normals of the plane constructed when going from target to source as is shown in figure 17.6.

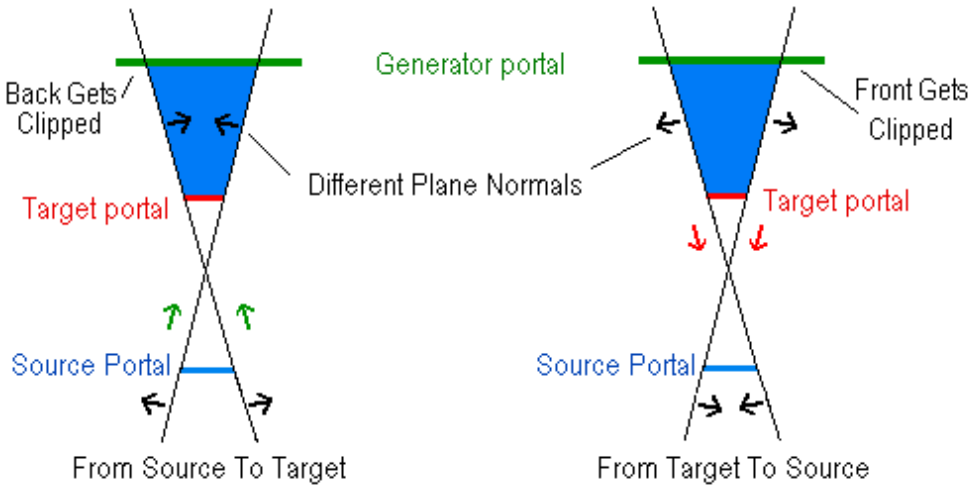

Figure 17.55

The leftmost image shows a 2D representation of the planes generated when the anti-penumbra is being constructed from the vertices of the source portal to the edges of the target portal. We can see that on the opposite side of the target portal the visible region is bounded by planes that face inwards and as such, any portion of the portal that is to be clipped that is located in the back space of any anti-penumbra plane is clipped away. In the right most image we see that when the direction of the anti-penumbra is reversed and is instead constructed from the target portal to the source portal, the visible region on the opposite side of the target portal is now bounded by outward facing planes and as such, the function should clip away any section of the generator portal that is located in the front space of any of these planes. That is why we flick this Boolean switch with each call in the above section of code. We are informing the ClipToAntiPenumbra method as to whether the portal should be clipped to the back or front spaces of the anti-penumbra's clip planes respectively.

If we survive the clip tests performed in the previous section of code then it means the source portal can clearly see the generator portal and as such, we should recur through the generator portal into its neighbor leaf. Before doing that we store the new clipped source portal polygon and the clipped generator portal polygon in the PVSData structure (Data) and then pass it into the RecursePVS function to recur into the next leaf.

Below we show the remainder of the function that performs this task and shows the clean up of the temporarily clipped source and generator portals inside the bottom of the loop.

```
        // Store data for next recursion
        Data.SourcePoints = SourcePoints;
        Data.TargetPoints = GeneratorPoints;

        // Flow through it for real
        RecursePVS( GeneratorPortal->NeighbourLeaf, SourcePortal, Data );

        // Clean up
        FreePortalPoints( SourcePoints );
        FreePortalPoints( GeneratorPoints );

    } // Next Portal

    // Clean up
    if (Data.VisBits) delete []Data.VisBits;

    // Success
    return BC_OK;
}
```

When we reach the bottom of this loop we will have processed every generator portal in this leaf and will have calculated its contribution to the source portal's ActuaVis array. Before returning we release the Data.VisBits array which we allocated earlier.

ClipToAntiPenumbra - CProcessPVS

The ClipToAntiPenumbra function has the task of finding all separating planes that divide the source and target portals into opposing half spaces. Such a plane is a valid anti-penumbra plane which is used to clip the generator portal.

> **Note:** In this function we are using the term generator portal to refer to the portal passed in as the third parameter to this function. However, as we saw in the above code, this may be a pointer to either the actual source or generator portal depending on which clip test is being performed.

This function first sets up a loop to iterate through every edge in the source portal as shown below.

```
CPortalPoints * CProcessPVS::ClipToAntiPenumbra( CPortalPoints * Source,
                                                 CPortalPoints * Target,
                                                 CPortalPoints * Generator,
                                                 bool ReverseClip )
{
    CPlane3         Plane;
    CVector3        v1, v2;
    float           Length;
    ULONG           Counts[3];
    ULONG           i, j, k, l;
    bool            ReverseTest;
    CPortalPoints  *NewPoints;

    // Check all combinations
    for ( i = 0; i < Source->VertexCount; i++ )
    {
```

```
        // Build first edge
        l = ( i + 1 ) % Source->VertexCount;
        v1 = Source->Vertices[l] - Source->Vertices[i];
```

Loop variable ‘i’ describes the index of the first vertex in the edge we are testing and the ‘l’ local variable describes the index of the next vertex forming the edge. This is calculated as being i+1 with a modulus performed with the vertex count of the source polygon so that ‘l’ will wrap around to the first vertex for the last edge of the portal. Vector v1 is then calculated by subtracting vertex position l from i thus generating the current edge vector in the source portal we wish to process.

Now that we have an edge in the source portal we need to create a plane with that edge and every vertex in the target portal. Next we set up a loop to loop through each vertex in the target portal and create an additional vector v2. This is a vector from the one of the source vertices in the edge and the current vertex in the target portal we are processing. Vectors v1 and v2 are now vectors tangent to a plane generated from the source to the target portal so we will next perform the cross product between these two vectors to retrieve the normal of that plane.

```
        // Find a vertex belonging to the generator that makes a plane
        // which puts all of the vertices of the target on the front side
        // and all of the vertices of the source on the back side
        for ( j = 0; j < Target->VertexCount; j++ )
        {
            // Build second edge
            v2 = Target->Vertices[ j ] - Source->Vertices[ i ];
            Plane.Normal = v1.Cross( v2 );
```

Next we record the length of the returned normal (which has not yet been normalized) and if the length is found to be zero (with tolerance) it means we have an invalid plane so will continue to the next iteration of the loop where we will process the next target vertex.

```
            // If points don't make a valid plane, skip it
            Length = Plane.Normal.x * Plane.Normal.x +
                     Plane.Normal.y * Plane.Normal.y +
                     Plane.Normal.z * Plane.Normal.z;
            if ( Length < 0.1f ) continue;
```

If we get this far it means that we have a valid plane and as such we will normalize the plane normal and will calculated the plane’s distance from the origin by dotting the plane normal with the target vertex (which is a point known to be on the plane).

```
            // Normalize the plane normal
            Length = 1 / sqrtf( Length );
            Plane.Normal *= Length;

            // Calculate the plane distance
            Plane.Distance = -Target->Vertices[ j ].Dot( Plane.Normal );
```

At this point we have a valid plane so our next step is to test if this is a separating plane. That is, if it has the source portal completely contained in one half space and the target portal in the other. If not then this is not a valid an anti-penumbra plane. Figure 17.7 reminds us of what a separating plane looks like by

showing us both a separating plane and a non-separating plane. Only the plane generated in the leftmost image is a valid anti-penumbra clip plane and will be used to clip the generator portal.

Figure 17.7

Our first task in achieving this goal is to loop through each vertex in the source portal and classify it against our plane. As it was one of the source portal's vertices that was used to generate this plane, it is impossible to have vertices in the source portal located in both half spaces of the plane. Therefore, in this loop we are searching for the first vertex that is found in either the front or back half spaces at which point we can break. We know that if one of the vertices is contained in the front space of the plane then the entire polygon must be and likewise for the back half space. If the source portal is found to be located in the back half space of the plane we set the ReverseTest Boolean to false before breaking so that we know that when we test the target portal we are wishing it to be contained in the front half space. Alternatively, this Boolean is set to true if the source portal is found to be located in the front space of the plane meaning we wish to find the target portal located in the back space.

```
            // Find out which side of the generated separating plane has the source portal
            ReverseTest = false;
            for ( k = 0; k < Source->VertexCount; k++ )
            {
                // Skip if it matches other verts
                if ( k == i || k == l ) continue;

                // Classify the point
                CLASSIFYTYPE Location = Plane.ClassifyPoint( Source->Vertices[ k ] );
                if ( Location == CLASSIFY_BEHIND )
                {
                    // Source is on the negative side, so we want all pass
                    // and target on the positive side.
                    ReverseTest = false;
                    break;

                } // End If Behind
                else if ( Location == CLASSIFY_INFRONT )
                {
                    // Source is on the positive sode, so we want all pass
                    // and target on the negative side.
                    ReverseTest = true;
                    break;

                } // End if In Front

            } // Next Source Vertex
```

As the above loop has no conditional to deal with the on-plane case, if all its vertices are co-planar with the candidate plane then the loop will be allowed to carry out to its conclusion. This means outside the loop, the loop variable ‘k’ will be equal to the vertex count of the source portal. This tells us that the source portal is co-planar and as such, this plane could not possibly be a separating plane so we should skip it and continue on to test the next vertex in the target portal.

```
            // Planar with the source portal ?
            if ( k == Source->VertexCount ) continue;
```

In the next section we will loop through each vertex in the target portal and will classify it against the plane. Before doing so we test the value of the ReverseTest local Boolean and flip the direction of the plane normal if it is set to true. This allows us to treat the source portal as having existed in the back space of the plane (regardless of where it was actually located) which means in this code we are searching for a portal that has its vertices contained in the front space of the plane.

```
            // Flip the normal if the source portal is backwards
            if ( ReverseTest ) { Plane.Normal = -Plane.Normal;
                                 Plane.Distance = -Plane.Distance; }

            // If all of the pass portal points are now on the positive
            // side then this is the separating plane.
            ZeroMemory( Counts, 3 * sizeof(ULONG) );
            for ( k = 0; k < Target->VertexCount; k++ )
            {
                // Skip if the two match
                if ( k == j ) continue;

                // Classify the point
                CLASSIFYTYPE Location = Plane.ClassifyPoint( Target->Vertices[ k ] );
                if ( Location == CLASSIFY_BEHIND )
                    break;
                else if ( Location == CLASSIFY_INFRONT )
                    Counts[0]++;
                else
                    Counts[2]++;

            } // Next Target Vertex

            // Points on the negative side ?
            if ( k != Target->VertexCount ) continue;

            // Planar with separating plane ?
            if ( Counts[0] == 0 ) continue;
```

As you can see, as soon as we find a vertex that is situated behind the plane it means this portal is in the same half space of the plane as the source portal (pay attention to the flipping of the plane depending on the result of ReverseTest that allows us to make that determination). This means we break instantly as this is not a separating plane. If any vertices are found to exist in the front space of the plane then we increase the value of Counts[0].

Outside the loop we can see that if loop variable ‘k’ is not equal to the vertex count of the target portal it means we broke from the loop early after finding a vertex in the same half space of the source portal. This means this plane can not possibly separate the source and target portals into two half spaces so we continue on to the next iteration of the loop and the next plane to test. We can also see that if Counts[0]

equal zero, it means we never incremented it in the loop meaning no vertex was every found to be in the front space of the plane either. This must mean the target portal is located on the candidate plane and as such, this can not possibly be a separating plane. Once again, if this is the case we skip any further processing of this plane and skip to the next iteration of the loop.

If we reach this point it means we have found a separating plane and the generator portal passed into the function should be clipped to it. Before doing so we test the value of the ReverseClip parameter remembering that if this is set to true then the caller would like us to clip away portal fragments that are in the front space of the separating plane instead of in the back space as is usually the case. We address this by simply flipping the direction of the clip plane prior to clipping the portal.

As the next and final section of this function shows, we clip the generator portal to the clip plane and if we find that a new portal was created by the clip procedure, the original portal (Generator) is released. We then assign the passed Generator portal pointer to point at the new clipped polygon returned from the clipping function instead. In the last line of the loop for this plane, we test that the Generator has not been assigned a value of NULL and if so, it means we must have completely clipped away the generator portal with this plane and as such, the generator portal is outside the anti-penumbra and NULL is returned.

```
            // Flip the normal if we want the back side
            if ( ReverseClip ) { Plane.Normal = -Plane.Normal;
                                 Plane.Distance = -Plane.Distance; }

            // Clip the target by the separating plane
            NewPoints = Generator->Clip( Plane, false );
            if ( NewPoints != Generator ) FreePortalPoints( Generator );
            Generator = NewPoints;

            // Target is not visible ?
            if (!Generator) return NULL;

        } // Next Target Vertex

    } // Next Source Vertex

    // Success!!
    return Generator;
}
```

The bottom of the function is only ever reached if some portion of the generator portal survived being clipped to all the separating planes generated in the above loops. This new clipped generator portal is returned from the function back to the caller.

Where Are We?

At this point we have covered the core PVS generation procedure that was invoked from the CProcessPVS::Process method via a call to the CalcPortalVis method. When the CalcPortalVis method returns program flow back to the Process method, every portal will have had its PVS generated. Let us have another look at the CProcessPVS::Process method to remind us of what is let to do.

```
HRESULT CProcessPVS::Process( CBSPTree * pTree )
{
    HRESULT hRet;

    // Validate values
    if (!pTree) return BCERR_INVALIDPARAMS;

    // Validate Input Data
    if ( pTree->GetPortalCount() == 0 ) return BCERR_BSP_INVALIDTREEDATA;

    // Store tree for compilation
    m_pTree = pTree;

    // Calculate Number Of Bytes needed to store each leafs
        // vis array in BIT form (i.e 8 leafs vis per byte uncompressed)
    m_PVSBytesPerSet = (pTree->GetLeafCount() + 7) / 8;

    // 32 bit align the bytes per set to allow for our early out long conversion
    m_PVSBytesPerSet = (m_PVSBytesPerSet * 3 + 3) & 0xFFFFFFFC;

    // Retrieve all of our one way portals
    hRet = GeneratePVSPortals();

    if ( FAILED( hRet ) ) return hRet;
    if ( m_pParent->GetCompileStatus() == CS_CANCELLED ) return BC_CANCELLED;

    // Calculate initial portal visibility
    hRet = InitialPortalVis();

    if ( FAILED( hRet ) ) return hRet;
    if ( m_pParent->GetCompileStatus() == CS_CANCELLED ) return BC_CANCELLED;

    // Perform actual full PVS calculation
    hRet = CalcPortalVis();

    if ( FAILED( hRet ) ) return hRet;
    if ( m_pParent->GetCompileStatus() == CS_CANCELLED ) return BC_CANCELLED;

    // Export the visibility set to the final BSP Tree master array
    hRet = ExportPVS( pTree );

    if ( FAILED( hRet ) ) return hRet;
    if ( m_pParent->GetCompileStatus() == CS_CANCELLED ) return BC_CANCELLED;

    // Success
    return BC_OK;
}
```

As you can see, we have covered all methods in the process with the exception of the final one called ExportPVS. It is this method, which we will look at next, that is responsible for combining the PVS data

for each portal that resides in a given leaf to generate the PVS for that leaf in the BSP tree. This method will also compress the data using zero run length encoding and will store in the leaves of the BSP tree the index into which each leaf's visibility data begins in the master PVS data block

ExportPVS - CProcessPVS

At the time this function is called each portal will contain its own PVS in its ActualVis array. However, our PVS rendering code will not be interested in what each of the portals can see and in fact, there is no need for the portals to even be saved to file. Our PVS renderer wants to know what each leaf can see and it is this function that takes care of building the master PVS data block that will be stored in the BSP tree and will describe the visibility sets for each leaf instead of each portal.

Now that we have the visibility sets for each portal, determining what each leaf can see is trivial. The PVS of a leaf is simply the accumulation of the PVS's of each portal that resides in that leaf and as such can be calculated with a simple loop at each leaf.

Let us cover the function a section at a time. The first section of the function writes out logging information to the PVS channel describing whether it is going to create a compressed leaf PVS or whether it will calculate the leaf PVS for the BSP tree as an uncompressed bit set (this is controller by a #define).

```
HRESULT CProcessPVS::ExportPVS( CBSPTree * pTree )
{
    UCHAR * PVSData = NULL;
    UCHAR * LeafPVS = NULL;
    ULONG   PVSWritePtr = 0, i, p, j;

    try
    {
        // ************************
        // * Write Log Information *
        // ************************
        if ( m_pLogger )
        {

            #if ( PVS_COMPRESSDATA )
                m_pLogger->LogWrite( LOG_PVS,
                                     0,
                                     true,
                                     _T("ZRLE compressing PVS data for export \t\t- " ) );
            #else
                m_pLogger->LogWrite( LOG_PVS,
                                     0,
                                     true,
                                     _T("Building final PVS data for export \t\t- " ) );
            #endif

            m_pLogger->SetRewindMarker( LOG_PVS );
            m_pLogger->LogWrite( LOG_PVS, 0, false, _T("0%%" ) );
            m_pLogger->SetProgressRange( pTree->GetLeafCount() );
            m_pLogger->SetProgressValue( 0 );
        }
        // ************************
        // *    End of Logging    *
```

```
        // ************************
```

Notice that the progress range of the logger in the above code is set to the number of leaves in the passed BSP tree. That is because this process will be complete once we have looped through each leaf in the BSP tree and have calculated its PVS and added it to a master PVS array.

Our next step is to allocate some memory that will be used to store the master PVS data array. This must be large enough to store the visibility for every leaf in the tree in compressed format. One might imagine that if m_PVSBytesPerSet contains the number of bytes needed to store a leaf's visibility information in uncompressed format, then we can allocate an array large enough to store LeafCount*m_PVSBytesPerSet bytes. This should always be large enough to store everything we need as it is large enough to store a visibility set for each leaf in uncompressed format. Is that correct?

Well, in practice yes that will almost definitely be the case and in fact this array will be much larger than we actually need once the data is compressed. That doesn't matter though because after we have compressed the data we can resize the array to its correct actual size. However, look at how we allocate this array and initialize its memory.

```
        // Reserve Enough Space to hold every leafs PVS set
        PVSData = new UCHAR[pTree->GetLeafCount() * (m_PVSBytesPerSet*2)];
        if (!PVSData) throw std::bad_alloc();

        // Set all visibility initially to off
        ZeroMemory( PVSData, pTree->GetLeafCount() * (m_PVSBytesPerSet*2));
```

Why are we multiplying m_PVSBytesPerSet by 2 before multiplying it with the tree's leaf count? Although incredibly unlikely, there is very slim chance that compressing our data using ZRLE could actually make it larger than in its uncompressed format. Imagine for example we had 6 bytes in each of our visibility sets and the 2^{nd}, 4^{th} and 6^{th} bit were set to zero.

Leaf Set = N , 0 , N , 0 , N , 0

Imagining that N is some placeholder for a non zero byte in a leaf's PVS. We know that ZRLE encoding will try to compress runs of zero bytes by collapsing those runs in to two bytes. The first is the zero itself and the second is the byte that tells us how many bytes of zero the run represents. However, in the above scenario there are no runs of zeros and as such, an additional byte (the run byte) would be inserted after each zero describing a run of 1. Obviously this provides no benefit and actually would increase the size of our 6 byte visibility array to a 9 byte array.

Leaf Set = N , 0 , 1 , N , 0 , 1 , N , 0 , 1

Therefore we can see that in the most unusual circumstances we may generate a compressed PVS that is larger than its uncompressed counterpart and in the most appalling of circumstances, compressing the PVS could actually double its size.

> **Note:** it should be noted that the above scenario is very unlikely as the PVS by its very nature in an occluded environment will generate leaf based PVS sets where most of the other leaves of not visible and as such, huge runs of zeros will be compressed into only two bytes providing us with huge memory

savings in nearly every case. However, as it is ***possible*** that we could double its size by compressing it, we had better allocate the PVS data block large enough to handle it so that our compiler does not crash and burn mid way through the compression procedure.

With the master PVS data array allocated we will now allocate a temporary buffer that will be used by each leaf to accumulate and collect the combined ActualVis arrays of each portal contained in that leaf. This buffer should be large enough to store an uncompressed bit set for each leaf. That is, this buffer should be equal in size to the portal's ActualVis array.

```
        // Allocate enough memory for a single leaf set
        LeafPVS = new UCHAR[ m_PVSBytesPerSet ];
        if (!LeafPVS) throw std::bad_alloc();
```

Now we will loop through each leaf in the tree. Inside the loop we will use the loop variable to fetch from the BSP tree the structure of the leaf we are currently processing. We also update the progress of the logger which is incremented on a per leaf bases.

```
        // Loop round each leaf and collect the vis info
        // this is all OR'd together and ZRLE compressed
        // Then finally stored in the master array
        for ( i = 0; i < pTree->GetLeafCount(); i++ )
        {
            CBSPLeaf * pLeaf = pTree->GetLeaf(i);

            // Update progress
            if (!m_pParent->TestCompilerState()) break;
            if ( m_pLogger ) m_pLogger->UpdateProgress( );
```

In the next step we will initialize the temporary LeafPVS buffer to zero prior to collecting the visibility sets of each of its portals into it. We also set the PVSIndex member of the leaf to that of the value stored in the PVSWritePtr local variable. We will see in a moment that this variable will be increased each time we compress the PVS data for a leaf and add it to the master PVS data block and as such, it will always describe the index into this array where the compressed PVS data of the leaf we are about to process will be placed into this array. We also set the visibility bit in the LeafPVS buffer for the current leaf we are processing as it can obviously see itself.

Note: PVSWritePtr is zero the first time this loop executes which describes leaf 0's PVS as starting at the very beginning of the master PVS data array

```
            // Clear Temp PVS Array Buffer
            ZeroMemory( LeafPVS, m_PVSBytesPerSet );
            pLeaf->PVSIndex = PVSWritePtr;

            // Current leaf is always visible
            SetPVSBit( LeafPVS, i );
```

Now we loop through every portal in this leaf and use the familiar methods to retrieve the index of the one-way portal that it represents.

```
            // Loop through all portals in this leaf
            for ( p = 0; p < pLeaf->PortalIndices.size(); p++ )
            {
```

```
                // Find correct portal index (the one IN this leaf)
                ULONG PortalIndex = pLeaf->PortalIndices[ p ] * 2;
                if ( GetPVSPortal( PortalIndex )->NeighbourLeaf == i ) PortalIndex++;
```

At this point we have a pointer to the current portal so we will loop through each byte in its ActualVis array and will bitwise OR it with the current contents of the LeafPVS buffer so that the necessary visibility bits are enabled.

```
                // Or the vis bits together
                for ( j = 0; j < m_PVSBytesPerSet; j++ )
                {
                        LeafPVS[j] |= GetPVSPortal( PortalIndex )->ActualVis[j];

                } // Next PVS Byte

            } // Next Portal
```

At this point the LeafPVS buffer contains the complete uncompressed PVS set for the current leaf that we are processing so our next task is to store this in the master PVSData array. If compression has not been enabled then we literally just copy the information stored in LeafPVS into the master data array at the location contained in PVSWritePtr and then increase the write pointer by the size of the LeafPVS array. This is done so that when we process the next leaf, it will contain an index to the location where its data should be copied to in the master PVS data array. However, if we have chosen to compress the data set then the data is added to the master PVSData array using a function called CompressLeafSet as shown below.

```
            #if ( PVS_COMPRESSDATA )

                // Compress the leaf set here and update our master write pointer
                PVSWritePtr += CompressLeafSet( PVSData, LeafPVS, PVSWritePtr );

            #else

                // Copy the data into the Master PVS Set
                memcpy( &PVSData[ PVSWritePtr ], LeafPVS, m_PVSBytesPerSet );
                PVSWritePtr += m_PVSBytesPerSet;

            #endif

        } // Next Leaf
```

The CompressLeafSet method will be discussed in a moment but for now just know that it is passed the master PVSData array as its first parameter as this is where the function will need to copy the compressed data into. As the second parameter we will pass the LeafPVS buffer which contains the uncompressed PVS for the current leaf. This is the data that the function will compress and copy into the PVSData array. As the third parameter we pass the write pointer index value which describes the starting location in the PVSData array where the new compressed data should be written to. As this function returns the size that the passed LeafPVS data array was ultimately compressed to, we can use this value to increment the write pointer value on function return so that it contains the index of the first byte after the block of data we have just added. This will be the starting location for the next leaf's compressed data and the byte at which its PVS data will begin in the master array.

At this point we will have compressed every leaf's PVS and stored it in the PVSData array and each leaf in the tree will also have had its PVSIndex member set so that it describes the index of the first byte in this array where its visibility information begins. We can now delete the LeafPVS buffer as it is no longer needed and can call the BSP tree's SetPVSData method (discussed earlier) so that it can make a copy of the PVSData array we haven just compiled.

```
        // Clean up after ourselves
        delete []LeafPVS;
        LeafPVS = NULL;

        // Pass this data off to the BSP Tree (data, size, compressed)
        if (FAILED(pTree->SetPVSData( PVSData,
                                      PVSWritePtr,
                                      PVS_COMPRESSDATA ))) throw std::bad_alloc();

        // Free our PVS buffer
        delete []PVSData;

        // If we're cancelled, bail
        if ( m_pParent->GetCompileStatus() == CS_CANCELLED ) return BC_CANCELLED;

    } // End Try Block

    catch (...)
    {
        // Clean up and return (Failure)
        if ( LeafPVS ) delete []LeafPVS;
        if ( PVSData ) delete []PVSData;
        if ( m_pLogger ) m_pLogger->ProgressFailure( LOG_PVS );
        return BCERR_OUTOFMEMORY;

    } // End Catch Block

    // Success!!
    if ( m_pLogger ) m_pLogger->ProgressSuccess( LOG_PVS );
    return BC_OK;
}
```

Recall that the CBSPTree::SetPVSData method will make a copy of the passed PVS data array and by passing in PVSWritePtr as the second parameter we also inform it of the final size of the compressed data. As it uses this to allocate its PVS array this means that whilst the PVSData array allocated in this function may have been allocated much larger than necessary, the actual array stored in the PVS tree will be the correct size. The CBSPTree::SetPVSData method copies over all the PVS data into its own array and therefore, on function return we can delete the local PVSData array as it is no longer needed. The third parameter to the SetPVSData method simply informs the function that the data is compressed which the run time component will need to know when reading the PVS data at render time.

CompressLeafSet - CProcessPVS

This method is passed as its first parameter a master PVS data buffer that the compressed data will be copied into and as its 3rd parameter the location within this array where we should start writing the compressed data. As the second parameter the uncompressed PVS of a single leaf of passed. This is the data that is to be compressed.

The function first sets up a loop to iterate through every byte in the passed PVS set (VisArray).

```
ULONG CProcessPVS::CompressLeafSet ( UCHAR MasterPVS[],
                                     const UCHAR VisArray[],
                                     ULONG WritePos)
{
    ULONG   RepeatCount;
    UCHAR  *pDest = &MasterPVS[ WritePos ];
    UCHAR  *pDest_p;

    // Set dynamic pointer to start position
    pDest_p = pDest;

    // Loop through and compress the set
    for ( ULONG j = 0; j < m_PVSBytesPerSet; j++ )
    {
        // Store the current 8 leaves
        *pDest_p++ = VisArray[j];

        // Don't compress if all bits are not zero
        if ( VisArray[j] ) continue;
```

pDest_p is used to point at the current byte in the master PVS data array (passed as the first parameter) that we are currently copying information into. As you can see in the first line inside the loop in the above code, we copy the contents of the current byte being processed in the leaf set (VisArray) into the master PVS data array. In the bottom line in the above code we can see that after copying over this byte we test to see if it was zero or not. If it isn't zero then this byte has visible leaves in its bitset and can not be compressed. This means we can just skip to the next byte in the buffer having copied over this byte into the master array.

If we make it past the last line in the above code however, it means the current byte we have just copied over is a zero byte and therefore we must set up a loop to see how many zero bytes follow it. Once we have counted the run of zeros, we can simply insert this run length byte into the master PVS data array just after the zero byte we just copied over. Here is the remainder of the function.

```
        // Count the number of 0 bytes
        RepeatCount = 1;
        for ( j++; j < m_PVSBytesPerSet; j++ )
        {
            // Keep counting until byte != 0 or we reach our max repeat count
            if ( VisArray[j] || RepeatCount == 255) break; else RepeatCount++;

        } // Next Byte

        // Store our repeat count
        *pDest_p++ = (UCHAR)RepeatCount;
```

```
        // Step back one byte because the outer loop
        // will increment. We are already at the correct pos.
             j--;

    } // Next Byte

    // Return written size
    return pDest_p - pDest;
}
```

As you can see, we loop from our current byte position through the bytes that follow counting how many zero bytes we encounter in a continuous run. The RepeatCount is set to 1 to begin with as before this loop we only know of one zero that exists, the zero byte we just copied over. In the middle of this inner loop you can see that we break from the loop as soon as a non-zero byte is encountered or if the repeat count reaches 255 which is the highest run length value we can store in a byte. Otherwise, for each consecutive zero byte we find in the run we increment the repeat count.

Outside the inner loop, RepeatCount will contain the length of the run of zeros that were found starting from the original zero byte we copied into the master array. We then write this run length into the PVS data buffer (pDest_p).

Finally, we return from the function the total size of the data we managed to compress by subtracting from pDest_p, which contains the address of the last byte we have just written to the PVS data array, the value of pDest which contains the address of the first byte that was written by this function. That is, we return the number of bytes of compressed data that we have written to the PVS data array.

Conclusion

Writing a portal and PVS compiler has perhaps been our most challenging task to date. However, our compiler tool has now evolved into something quite significant. You are certainly not expected to grasp every nuance of the code we have written in this chapter after a single read through the work book however, using this book as an aid to help you navigate the source code will have you up to speed on exactly how all this stuff works in no time at all.

It is nice that the ultimate work book in this course was dedicated to writing such a useful and reusable tool and that the data generated by such a tool will certainly be used in GP3 where it will be used in conjunction with a more complete graphics engine. When using complex pixel shaders with multiple passes (as we will be in GP3), reducing overdraw has once again become a premier design goal. The more wonderful and complex these programmable pixel shaders are, the more strain is placed on the 3D hardware for each pixel that it renders. Using a PVS we can make sure that our 3D hardware does not grind to a halt spending most of its time performing multiple passes on pixels that are occluded and can not even be seen. If it has not become apparent to you yet, let me just say that by developing this tool and the means to render its data, we have overcome a huge obstacle in game engine development. The ability to render only the small region of the scene that is currently visible from the camera. Our games can now spend that GPU processing power rendering high detail objects in the immediate vicinity instead of rendering an abundance of low detail objects that can never been seen but are rendered anyway.

The lab projects in this course have certainly become rather large at times but we have many re-usable modules in place now and have acquired many techniques that were necessary to learn before we could even start to construct a real graphics engine. We are certainly ready for Graphics Programming with DirectX Part III.
