Graphics Programming with Direct X 9

Module II

(14 Week Lesson Plan)

Lesson 1: Meshes

Textbook: Chapter Eight (pgs. 2 – 77)

Goals:

The course begins by introducing some of the important mesh containers provided by the D3DX library. Discussion will center on performance issues, including attribute batching across mesh boundaries and subset rendering, as well as optimization techniques that speed up rendering on modern hardware. From there we will look at how to import X file geometry into our applications as well as how to construct and fill the mesh buffers manually. This will lead into a discussion of cloning (copying) mesh data and some of the features that can be exploited in the process. The next topic of discussion will be the management of geometric level of detail using view independent progressive meshes. We will look at how to construct and use progressive meshes and see how they work algorithmically. This will lead into an examination of one-off mesh simplification and how it can be done with D3DX support. We will conclude this lesson with a quick overview of a number of useful mesh utility functions.

Key Topics:

- ID3DXMesh Interface
  - Vertex/Index/Adjacency Buffers
  - Attribute Buffers and Subset Rendering
- Mesh Optimization
- ID3DXBuffer
- Mesh Loading
- Manual Mesh Creation
- Mesh Cloning
- ID3DXPMesh Interface
  - View Independent Progressive Meshes (VIPM)
  - Data Validation and Cleaning
  - Setting LOD
  - LOD Trimming
  - Vertex History
- ID3DXSPMesh Interface
- Global Mesh Utility Functions

Projects:

Lab Project 8.1: The CTriMesh Class (Mesh Viewer I)

Exams/Quizzes: NONE

Recommended Study Time (hours): 8 - 10

Lesson 2: Frame Hierarchies

Textbook: Chapter Nine (pgs. 2 – 87)

Goals:

In this lesson we will now look at how to import and manage more complex 3D models and scenes. We will introduce the concepts of frame of reference and parent-child hierarchical relationships and see how we can use these ideas to build elaborate scenes consisting of independent, animation-ready meshes. Early on in the process we will delve into the inner workings of X file templates to see how scene data is stored. This will set us up for a discussion of the very important D3DXLoadMeshHierarchyFromX function, which we will use many times in the coming lessons. Using this function properly will require an examination of the callback mechanisms and data structures used for application memory management. We will even talk about how to load custom data chunks. Finally, we will wrap up the lesson with a look at how to traverse, transform, and render a hierarchy of meshes. A very simple animation controller will be introduced during the process and in our lab project to setup our discussions in the next lesson.

Key Topics:

- Hierarchies
  - Frame of Reference
  - Parent/Child Relationships
- X File Templates
  - Open/Closed/Restricted Templates
  - Hierarchical X Files
- D3DXLoadMeshHierarchyFromX
- ID3DXAllocateHierarchy Interface
  - Allocating/De-allocating Frames
- ID3DXMeshContainer Interface
  - Allocating/De-allocating Mesh Containers
- Extending Hierarchy Data Types
- ID3DXLoadUserData Interface
  - Loading Custom Top-Level Data
  - Loading Customer Child Data
- Hierarchy Traversal and Rendering
- Simple Hierarchy Animation

Projects:

Lab Project 9.1: The CActor Class (Mesh Viewer II)

Exams/Quizzes: NONE

Recommended Study Time (hours): 10 - 12

Lesson 3: Keyframe Animation I

Textbook: Chapter Ten (pgs. 2 – 64)

Goals:

In this lesson our goal will be to learn the fundamentals of animating game scenes. The primary focus will be on using keyframe data to animate the hierarchies introduced in the previous lesson. Our initial discussions will take us back into the inner workings of X file templates, where we will learn about the various ways that animation data can be represented and how it all translates into D3DX data structures. From there we will begin our exploration of the powerful animation system available in DirectX. This exploration will involve understanding how the animation controller interpolates keyframe data and how that process can be controlled using various subsystems in the controller. Along the way we will examine the construction of a custom animation set object that can be plugged into the D3DX animation system.

Key Topics:

- Animation Blending
  - The Animation Mixer
    - Setting track weight, speed, priority
    - Enable/Disable Tracks
  - Priority Blending
- Animation Controller Cloning
- The Animation Sequencer
  - Registering Events
  - Event Handles
- The Animation Callback System
  - Callback keys and animation sets
  - Executing callback functions
  - ID3DXAnimationCallbackHandler Interface

Projects:

Lab Project 10.1: Animated CActor (Mesh Viewer III)
Lab Project 10.2: The Animation Splitter

Exams/Quizzes: NONE

Recommended Study Time (hours): 10 – 12

Lesson 4: Keyframe Animation II

Textbook: Chapter Ten (pgs. 64 – 114)

Goals:

In this lesson our goal will be to continue our discussion of animation fundamentals by examining some different animation controller subsystems. The first major controller subsystem encountered will be the animation mixer, where we will learn about the important topic of blending multiple simultaneous animations. After learning how to use the mixer and configure its tracks for blending, we will conclude our discussions by looking at how to setup various user-defined special events using both the animation sequencer and the animation callback system. These features will allow us to sync together our animation timeline with events like playing sound effects or triggering specific pieces of function code.

Key Topics:

- Animation Blending
  - The Animation Mixer
    - Setting track weight, speed, priority
    - Enable/Disable Tracks
  - Priority Blending
- Animation Controller Cloning
- The Animation Sequencer
  - Registering Events
  - Event Handles
- The Animation Callback System
  - Callback keys and animation sets
  - Executing callback functions
  - ID3DXAnimationCallbackHandler Interface

Projects:

Lab Project 10.1: Animated CActor (Mesh Viewer III) cont.
Lab Project 10.2: The Animation Splitter cont.

Exams/Quizzes: NONE

Recommended Study Time (hours): 10 – 12

Lesson 5: Skinning I

Textbook: Chapter Eleven (pgs. 2 – 115)

Goals:

In this lesson we will finally integrate animated game characters into our framework. This will build on all of the topics covered in the prior lessons including meshes, hierarchies, and the animation system. We will begin our examination by looking at some of the methods used for animating game characters in older games. What we learn will lead us straight into the idea of skinning and skeletal animation as a means for providing more realistic visual results. We will learn all about what skins and skeletons are, how they are constructed, and how they can be animated and rendered. As before we will look at the X file data templates and see how these translate into our game data structures. Then we will examine the various skinning options available via D3D. This will include detailed examinations of software skinning and hardware skinning; both non-indexed and palette-driven indexed skinning techniques.

Key Topics:

- Vertex Tweening
- Segmented Models and Animation
- Bone Hierarchies/Skeletons
- Vertex Blending
- Skinning
- X File Templates for Skinning
- The Bone Offset Matrix
- Software Skinning
- ID3DXSkinInfo Interface
- Non-Indexed Skinning
    - Setting multiple world matrices
    - Enabling/disabling vertex blending
    - ConvertToBlendedMesh
- Indexed Skinning
    - Determining Support
    - Matrix Palette Indices
    - ConvertToIndexedBlendedMesh
- Transforming and Rendering Skinned Characters

Projects:

Lab Project 11.1: Skinned CActor (Mesh Viewer IV)
Lab Project 11.2: The Animation Splitter II

Exams/Quizzes: NONE

Recommended Study Time (hours): 10 - 12

Lesson 6: Skinning II

Textbook: Chapter Twelve (pgs. 2 – 160)

Goals:

In this lesson we will conclude our exploration of skinning and animation by taking a different angle from the prior lesson. This time, rather than load skinned characters from an X file, we are going to construct an entire skeleton and skin model programmatically. The end result will be a robust tree class that we can use to generate realistic looking animated trees for populating our outdoor landscape scenes. Since this is the halfway point in the course, we are also going to make an effort to bring together much of what we have learned to date into a single demonstration lab project. One important focus in this second lab project will be the extension of our middle-tier to include data driven support between our application and the D3DX animation system. This upgraded system will handle animation switching, blending, and the other key areas that are necessary to simplify the communication pipeline between the application and the low level animation code. This will allow students to more easily integrate animation support into their game projects and have their AI or user-input systems interact and control the process.

Key Topics:

- Trees
  - Procedural Skins and Skeletons
  - Procedural Keyframe Animation
- The Animation Middle Layer
  - Data Driven File Support
  - Animation Set Blending
  - Controller Configuration
  - Playing Back Complex Animations

Projects:

Lab Project 12.1: The CTreeActor Class (Mesh Viewer V)
Lab Project 12.2: Summary Lab Project

Exams/Quizzes: NONE

Recommended Study Time (hours): 10 – 12

Lesson 7: Midterm Exam Preparation and Review

Textbook: Chapters 8 - 12

Goals:

The midterm examination in this course will consist of 50 multiple-choice and true/false questions pulled from the first five textbook chapters. Students are encouraged to use the lecture presentation slides as a means for reviewing the key material prior to the examination. The exam should take no more than two hours to complete. It is worth 30% of the final grade.

Office hours will be held for student questions and answers.

Key Topics:

Projects: NONE

Exams/Quizzes: Midterm Examination (50 questions)

Recommended Study Time (hours): 12 - 15

Lesson 8: Collision Systems I

Textbook: Chapter Thirteen

Goals:

In the second half of the course students will begin to explore important generic topics in the area of game engine design. While we will not conclude our game engine design studies until Module III, we will begin to lay the foundation for most of the core systems. In this lesson and the next we will undertake the development of a robust collision detection and response system. We begin with an overview of collision detection and look at the difference between broad and narrow phase algorithms. From there we will explore a sliding response system that is a staple of many first and third person games. After we have tackled the overall system architecture, including the management of geometry, we will introduce the concept of ellipsoid space and see how it will be used to facilitate the entire process. Then we will start our examination of the intersection algorithms that are going to be used in the narrow phase of our collision detection engine. We will talk about rays, what they are and how they can be tested against common game primitives. Then we will begin to look at how spheres can be tested against triangle interiors. This will lead into the additional testing algorithms covered in the next lesson.

Key Topics:

- Collision Systems Overview
- Broad Phase vs. Narrow Phase Collision Detection
- Collision Response
  - Sliding
- Ray Intersection Testing
  - Ray vs. Plane
  - Ray vs. Polygon
- Ellipsoids, Unit Spheres, and Ellipsoid Space
- Swept sphere vs. Triangle

Projects:

Lab Project 13.1: Collision System

Exams/Quizzes: NONE

Recommended Study Time (hours): 10 - 12

Lesson 9: Collision Systems II

Textbook: Chapter Thirteen

Goals:

In this lesson we will complete the development of our collision detection and response system. Since intersection testing is fundamentally about solving equations, we will begin by reviewing the concept of quadratic equations and some of the fundamental mathematics used during the detection phase. Quadratic equations are used in a number of our system's most important routines, so this overview should prove helpful to students who have forgotten some of this basic math. This will ultimately lead into an examination of intersection testing between swept spheres and the edges and vertices of our triangles. This is where we will wrap up our core routines for the narrow phase tests against static objects and environments. Once done, we will move on to discuss the means for colliding against dynamic objects that are part of the game environment. Dynamic object support will require a number of upgrades to both the detection and response stages in our code.

Key Topics:

- Quadratic Equations
- Swept Sphere Intersection Testing
  - Swept Sphere vs. Edge
  - Swept Sphere vs. Vertex
- Animation and the Collision Geometry Database
- Dynamic Object Collision Support

Projects:

Lab Project 13.1: Collision System

Exams/Quizzes: NONE

Recommended Study Time (hours): 10 - 12

Lesson 10: Spatial Partitioning I

Textbook: Chapter Fourteen

Goals:

In this lesson we will introduce some of the most important data structures and algorithms that are used to improve game engine performance. We will begin with simple axis-aligned hierarchical spatial partitioning data structures like quadtrees, octrees, and kD-trees. These systems will allow us to introduce broad phase collision detection into the system we developed in the prior lessons. Once done, we will introduce the very popular non axis-aligned spatial subdivision technique called binary space partitioning (BSP). BSP trees will actually be used in the next few lessons of the course to accomplish some very important ends, but for now only basic theory will be covered. The goal in our lab project will be to create a single base class with a core set of polygon querying functionality (intersection testing) and a set of derived classes for all tree types. This will allow students to mix and match the tree types as it suits the needs of their own projects.

Key Topics:

- Spatial Partitioning Data Structures/Algorithms
  - Quadtrees
  - Octrees
  - kD Trees
  - BSP Trees
- Polygon Clipping
- Polygon Database Intersection Querying
  - Ray/AABB/Sphere testing
- Broad Phase Implementation for Collision System

Projects:

Lab Project 14.1: Broad Phase Collision Detection

Exams/Quizzes: NONE

Recommended Study Time (hours): 10 - 12

Lesson 11: Spatial Partitioning II

Textbook: Chapter Fourteen

Goals:

In the last lesson we introduced some of the core partitioning structures that are used to improve game engine performance. Our prior focus was on the means for assembling the tree data structures and for traversing them to do polygon queries. This allowed us to add the very crucial broad phase to our collision detection system. In this lesson we will examine another aspect of using these trees – rendering. Hardware friendly rendering is an important idea that students need to think about when designing their partitioning systems. This can be a challenging thing to accomplish and there are many considerations, so this is something we will examine in this lesson. We will also introduce some additional concepts to speed up scene rendering by exploiting the hierarchical nature of our data during frustum culling and integrating the idea of frame coherence to add some additional optimization. Finally, we will look at using a BSP tree to perform accurate front to back sorting for rendering transparent polygons.

Key Topics:

- Accurate Alpha Polygon Sorting
- Frame Coherence
- Hardware Friendly Rendering
    - Static vs. Dynamic Solutions
    - Polygon Caches (Pros/Cons)
- Hierarchical Frustum Culling/Rendering

Projects:

Lab Project 14.2: Hierarchical Scene Rendering w/ BSP Alpha Sorting

Exams/Quizzes: NONE

Recommended Study Time (hours): 10 - 12

Lesson 12: Spatial Partitioning III

Textbook: Chapter Fifteen

Goals:

This lesson will conclude our studies of spatial partitioning techniques and begin the transition into the development of potential visibility sets. We will begin by learning how to add solid and empty space information to our BSP tree representation. This will provide the foundation for a number of important tasks that follow in this lesson and the next. With that code in place, we will look at how to build BSP trees out of scene brushes in order to perform constructive solid geometry (CSG). The CSG techniques we study will allow for merging together of geometric objects, carving shapes out of other shapes, and other interesting dynamic tasks. We will conclude the lesson by introducing the concept of portals, the first step towards development of PVS. We will look at how to generate them, split them, and remove any duplicates.

Key Topics:

- Solid Leaf BSP Trees
  - Rendering
  - Line of Sight
- Constructive Solid Geometry (CSG)
  - Union/Intersection/Difference Operations
- Portal Generation
  - Portal Splitting

Projects:

Lab Project 15.1: Solid Leaf Tree Compiler/Renderer
Lab Project 15.2: CSG Operations

Exams/Quizzes: NONE

Recommended Study Time (hours): 10 – 12

Lesson 13: Spatial Partitioning IV

Textbook: Chapter Fifteen

Goals:

Our final lesson will complete the development of our first performance oriented game engine design. We will begin by looking at the process of calculating potential visibility sets. The first step is the discussion of penumbras and anti-penumbras and how volumetric lighting models can be used to determine visibility. Using the portals created in the last lesson we will model the flow of light through the scene to mark off areas of shadow and light. This will provide enough information to be able to draw conclusions about visible areas in the level. After we have calculated our PVS, we will look at how to compress the information and then use it to efficiently render our scenes. We will conclude the lesson with a look at a different approach to BSP tree compilation. Since illegal geometry can corrupt the BSP building process, we will look at methods that allow us to avoid these problems and at the same time generate BSP trees and PVS for just about any type of scene our artists can create. These BSP trees will not use the level polygons as the means for compilation, but will instead use artist-generated simplified primitives that bound the actual level data. With fast rendering technology, efficient collision detection, spatial subdivision, and geometry and animation support all in place, students will be fully ready to wrap up their game engine development studies in Module III.

Key Topics:

- Potential Visibility Sets
  - Zero Run Length Encoding
  - Scene Rendering
- Anti-Penumbras
  - Generator Portal Visibility
  - Portal Flow
- Polygon-less BSP Trees
  - Illegal Geometry

Projects:

Lab Project 16.1: The BSP/PVS Compiler
Lab Project 16.2: Final Project

Exams/Quizzes: NONE

Recommended Study Time (hours): 12 - 15

Lesson 14: Final Exam Preparation and Review

Textbook: NONE

Goals:

The final examination in this course will consist of 75 multiple-choice and true/false questions pulled from all textbook chapters. Students are encouraged to use the lecture presentation slides as a means for reviewing the key material prior to the examination. The exam should take no more than three hours to complete. It is worth 70% of the final grade.

Office hours will be held for student questions and answers.

Key Topics:

Projects: NONE

Exams/Quizzes: NONE

Recommended Study Time (hours): 12 - 15

Chapter Eight

Meshes

Introduction

In Graphics Programming Module I we created our own mesh class (CMesh) to manage model geometry. While this is certainly an acceptable approach and can be useful for many tasks, the D3DX library provides a collection of mesh types that provide some key advantages over our simple vertex/index buffer wrapper class. This chapter will examine some of the core D3DX mesh types and we will learn how to work with them in our game development projects.

Some key features of D3DX provided meshes are:

Optimization: D3DX mesh objects are more than simple wrappers around a vertex and index buffer. They include important optimization features that allow for more efficient batching and rendering. These features alone make using D3DX mesh objects an attractive choice. Although D3DX mesh objects fully encapsulate batch rendering of their triangles, you are not required to use these features. If you wanted to store and render your meshes using proprietary mesh classes, you could use a D3DX mesh object to temporarily store and optimize your data for faster rendering with minimum state changes and better vertex cache coherency. Once done, you could lock the buffers and copy the optimized data back into your own mesh class and then destroy the D3DX mesh.

Asset Support: DirectX Graphics uses the X file as its native geometry file format for loading and storing 3D objects. Although we can store geometry in any file format we please, we are responsible for writing code to parse the data in that file and store it in our meshes. The X file format is flexible enough to store a wide variety of information, including complete scene hierarchies. While DirectX Graphics provides interfaces to help manually load and parse X file data structures, this is really not a task that will be relished by the uninitiated. Fortunately, we do not have to worry too much about that since the D3DX library provides functions that automate X file loading and data storage. With a single function call, we can load an X file and wind up with a 'ready to render' D3DX mesh, saving us a good deal of work. The X file format is now supported by most popular commercial 3D modeling applications, so we will be able to import high quality 3D artwork into our projects with ease. DirectX Graphics also ships (provided you also download the additional DirectX 9.0 Extras package) with command line tools that provide easy conversion of 3D Studio™ files (3ds) into the X file format. The *conv3ds.exe* is a command line tool that converts 3ds files to X files. Unfortunately these command line tools do not always work as well as one might hope. Instead of using the command line tools, DirectX Graphics now ships (provided once again that you download the Extras package) with various exporter plug-ins for popular graphics packages such as 3D Studio MAX™ and Maya™.

The Maya plug-in is called Xexport.mll. It is an mll (a Maya™ dynamic link library) that can be dragged and dropped into the plug-ins directory of the Maya™ application. This dll also ships with source code. The 3D Studio™ plug-in dll is called XskinExp.dle but using it is not quite as straightforward to integrate. First, only the source code is provided, so you will need to compile the dll yourself. Be sure that you have downloaded the 3D Studio MAX™ Software Development Kit and the Character Studio™ Software Development Kit for the source code to compile correctly (some versions of MAX may include the SDK on the CD). Unfortunately, one of the header files needed for the compile is missing from the DX9 extras package. To save confusion, we have supplied this missing file with the source code that accompanies this chapter.

> **Note**: GILES™ has the ability to import and export X files, so be sure to check out this feature if you choose to use this format in your applications. Since GILES™ imports .3ds files as well, it is worth considering as an alternative to the command line tools that ship with the DirectX SDK.

So even if you intend to use your own mesh classes for rendering, you can use a temporary D3DX mesh object to load in X file data. Again, it is little trouble to lock the mesh vertex and index buffers and copy out the data into your own mesh type. The result: fast and free X file loading for your application.

Utility: There are other useful features that become available when using D3DX meshes. For example there are intersection tests, bounding volume generation, vertex normal calculations, geometry cleaning functions to remove stray vertices, welding functions, level of detail algorithms, mesh cloning, and much more, all built right into the interfaces.

Although we are free to use the D3DX mesh solely as a utility object, often we will use all of its features: loading, optimization, and rendering. This will be the focus of our lab projects that accompany this chapter.

8.1 D3DX Mesh Types Overview

There are five mesh interfaces in D3DX, each providing a specific set of functionality. In this chapter we will discuss only four of these interfaces in detail: ID3DXBaseMesh, ID3DXMesh, ID3DXSPMesh and ID3DXPMesh. The remaining interface ID3DXPatchMesh, which manages curved surface rendering and related tasks, will be covered a bit later in this programming series.

Before getting under the hood with the four mesh types we are going to cover in this chapter, we will first briefly review the five D3DX mesh types and discuss the high level functionality they provide. After this brief overview, we will examine the mesh types in more detail and learn how to create them, optimize them, and render them.

8.1.1 ID3DXBaseMesh

ID3DXBaseMesh provides the inheritable interface for core mesh functionality. Features include vertex and index buffer management, mesh cloning, face adjacency information processing, rendering, and other housekeeping functions. Base meshes cannot be instantiated, so we will always create one of the derived mesh types -- the derived types support all of the base mesh interface methods.

> **Note:** While we will not use this interface directly, it serves a useful purpose in a game engine since we can store pointers of this type for all of our mesh objects. This allows us to query the interface to determine which of the other mesh types is actually being used. While we might use one or more derived class instances like ID3DXMesh and ID3DXPMesh in our scene, we can store pointers to each in an ID3DXBaseMesh array and cast between types as needed.

Because we will never explicitly instantiate an ID3DXBaseMesh, in this chapter we will cover its interface methods in the context of the more commonly used derived classes. We will indicate which functions belong to which interface as we progress, so that inherited functionality is not obscured by the examples. This will allow us to use code snippets that more closely reflect what we will see in our lab projects.

8.1.2 ID3DXMesh

This is the primary mesh container in DirectX and is the one we are likely to use most often. This mesh can be created and initialized manually (using functions like D3DXCreateMesh or D3DXCreateMeshFVF) or automatically as the result of file loading functions (like D3DXCreateMeshFromX). ID3DXMesh inherits all of the functionality of the ID3DXBaseMesh and provides additional functions for data optimization. Optimization involves algorithms for sorting vertex and index buffer data to provide maximum rendering performance.

8.1.3 ID3DXPMesh

ID3DXPMesh provides support for progressive meshes for run-time geometric level of detail (LOD) changes. Through this interface, the number of triangles used to render a model can be increased or decreased on the fly. The algorithm used is based on the VIPM (View Independent Progressive Mesh) technique. Models can have their triangles merged together to reduce the overall polygon count or alternatively, have their surface detail increased by using more of the original triangles in the rendered mesh. This allows us to adjust the detail level of the mesh to suit the needs of our application (ex. meshes further away from the camera might have polygonal detail reduced to speed up rendering).

8.1.4 ID3DXSPMesh

Simplification meshes provide the ability to reduce the vertex and/or triangle count in a model. Values can be provided by the application to specify which aspects of the model are more important than others during the reduction process. This provides a degree of control over which polygons are removed and which wind up being preserved in the final reduced model. Unlike progressive meshes, mesh simplification involves only face reduction and is a one-time-only operation. Since the results of the operation cannot be reversed, simplification is generally reserved for use in either a tool such as a model editor or as a one-time process that takes place during application initialization. This could be useful if you wanted to tailor your mesh triangle counts to suit the runtime environment. For example, you might wish to reduce the level of detail of certain meshes if you find that a software vertex processing device is all that is available on the current machine.

8.1.5 ID3DXPatchMesh

Patch meshes encapsulate the import, management, and manipulation of meshes which make use of higher-order curved surface primitives (called patches). A patch is defined by a series of control points describing the curvature of a surface. Because patch meshes store their data so differently from the other mesh representations, this interface does not inherit from ID3DXBaseMesh; it is derived directly from IUnknown. Most of the ID3DXBaseMesh interface methods would make little sense in terms of a patch mesh. Curved surfaces and higher-order primitives will be covered later in this series.

Let us now examine each mesh type in more detail.

8.2 ID3DXMesh

The ID3DXMesh interface is the basic mesh container in DirectX Graphics. As such, we begin our discussion by looking first at the internals of its data storage and move on to discuss its methods. There are four primary data storage buffers when working with meshes in DirectX: vertex buffers, index buffers, attribute buffers, and adjacency buffers. Let us look at each in turn.

8.2.1 The Vertex Buffer

D3DX meshes contain a single vertex buffer for storage of model vertex data. This is a standard IDirect3DVertexBuffer9 vertex buffer and is identical to the vertex buffers we have been using since Chapter Three. It can be created using any supported FVF, locked and unlocked, and read from and written to just like any other vertex buffer. All ID3DXBaseMesh derived interfaces inherit the LockVertexBuffer and UnlockVertexBuffer methods for obtaining direct access to the mesh's underlying vertex data.

```
HRESULT ID3DXMesh::LockVertexBuffer(DWORD Flags, VOID **ppData)
```

DWORD Flags
These are the standard locking flags that we have used when locking vertex buffers in previous lessons. The flags include `D3DLOCK_DISCARD`, `D3DLOCK_NOOVERWRITE`, `D3DLOCK_NOSYSLOCK`, `D3DLOCK_READONLY` and `D3DLOCK_NO_DIRTY_UPDATE` and can be used in combination to lock the buffer in an efficient manner (see Chapter Three).

VOID **ppData
This is the address of a pointer that will point to the vertex data if the lock is successful.

We release the lock on the mesh vertex buffer using the ID3DXMesh::UnlockVertexBuffer function.

```
HRESULT ID3DXMesh::UnlockVertexBuffer(VOID)
```

The following code snippet demonstrates mesh vertex buffer locking and unlocking. It is assumed that pd3dxMesh is a pointer to an already initialized ID3DXMesh.

```
ID3DXMesh *pd3dxMesh;

// Create the mesh here…

// Lock the vertex buffer and get a pointer to the vertex data
void *pVertices;
pd3dxMesh->LockVertexBuffer( 0, &pVertices );

// Fill the vertex buffer using the pointer

// When we are done, we must remember to unlock
pd3dxMesh->UnlockVertexBuffer();
```

8.2.2 The Index Buffer

D3DX meshes use a single index buffer to store model faces. In the context of the D3DX mesh functions, a face is always a triangle and the index buffer always contains indices that describe an indexed triangle list. Thus, if we called the ID3DXMesh::GetNumFaces method, we will be returned the total number of triangles in the mesh. This will always equal the total number of indices in the index buffer divided by three. D3DX meshes have no concept of quads or N-sided polygons. This is an important point to remember, especially when constructing your own mesh data and manually placing it into the vertex and index buffers of a D3DXMesh object.

Like the vertex buffer, the mesh index buffer is a standard IDirect3DIndexBuffer9 index buffer, as seen in previous lessons. Thus it can be accessed and manipulated in a similar fashion. All ID3DXBaseMesh derived interfaces inherit the LockIndexBuffer and UnlockIndexBuffer methods from the base class. This provides direct access to the mesh's underlying index data.

`HRESULT ID3DXMesh::LockIndexBuffer(DWORD Flags, VOID **ppData)`

DWORD Flags
These are the standard `D3DLOCK` flags that we have used when locking index buffers in previous lessons. The flags include `D3DLOCK_DISCARD`, `D3DLOCK_NOOVERWRITE`, `D3DLOCK_NOSYSLOCK`, `D3DLOCK_READONLY` and `NO_DIRTY_UPDATE` and can be used in combination to lock the buffer in an efficient manner.

VOID ** ppData
This is the address of a pointer that will point to the index data if the lock is successful.

We release the lock on a mesh index buffer with a single call to ID3DXMesh::UnlockIndexBuffer.

`HRESULT ID3DXMesh::UnlockIndexBuffer(VOID)`

The following code demonstrates how to lock and unlock a mesh index buffer. It is assumed in that pd3dxMesh is a pointer to an already initialized ID3DXMesh.

```
ID3DXMesh *pd3dxMesh;

// Pretend that we create the mesh here

WORD  *pIndices16;
DWORD *pIndices32;

if ( pd3dxMesh->GetOptions() & D3DXMESH_32BIT)
{
        // Lock the index buffer and get a pointer to the vertex data
        pd3dxMesh->LockIndexBuffer( 0, &pIndices32 );

        // This is where you could fill the index buffer using the pointer

        // When we are done we must remember to unlock
        pd3dxMesh->UnlockIndexBuffer();
}
else
{
        // Lock the index buffer and get a pointer to the vertex data
        pd3dxMesh-> LockIndexBuffer( 0, &pIndices16);

        // This is where you could fill the index buffer using the pointer

        // When we are done we must remember to unlock
        pd3dxMesh-> UnlockIndexBuffer();
}
```

In the above code, a call to ID3DXMesh::GetOptions is used to determine whether the mesh index buffer uses 32-bit or 16-bit indices. We will see in a moment that we will specify a number of option flags that inform the mesh creation and loading functions about the properties we would like our mesh buffers to exhibit. These properties include which memory pools we would like to use for our vertex/index buffers or whether the index buffer should contain 16-bit or 32-bit indices. The ID3DXMesh::GetOptions method allows us to retrieve the flags that were used to create the buffer. The return value is a bit-set stored in a DWORD that can be tested against a number of flags.

8.2.3 The Adjacency Buffer

To perform optimization and/or LOD on a mesh, it is necessary to know some information about the connectivity of the faces. That is, we wish to know which faces neighbor other faces. For example, LOD is performed by ‘collapsing’ two or more triangles into a single triangle. In order for this to be possible, the information must be at hand that tells the mesh how faces are connected to other faces. As a face in the context of any of the D3DX mesh types is always a triangle, and since a triangle always has three edges, we know that a single face can at most be adjacent to three other triangles. Therefore, when we need to send adjacency information to the mesh to perform one function or another, we will pass in an array with three DWORDs for each face. These values describe the face index numbers for neighboring

faces. If we have a mesh with 10 faces, then the adjacency information required would be an array of 30 DWORDs.

Fig 8.1 depicts a mesh with eight faces and the associated adjacency array. Keep in mind that while a triangle may be connected along its three edges to at most three other triangles, this does not mean that every triangle will be connected to three other faces. A mesh that contains a single triangle for example would obviously have no adjacent neighbors. Nevertheless, whether each face in the mesh is connected to three other faces or not, we still store three DWORDs per face. If a triangle edge is not connected to any other triangle in the mesh, then we will use a value of 0xFFFFFFFF to indicate this.

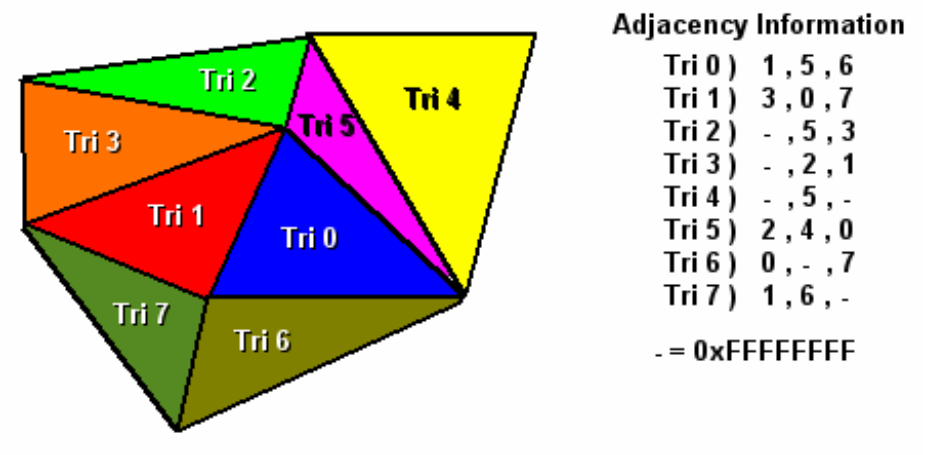

Figure 8.1

Looking at the list in Fig 8.1 we can see that triangle 0 is connected to faces 1, 5, and 6. Triangle 3 is only connected to two other triangles: 1 and 2. Using this adjacency information, a simplification process might decide to collapse triangles 0, 1, 6, and 7 by removing the shared middle vertex and collapsing the four triangles into two triangles.

While calculating face adjacency is not very difficult to do, we are spared even that minor hassle by D3DX. All mesh types derived from the ID3DXBaseMesh interface inherit a function called ID3DXBaseMesh::GenerateAdjacency to generate face adjacency data. To minimize per-mesh memory requirements, D3DX meshes do not generate this information automatically when meshes are created, so we must explicitly call this procedure if we require this data. Since we often require the use of adjacency data only once when optimizing a mesh, there is little point in keeping it in memory after the fact. For progressive meshes however, we may decide to keep this information handy as we will see later.

```
HRESULT ID3DXMesh::GenerateAdjacency(FLOAT fEpsilon,
                                     DWORD*pAdjacency);
```

FLOAT fEpsilon

Sometimes modeling packages create meshes such that faces that are supposed to be adjacent are not precisely so. This can happen for a number of reasons. For example, the level designer may have not used a correct alignment, leaving miniscule but significant gaps between faces. Sometimes this can be due to floating point rounding errors caused by cumulative vertex processing done on the mesh (such as

a recursive CSG process). Further, perhaps the two faces are not actually supposed to be touching, but you would like LOD and optimization functions to treat them as neighbors anyway. Fig 8.2 shows two triangles which should probably be connected, but in fact have a small gap between them. We can see immediately that the triangles would share no adjacent edges.

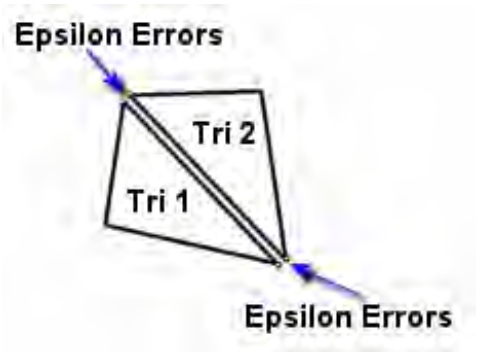

Figure 8.2

It can be frustrating when these tiny gaps prevent proper optimization or simplification. The fEpsilon value allows us to control how sensitive the GenerateAdjacency function is when these gaps are encountered. It is used when comparing vertices between neighboring triangles to test whether they are considered to be on the same edge, and therefore exist in a neighboring face. This is no different than testing floating point numbers or 3D vectors using an epsilon value. It simply allows us to configure the function to be tolerant about floating point errors. The larger the epsilon values, the more leeway will be given when comparing vertices and the more likely they are to be considered the same.

DWORD *pAdjacency
The second parameter is a pointer to a pre-allocated DWORD array large enough to hold three DWORDS for every face in the mesh.

The following code shows how we might generate the adjacency information for an already created mesh.

```
// Allocate adjacency buffer
DWORD *pAdjacency = new DWORD[pd3dxMesh->GetNumFaces() * 3];

// Generate adjacency with a 0.001 tolerance
pd3dxMesh->GenerateAdjacency( 0.001 , pAdjacency );
```

8.2.4 The Attribute Buffer

In Graphics Programming Module I we looked at how to assign textures and materials to our model faces. Recall that for each face we stored indices into global arrays that contained scene materials and textures. This is how we mapped faces in our mesh to textures and materials stored elsewhere in the application. During rendering, we would loop through each texture used by the mesh and render only the

faces that used that texture in a single draw primitive call. We would repeat this process for each texture used by the mesh until all faces had been rendered. D3DX mesh objects also provide this batch rendering technique which we know is so essential for good rendering performance.

Since D3DX meshes store data in vertex and index buffers and include no explicit face type per se, it becomes necessary to organize those buffers such that it is known in advance which groups of indices map to particular textures or materials. As we can no longer store texture and material indices in our mesh faces (because a mesh face is now just a collection of three indices in the mesh's index buffer) another buffer, called an *attribute buffer*, provides the means for doing so.

Whenever a D3DXMesh is created (either manually or via a call to the D3DXLoadMeshFromX function), an attribute buffer is created alongside the standard vertex and index buffers. There is one DWORD entry in this attribute buffer for every triangle in the index buffer. Each attribute buffer entry describes the Attribute ID for that face. All faces that share the same Attribute ID are said to belong to the same *subset* and are understood to require the same device states to be rendered. Therefore, all triangles in a subset can be rendered with a single draw primitive function call to minimize device state changes. All faces that belong to the same subset are not necessarily arranged in the index buffer in any particular order (although they can be, as we will soon discuss), but they will still be rendered together. Note that the mesh object itself does not contain any texture or material information; Attribute IDs provide the only potential link to such external concepts. In short, Attribute IDs provide a means to inform D3DX that faces with like properties can be rendered in a single draw call.

When building a mesh ourselves, the Attribute ID can describe anything we would like. It might be the index of a material or texture in a global array, or even an index into an array of structures that describe a combination of material, texture, and possibly even the lights used by the subset. Ultimately this ID is just a way for the application to inform the ID3DXMesh rendering function which faces belong to the same group and should be rendered together. It is important to understand that the application is still responsible for managing the assets that the face attributes map to (texture, materials, etc.) and for setting up the appropriate device states before rendering the subset.

Fig 8.3 depicts a nine triangle mesh, where each triangle uses one of five different textures. When the ID3DXMesh is created, there are empty vertex, index, and attribute buffers. The mesh itself contains no texture information. The textures used by the mesh are stored in a global texture array managed by the application. This is similar to the approach we took in our lab projects that used IWF files in earlier lessons -- we extracted the texture names from the file, loaded the textures into a global array, and stored the texture index in the face structure. We can no longer store the texture index in the face structure because the ID3DXMesh has no such concept. However we can store the texture index for each face in the attribute buffer instead.

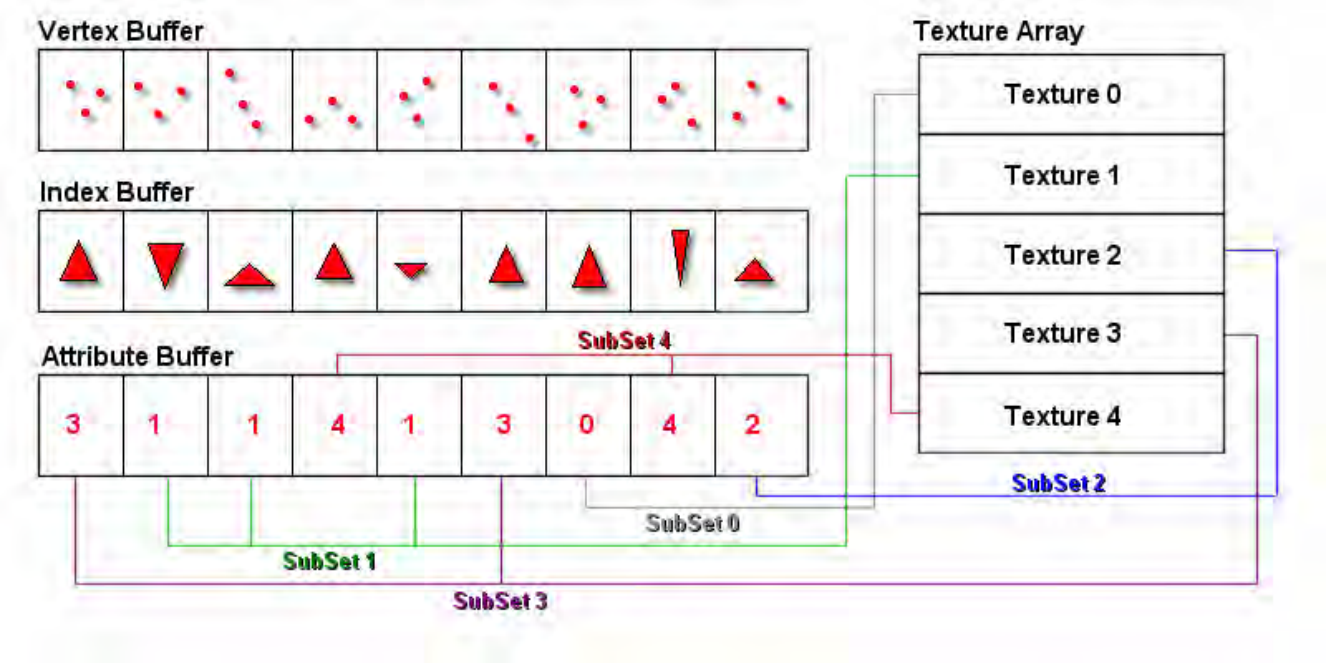

Figure 8.3

In this example, the ID3DXMesh itself has no knowledge that the Attribute IDs are in fact texture indices, but it does know that all faces with a matching Attribute ID are considered part of the same subset and can all be rendered together.

Fig 8.3 depicts the relationship between the triangle data stored in the index buffer and the Attribute ID stored in the attribute buffer. The 7th triangle uses texture 0, the 8th triangle uses texture 2, the 1st and 6th triangles use texture 3, the 2nd, 3rd, and 5th triangles use texture 1, and so on. Even in this simple example the mesh would benefit from attribute batching, as the faces belonging to a particular subset are fairly spread out inside the index buffer.

In a short while we will examine the D3DXLoadMeshFromX function. When the mesh is created using this function, its vertex, index, and attribute buffers are automatically filled with the correct data. To determine which Attribute IDs map to which asset types, the function returns an array of D3DXMATERIAL structures which contain a texture and material used by a given subset as specified by the X file that was loaded. So when we render subset 0 of the mesh, we set the texture and the material stored in the first element of the D3DXMATERIAL array. When rendering the second subset we set the texture and material stored in the second element of the D3DXMATERIAL array, and so on for each subset. Therefore, while the mesh itself does not maintain texture and material data, the D3DXLoadMesh… family of functions does return this information. The loading function correctly builds the attribute buffer such that each Attribute ID indexes into this D3DXMATERIAL array.

When loading an X file, the mesh and its internal buffers are created and filled automatically. While we rarely need to lock any of the mesh's internal buffers under these circumstances, when creating an ID3DXMesh object manually, we definitely need to be able to lock and unlock the attribute buffer.

The ID3DXMesh::LockAttributeBuffer and the ID3DXMesh::UnlockAttributeBuffer are not inherited from the ID3DXBaseMesh interface. Instead these are two of the new functions added to the ID3DXMesh interface beyond its inherited function set.

HRESULT LockAttributeBuffer(DWORD *Flags*, DWORD *ppData*);**

When locking the attribute buffer, we pass in one or more of the standard buffer locking flags to optimize the locking procedure. The second parameter is the address of a DWORD pointer which will point to the beginning of the attribute data on successful function return.

Unlocking the attribute buffer is a simple matter of calling the following function:

HRESULT UnlockAttributeBuffer(VOID);

8.2.5 Subset Rendering

To render a given subset in a mesh, we call ID3DXMesh::DrawSubset and pass in an Attribute ID. This function will iterate over the faces in the index buffer and render only those that match the ID passed in. Therefore, rendering a mesh in its entirety adds up to nothing more than looping through each subset defined in the mesh, setting the correct device states for that subset (texture and material, etc.) and then rendering the subset with a call to the ID3DXMesh::DrawSubset method. More efficient rendering is made possible when the subset data is grouped together in the mesh vertex and index buffers. We will discuss mesh optimization in detail a little later in the chapter.

HRESULT DrawSubset(DWORD *AttribId*);

The mesh in Fig 8.3 could be rendered one subset at a time using the following code.

```
for(int I = 0; I < m_nNumberOfTextures; I++)
{
     pDevice->SetTexture(0, pTextureArray[I]);     // Set Subset Attribute
     pd3dxMesh->DrawSubset(I);                     // Render Subset
}
```

Again it should be noted that while this example is using the texture index as the Attribute ID for each subset, this ID could instead be the index of an arbitrary structure in an array which might hold much more per-face information: materials, transparency, multiple textures, lights, etc. used by that subset. All that matters to D3DX is that faces with the same Attribute ID share like states and can be batch rendered. What these Attribute IDs mean to the application is of no concern to the mesh object. It is the application that is responsible for setting the correct device states before rendering the subset that corresponds to the particular Attribute ID.

8.3 ID3DXBaseMesh Derived Functions

The purpose of most of the base mesh derived functions is pretty self-explanatory, but we will quickly review them just to get a feel for the information that a mesh stores and how to access it. Then in the next section, we will look at how to actually create and use a mesh.

```
HRESULT GetDevice( LPDIRECT3DDEVICE9 *ppDevice );
```

When we create a mesh using the D3DXCreateMesh function or the D3DXLoadMesh… family of functions, we must specify a pointer to the device interface through which the mesh will be created. This is required because the device owns the vertex buffer and index buffer memory that is allocated, and thus the mesh object is essentially owned by the device as well. The ID3DXBaseMesh::GetDevice function allows us to retrieve the device that owns the mesh.

```
DWORD GetFVF(VOID);
```

When we create a mesh using the D3DXCreateMeshFVF function, we directly specify the flexible vertex format flags for the mesh vertex buffer. The ID3DXBaseMesh::GetFVF function allows us to retrieve this information so that we know the layout of the vertices stored in this internal vertex buffer.

When using the D3DXLoadMesh… family of functions, being able to retrieve the FVF flags for the mesh vertex structure is important because we often have no direct control over the original vertex format the mesh was created with. For example, when using the D3DXLoadMeshFromX function, the function will choose a vertex format that most closely matches the vertex information stored in the X file. If the vertices in the X file contain vertex normals and three sets of texture coordinates, the mesh vertex buffer will automatically be created to accommodate this information. Therefore, when the mesh is created from an X file, we need this function to determine the format with which the vertex buffer was initialized. You will see later when we discuss mesh cloning that we are not restricted to using vertices in the format specified in the X file. We can clone the mesh and specify a different vertex format to better suit the needs of our application.

```
HRESULT GetIndexBuffer( LPDIRECT3DINDEXBUFFER9 *ppIB );
```

The ID3DXBaseMesh::GetIndexBuffer function returns a pointer to the IDirect3DIndexBuffer9 interface for the internal mesh index buffer. Retrieving the index buffer interface (or the vertex buffer interface) can be useful if we wish to render the mesh data manually and not use the DrawSubset functionality. If you had your own custom rendering code that you needed to use and merely wanted to use the ID3DXMesh to optimize your dataset, this would be your means for accessing the indices. After the data was optimized, you would simply retrieve the vertex and index buffer interfaces and use them as you would under normal circumstances.

```
HRESULT GetVertexBuffer( LPDIRECT3DVERTEXBUFFER9 *ppVB );
```

Like the previous function, this function returns an interface pointer to the mesh vertex buffer so that you can use it for custom rendering or other application required manipulation.

```
DWORD GetNumBytesPerVertex(VOID);
```

This function returns the size (in bytes) of the vertex structure used by this mesh. This is useful when you need to render the mesh data manually since you need to specify the stride of the vertex when binding the vertex buffer with the IDirect3DDevice9::SetStreamSource function.

```
DWORD GetNumFaces(VOID);
```

This function returns the number of faces (triangles) stored in the mesh index buffer. Since the mesh always stores its geometry as an indexed triangle list, the result of this function will be the total number of indices in the mesh index buffer divided by 3.

```
DWORD GetNumVertices(VOID);
```

This function returns the number of vertices in the mesh vertex buffer.

```
DWORD GetOptions(VOID);
```

This function returns a DWORD which stores a series of flags that were used during creation of the mesh. The flags include information about the memory pools used for the vertex and index buffers, the size of the indices (32-bit or 16-bit) in the index buffer, whether the vertex or index buffer have been created as dynamic buffers, and whether or not they are write-only buffers.

8.4 Mesh Optimization

There is one more topic to discuss before we finally look at how to create/load a mesh: optimization of vertex and index data. While this may seem like a strange way round to do things, it should help us better understand exactly what information the D3DXLoadMeshFromX function is returning to us as well as how to efficiently organize our data when we create meshes manually.

Whether or not you intend to use the ID3DXMesh (or any of its sibling interfaces) for your own mesh storage or rendering, it would be a mistake to overlook the geometry optimization features offered by the ID3DXMesh::Optimize and the ID3DXMesh::OptimizeInPlace functions we are about to examine. Even if you have your own mesh containers and rendering API all worked out, your application may well benefit from temporarily loading the mesh data into an ID3DXMesh and using its optimization functions before copying the optimized data back into your proprietary structures. This can save you some time and energy developing such optimization routines yourself.

It is a sad but true fact that if you are starting off as a hobbyist game developer, you will likely not have access to artists to develop 3D models specifically for your applications. Often you will be forced to use models that you find on the Internet or other places where they may or may not be stored in the file in an optimal rendering arrangement. The Optimize and OptimizeInPlace functions are both introduced in the ID3DXMesh interface and will provide some relief. Both functions perform identical optimizations to the mesh data and, for the most part, take identical parameter lists. The difference between them is that the Optimize function generates a new mesh containing the optimized data and the original mesh

remains intact. The OptimizeInPlace function does not create or return a new mesh, it directly optimizes the data stored in the current mesh object. Let us take a look at the OptimizeInPlace function first.

```
HRESULT OptimizeInPlace( DWORD Flags,
                         CONST DWORD *pAdjacencyIn,
                         DWORD *pAdjacencyOut,
                         DWORD *pFaceRemap,
                         LPD3DXBUFFER *ppVertexRemap
                        );
```

DWORD Flags

The Flags parameter describes the type of optimization we would like to perform. We typically choose only one of the standard optimization flags, but we can combine the standard optimization flags with additional modifier flags. The standard optimization flags are ordered and cumulative. That is, each one listed also contains the flags for the optimizations that precede it.

D3DXMESHOPT_COMPACT – When specifying this flag, the optimizer removes vertices and/or indices that are not required. A classic example of this would be stray vertices in the vertex buffer that are never referenced by any indices in the index buffer. It is also possible that the geometry from which the mesh was created contains degenerate triangles. Because meshes are always stored as triangle lists and degenerate triangles are of little use in these situations, they will also be removed. This is the base optimization method that is performed by all other optimization flags. It is also the quickest and cheapest optimization that we can perform. Note that it may involve index and vertex data reshuffling or reordering in order to fulfill the compaction requirements.

D3DXMESHOPT_ATTRSORT - The attribute sort optimization is performed in addition to the compaction optimization listed above. That is, you do not have to specify both `D3DXMESHOPT_COMPACT` and `D3DXMESHOPT_ATTRSORT` since the `D3DXMESHOPT_ATTRSORT` flag by itself will cause a compaction and an attribute sort optimization to be performed. When a mesh is first created, either in code or by the D3DXLoadMeshFromX function, faces are typically added to the index buffer as they are encountered. This means that we may have faces that share the same Attribute ID (and are therefore part of the same subset) randomly dispersed within the index buffer. The optimizer sorts the data stored within the mesh so that all the faces that share the same Attribute ID are consecutive within the index buffer. This allows them to be efficiently batch rendered.

Fig 8.4 shows how a D3DX mesh might be created. In this example we shall assume that we have loaded geometry from an IWF file and stored it inside a D3DXMesh. This would be a simple case of calling D3DXCreateMesh to create the empty mesh object and then locking the vertex and index buffers and copying in the IWF data (we discussed how easy it was to load IWF files into memory with the IWF SDK in Chapter Five). Once we have the data file in memory, we loop through each face that was loaded (temporarily stored in the IWFSurface vector) and copy the vertices of the face into the vertex buffer and the indices of the face into the index buffer (arranged as indexed triangle lists).

To keep this example simple, we have used only the render material referenced by the surface as the Attribute ID for the face. Thus all faces that use the same material in the IWF file are said to belong to the same subset. The point here is not how the data gets into the mesh, but that when we add data in an arbitrary order to the internal buffers, triangles belonging to the same subset may not be consecutive in the buffers. In this example, we added nine triangles to the mesh in an arbitrary order; the order that they were encountered in the external file. When we add each triangle, we add its three vertices to the vertex buffer, its indices to the index buffer, and the triangle Attribute ID (the material index) to the attribute buffer.

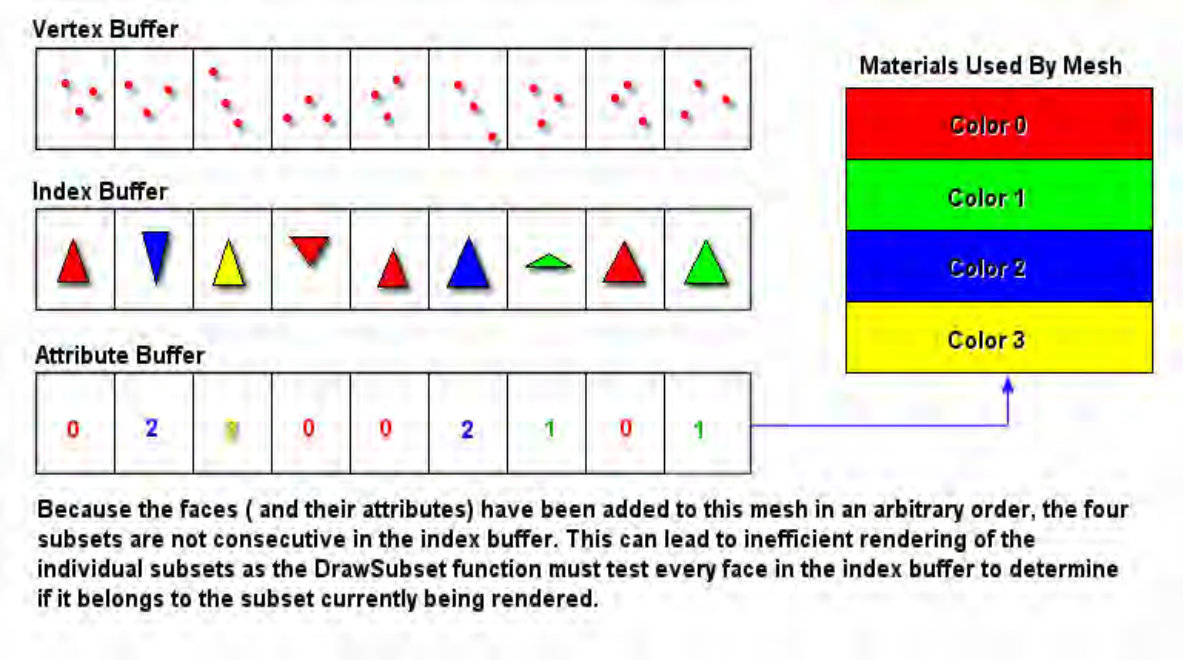

Figure 8.4

Given the disorganized nature of the buffers in Fig 8.4, if we were to call the ID3DXMesh::DrawSubset method and pass in an ID of 0, the function would need to render the 1st, 4th, 5th, and 8th triangles. Because the mesh cannot assume that all triangles belonging to the same subset are batched together by default, when we issue the render call for a subset, the function must loop through the entire attribute buffer to find and render all triangles that match the selected Attribute ID one at a time.

When we use the `D3DXOPTMESH_ATTRSORT` flag, the vertex and index buffers will be reordered such that vertices and indices belonging to the same subsets are batched together in their respective buffers. The function internally builds an *attribute table* that describes where a subset's faces begin and end in the index buffer and where the subset's vertices begin and end in the vertex buffer. This sets the stage for efficient DrawIndexedPrimitive calls.

Fig 8.5 shows how the mesh might look after an attribute optimization has been performed. Study the following image and see if you notice anything strange about the attribute buffer.

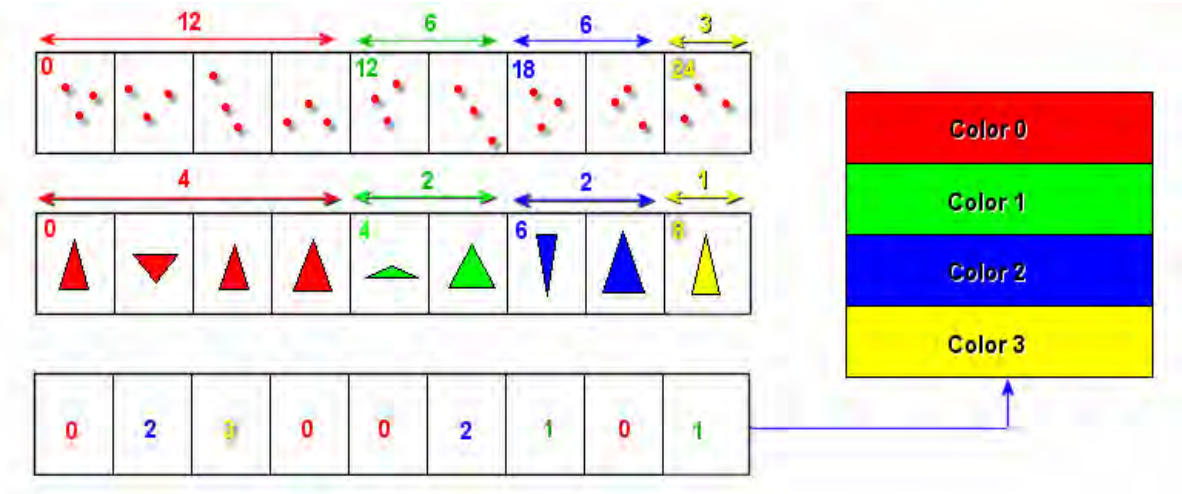

Figure 8.5

Notice how the attribute buffer no longer correctly maps to the faces. When we perform an attribute sort on a mesh, the mesh is flagged internally as having been attribute sorted and an attribute table is built. From that point on, the attribute buffer is no longer used in any calls to the DrawSubset function. Instead, batch rendering information is pulled from the from the attribute table. The DrawSubset function no longer needs to loop through the attribute buffer for each subset and find the matching triangles, because the attribute table describes where a subset begins and ends in the index and vertex buffers.

We can see in Fig 8.5 that the attribute sort has correctly batched all faces belonging to the same subset in the index and vertex buffers. It also shows how subset 0 starts at face 0 in the index buffer and consists of four triangles. The vertices for subset 0 begin at vertex 0 in the vertex buffer and the range consists of 12 vertices. Now the DrawSubset function can quickly jump to the beginning of the subset in the vertex and index buffers and pump them into the pipeline with a single DrawIndexedPrimitive call.

Once a mesh has been attribute sorted, we can gain access to the internal attribute table using the ID3DXBaseMesh::GetAttributeTable method. This returns an array of `D3DXATTRIBUTERANGE` structures (one per subset) describing where a given subset begins and ends in the vertex and index buffers. If you intend to perform geometry or attribute manipulation on an already optimized mesh, you may want to update the attribute table with the new information rather than calling the Optimize function again.

The `D3DXATTRIBUTERANGE` range structure is shown below.

```
typedef struct _D3DXATTRIBUTERANGE {
    DWORD AttribId;
    DWORD FaceStart;
    DWORD FaceCount;
    DWORD VertexStart;
    DWORD VertexCount;
} D3DXATTRIBUTERANGE;
```

The first member of the structure contains the zero-based Attribute ID for the subset. If this value was set to 5 for example, then this structure would describe where the vertices and indices for subset 5 begin and end in the vertex and index buffers. The FaceStart member holds the triangle number (offset from zero) where the subset begins in the index buffer. The FaceCount member describes how many triangles beginning at FaceStart belong to the subset. The VertexStart member describes the zero-based index of the vertex in the vertex buffer where the subset vertices begin. The VertexCount member describes the number of vertices that belong to the subset. Essentially, these are the members you would use if you decided to call DrawIndexedPrimitive yourself.

To retrieve the attribute table, we use the ID3DXBaseMesh inherited function GetAttributeTable.

```
HRESULT GetAttributeTable
(
    D3DXATTRIBUTERANGE *pAttribTable,
    DWORD *pAttribTableSize
);
```

The first parameter is a pointer to a pre-allocated array of `D3DXATTRIBUTERANGE` structures that the function will fill with subset information. The second parameter is the number of subsets (starting at zero) we would like to retrieve information for. We must make sure that we have allocated at least as many `D3DXATTRIBUTERANGE` structures as the number specified in the pAttribTableSize parameter.

If we would like all of the information for every subset the mesh contains, we must first know how many `D3DXATTRIBUTERANGE` structures to allocate memory for. If we call this function and set the first parameter to NULL and pass the address of a DWORD as the second parameter, the function will fill the passed DWORD with the number of subsets in the mesh. This allows us to allocate the memory for the `D3DXATTRIBUTERANGE` structures before issuing a second call to the function to retrieve the actual attribute table. It should be noted that an attribute table does not exist until the mesh has undergone an attribute sort. If you call this function without first attribute sort optimizing the mesh, 0 will be returned in the pAttributeTableSize parameter.

The following code snippet demonstrates how we might optimize a mesh such that it is compacted and attribute sorted. We then retrieve the mesh attribute table. The code assumes that pd3dxMesh has already been created and filled with data but has not yet been optimized.

```
// Allocate adjacency buffer needed for optimize
DWORD *pAdjacency = new DWORD[ pd3dxMesh->GetNumFaces() * 3];

// Generate adjacency with a 0.001 tolerance
pd3dxMesh->GenerateAdjacency( 0.001 , pAdjacency );

// Optimize the mesh ( D3DXOPTMESH_ATTRSORT = Attribute Sort + Compact )
pd3dxMesh->OptimizeInPlace(D3DXOPTMESH_ATTRSORT,pAdjacency,NULL,NULL,NULL);

// No longer need the adjacency information
delete []pAdjacency;
```

```
// We need to find out how many subsets are in this optimized mesh
DWORD NumberOfAttributes;

// Get the number of subsets
pd3dxMesh->GetAttributeTable( NULL , &NumberOfAttributes );

// Allocate enough D3DXATTRIBUTERANGE structures, one for each subset
D3DXATTRIBUTERANGE *pAttrRange = new D3DXATTRIBUTERANGE[NumberOfAttributes];

// Call the function again to populate array with the subset information.
pd3dxMesh->GetAttributeTable( pAttrRange , &NumberOfAttributes );

// Examine the actual attribute range data here and do what you want with it
```

Notice that in order to perform an optimization of any kind, we must supply the function with face adjacency information.

The ID3DXMesh interface includes an additional function (beyond the ID3DXBaseMesh inherited functions) that can be used to specify an attribute table manually.

HRESULT SetAttributeTable(CONST D3DXATTRIBUTERANGE *_pAttrTable_,
DWORD _cAttrTableSize_);

The first parameter is the new array of `D3DXATTRIBUTERANGE` structures and the second parameter is the number of attributes in the array. It is very rare that you will need to modify the attribute table of an optimized mesh, but if necessary, then this is the function you should use to set the new data. Note that it does not alter the index and vertex buffer information in any way; it simply sets the attribute table internally. When a mesh has been attribute sorted, it is marked as having been so.

> **Note:** When you set the attribute table manually you must make sure that you correctly identify the subset ranges, because the DrawSubset function will blindly use this information to render each subset. When we call DrawSubset for example and pass in an attribute ID of 5, the subset's vertex and index start and count values will be taken from this table regardless of what is stored in the attribute buffer.

D3DXMESHOPT_VERTEXCACHE – This flag is used to inform the optimizer that we would like the vertex and index buffers of the mesh to be optimized to better utilize the vertex cache available on most modern hardware accelerated 3D graphics cards. This will often involve reordering the vertex and index data of the mesh such that vertices that are transformed and stored in the vertex cache on the GPU are reused as much as possible. If a vertex is shared by 10 faces for example, this optimization will try to order the index buffer and vertex buffer such that this vertex is only transformed and lit once. It can then render all faces that use the vertex before it is evicted from the vertex cache. This is an extremely effective optimization which aims to increase the cache hit rate of hardware vertex caches.

Again, specifying this single flag also includes the optimizations performed by the two previous flags just discussed. Therefore, specifying `D3DXMESHOPT_VERTEXCACHE` also performs the `D3DMESHOPT_COMPACT` and `D3DXMESHOPT_ATTRSORT` optimization processes. The `D3DXMESHOPT_VERTEXCACHE` flag and the `D3DMESHOPT_STRIPREORDER` flags (discussed next) are mutually exclusive since they have very different goals.

D3DXMESHOPT_STRIPREORDER – The name of this optimization flag can sometimes cause some confusion. It seems to imply that the vertex and index buffer data would be modified to be rendered as indexed triangle strips, but this is not the case. A D3DXMesh will always be stored using an indexed triangle list format. So what does this optimization actually do?

Some 3D graphics cards can only render triangle strips at the hardware level. This means that when we render triangle lists or fans for example, the driver will convert these primitive types to strips before rendering. This is not something we are ever aware of or have to make provisions for, but this strip creation process can carry overhead on such cards. While the overhead is generally minimal, this optimization flag makes it clear that we would like the indexed triangle lists of the mesh to be re-arranged such that they can be more quickly be converted into strips by the driver. The optimizer reorders the faces so that, as much as possible, physically adjacent triangles are consecutively referenced. This increases the length of adjacent triangle runs in the buffer, which helps speed things up in cases where strip generation is required.

This flag and `D3DXMESHOPT_VERTEXCACHE` are mutually exclusive due to the fact that they both try to attain a best-fit ordering given a different set of rules. The `D3DOPTMESH_STRIPREORDER` flag, like the `D3DMESHOPT_VERTEXCACHE` flag, contains all the optimization processes previously described.

The optimization flags can thus be summed up as follows:

```
D3DXMESHOPT_COMPACT      =    Compact process only.
D3DXMESHOPT_ATTRSORT     =    Compact + Attribute Sort.
D3DXMESHOPT_VERTEXCACHE  =    Compact + Attribute Sort + Cache Reorder.
D3DXMESHOPT_STRIPREORDER =    Compact + Attribute Sort + Strip Reorder.
```

Modifier Flags

There are a number of modifier flags that can be combined with any of the previously discussed standalone optimization flags. They are listed below along with a brief description of their purpose.

D3DXMESHOPT_IGNOREVERTS - This flag instructs the optimizer not to touch the vertices and to work only with the face/index data. Thus, if we were to perform a compact optimization with this modifier flag, no vertices would be removed -- even if they were never referenced. In that case, only unused face indices would be removed. This is a useful modifier flag if you wish to optimize the mesh but want the vertex buffer to remain unchanged.

D3DXMESHOPT_DONOTSPLIT - This is a modifier flag that is used primarily for attribute sorting. When an attribute sort optimization is performed, vertices that are used by multiple attribute groups may be split (i.e. duplicated) so that a best-order scenario is obtained when batch rendering, while keeping vertices in a local neighborhood to the subset. This way, software vertex processing performance is not compromised.

For example, let us say that we had 300 attributes (subsets) and 5000 vertices. Assume that attribute 0 and attribute 299 both reference vertex 4999. In this case, the vertex attribute range for attribute 0 would span the entire contents of the vertex buffer. This would seriously hurt

software vertex processing performance since we know that when calling DrawIndexedPrimitive on a software vertex processing device, the entire range of specified vertices is transformed in one pass. In this example then, attribute 0 would have a vertex start index of 0 and a vertex count of 5000. So even if this was only a single triangle subset, all 5000 vertices would need to be transformed and possibly lit when rendering subset 0. This is not a problem when using a hardware vertex processing device because the vertex cache is used instead. So in order for mesh performance to downgrade gracefully to a software vertex processing device, under these conditions the vertex may be duplicated and moved to the beginning of the buffer. Attribute 0 would then have a localized set of vertices to minimize block vertex transformations on a software vertex processing device.

This duplication process is performed automatically by the attribute sort optimization process and normally that is a good thing. However, if for any reason you consider this a problem and wish to prevent the automatic duplication of vertices, specifying this flag will prevent this duplication optimization from being performed.

D3DXMESHOPT_DEVICEINDEPENDENT - During vertex cache optimization, a specific vertex cache size is used which coincides with the cache provided on the hardware. This approach works well for modern hardware. This flag specifies that the optimizing routine should alternatively assume a default, device-independent vertex cache size (a fixed cache size) because this usually works better on older hardware.

Example Combinations:

```
D3DXMESHOPT_VERTEXCACHE|D3DXMESHOPT_DEVICEINDEPENDANT|D3DXMESHOPT_DONOTSPLIT
```

With this combination, the data will be compacted to remove un-referenced vertices and degenerate triangles and will be attribute sorted. When the attribute sort is being performed, the optimization routine will not duplicate vertices to minimize subset vertex ranges. This would make the mesh transform and render much slower on a software vertex processing device. The mesh will also have its triangles and vertices reordered to better utilize the vertex cache. In this case we want a fixed, device-independent vertex cache size to be assumed.

```
D3DXMESHOPT_ATTRSORT|D3DXMESHOPT_IGNOREVERTS
```

This combination instructs the optimization routine to compact and attribute sort only the index data and not alter the vertex buffer in any way. If there are any un-referenced vertices in the vertex buffer, they will not be removed. Furthermore, since we are stating that we do not want the vertex data touched, vertices will not be duplicated to produce better localized vertices for a subset. This means that such a mesh will suffer the same poor software vertex processing performance if an attribute/subset references vertices over a large span of the vertex buffer.

CONST DWORD *pAdjacencyIn

This is a pointer to an adjacency array calculated using ID3DXBaseMesh::GenerateAdjacency. As discussed, this is an array of DWORDS (3 per face) describing how faces are connected. Although it might be argued that it would be nice if the Optimize and OptimizeInPlace functions called

GenerateAdjacency automatically, this would require that the adjacency information be recalculated with every call to the optimize functions. Since you may already have the adjacency information or need to call optimize several times for several copies of the mesh, you can just calculate the adjacency information once and pass it in each time it is needed.

DWORD *pAdjacencyOut

Most mesh optimizations involve the rearranging of vertices and indices in the internal buffers. Since it is possible that faces may be removed by the compaction algorithm or rearranged by the attribute sort/ vertex cache optimizations, the adjacency index information has likely changed as well. If your application needs to maintain the adjacency data, then this pointer can be filled with the new adjacency information when the function returns. If we pass NULL, the adjacency information will not be returned. Thus if you need the adjacency information in the future, you will need to call the GenerateAdjacency function again.

Since the optimization process never introduces new faces (at most it only removes triangles), as long as this buffer is at least as large as the original adjacency buffer (pAdjacencyIn), there will be enough room to house the adjacency information of the optimized mesh.

DWORD *pFaceRemap

This parameter allows us to pass in a pointer to a pre-allocated array that on function return will contain information describing how faces have been moved around inside the index buffer after the optimization step. This array is useful when you have external attributes/properties associated with the mesh triangles that need to be updated after the mesh is optimized. On function return, the following relationship will be true:

pFaceRemap[***OldFaceIndex***] = ***NewFaceIndex***

For example, imagine that you were writing a level editing system and that you have several decals in your levels that are attached to faces by an index. When the mesh is optimized, the faces may have been rearranged such that each face now has a completely different index. In such a case, you would want to update the face index stored in your decal structure so that it tracked the faces it was attached to after the optimization process. If the decal was attached to face 5 for example, after the optimization face 5 may have been moved to face slot 10 in the index buffer. The decal would need to be updated so that it did not blindly attach itself to face index 5, which would now be a completely different face.

Before calling the optimization function, you can inquire how many faces the mesh has and allocate an array of DWORDS (1 per face) and pass this buffer into the function. When the function returns, each element in the array will describe the new post-optimization index for each face. In our example we said that the decal was attached originally to face 5. When the optimization was performed, this face had been moved to become face 10 in the index buffer. In this case, we could simply check the value stored in pFaceRemap[5] and it would hold a value of 10 -- the new location of the original face 5. We could then update the face index stored in the decal.

If you do not require this information about the post optimized mesh (which is often the case), you can set this parameter to NULL and no face remap information will be returned.

LPD3DXBUFFER *pVertexRemap

The final parameter is the address of a pointer to an ID3DXBuffer interface. In principle, it serves the same purpose for vertices as the previous parameter did for faces. The ID3DXBuffer interface provides access to generic memory buffers that are used by various D3DX functions to return or accept different data types (vertex or adjacency information for example). Unlike the face remap parameter where we pre-allocated the array, the vertex remap parameter should be the address of a pointer only. This will be used to allocate the buffer inside the function and return the information to the caller. If your application does not need the returned vertex buffer re-map information, you can just pass NULL. But if you do use it, make sure to release the ID3DXBuffer interface to free the underlying memory.

If we do not specify the `D3DMESHOPT_IGNOREVERTS` modifier flag, it is likely that the vertex data was reorganized during the call. Therefore, we will get back a buffer that contains enough space to hold one DWORD for every vertex in the original pre-optimized mesh. For each element in the returned buffer the following relationship is true.

pVertexRemap [***OldVertexIndex***] = ***NewVertexIndex***

Optimization Example I

We have now covered all of the parameters to the ID3DXMesh::OptimizeInPlace function. We have seen that the optimization features are quite impressive and extremely easy to use. Most of the time we will not need the face re-map and vertex re-map information or the newly compiled adjacency information and we will pass NULL as the last three parameters. However, the following code shows how we might optimize the mesh and store all returned information just in case. This code assumes that pd3dxMesh is a pointer to a valid ID3DXMesh interface.

```
// Allocate adjacency buffer needed for optimize
DWORD *pOldAdjacency = new DWORD[ pd3dxMesh->GetNumFaces() * 3];
DWORD *pNewAdjacency = new DWORD[ pd3dxMesh->GetNumFaces() * 3];
DWORD *pFaceRemap    = new DWORD[ pd3dxMesh->GetNumFaces()    ];
ID3DXBuffer* pVertexRemap;

// Generate adjacency with a 0.001 tolerance
pd3dxMesh->GenerateAdjacency( 0.001 , &pOldAdjacency );

// Optimize the mesh ( D3DXOPTMESH_ATTRSORT = Attribute Sort + Compact )
pd3dxMesh->OptimizeInPlace ( D3DXMESHOPT_ATTRSORT, pOldAdjacency,
                             pNewAdjacency, pFaceRemap, &pVertexRemap );
```

Optimization Example II

In the next example we do not need the face re-map, vertex re-map, or new adjacency information. This simplifies the code to only a few lines. Here we perform a compaction, attribute sort, and a vertex cache optimization.

```
// Allocate adjacency buffer needed for optimize
DWORD *pOldAdjacency = new DWORD [ pd3dxMesh->GetNumFaces() * 3];

// Generate adjacency with a 0.001 tolerance
pd3dxMesh->GenerateAdjacency( 0.001 , &pOldAdjacency );

// Optimize the mesh ( D3DXMESHOPT_VERTEXCACHE = Cache + Attribute Sort + Compact )
pd3dxMesh->OptimizeInPlace(D3DXMESHOPT_VERTEXCACHE, pOldAdjacency,
                           NULL, NULL, NULL );
```

The ID3DXMesh::Optimize function works in almost exactly the same way as the OptimizeInPlace call we just studied. The exception is that the current mesh data is not altered in any way. Instead, a new mesh is created and the optimization takes place there. Once the function has returned, you will have two copies of the mesh: the original un-optimized version whose interface you used to issue the ID3DXMesh::Optimize call, and a new optimized D3DXMesh object. These meshes have no interdependencies, so the original un-optimized mesh could be released if no longer needed.

```
HRESULT Optimize
(
    DWORD Flags,
    CONST DWORD *pAdjacencyIn,
    DWORD *pAdjacencyOut,
    DWORD *pFaceRemap,
    LPD3DXBUFFER *ppVertexRemap,
    LPD3DXMESH   *ppOptimizedMesh
);
```

Unless otherwise specified, when we use the ID3DXMesh::Optimize function, the newly generated mesh will inherit all of the creation parameters of the original mesh.

> **Note:** When we create (or clone) a mesh, we can specify one or more creation flags using members of the D3DXMESH enumerated type. This allows us to control things such as the resource pools the index and vertex buffers are created in. Because the Optimize function is creating a new mesh for the optimized data, we can also combine members of the D3DXMESH enumerated type with the usual D3DXMESHOPT flags discussed previously. This allows us to specify not only the optimization flags we require, but also the creation flags for the newly created optimized mesh.
>
> Although the D3DXMESH enumerated type will be covered shortly, you should know for now that we cannot use the D3DXMESH32_BIT, D3DXMESH_IB_WRITEONLY and D3DXMESH_WRITEONLY mesh creation flags during this call.

8.5 ID3DXBuffer

Before we cover the mesh loading routines, let us briefly discuss the ID3DXBuffer interface in a little more detail. The ID3DXBuffer is used to return arbitrary length data from D3DX functions. It is used in a number of function calls to return things like error message strings, face adjacency, and vertex and material information from optimization and loading functions.

Once a buffer of information has been returned from a D3DX function, you can save it for later use, retrieve a pointer to the buffer data area, or discard the buffer information by releasing the interface. Typically we will copy the data out to more useful structures used by our application. Just remember to release the buffer interface when it is no longer needed.

This interface is derived from IUnknown and exposes only two methods. One returns the size of the buffer and the other returns a void pointer to the raw buffer data. The two methods of the ID3DXBuffer interface are shown and described next.

```
DWORD ID3DXBuffer::GetBufferSize(VOID);
```

This function returns a DWORD describing the size of the buffer in bytes.

```
LPVOID ID3DXBuffer::GetBufferPointer(VOID);
```

This function returns a void pointer to the raw buffer data. This is similar to a pointer that gets returned when we lock a vertex buffer or a texture. Notice that there is no concept of locking or unlocking an ID3DXBuffer object like we saw with other resources.

To use the ID3DXBuffer interface for storing your own data collections, you can create an ID3DXBuffer object by calling the global D3DX function D3DXCreateBuffer.

```
HRESULT D3DXCreateBuffer(DWORD NumBytes, LPD3DXBUFFER *ppBuffer);
```

To allocate an ID3DXBuffer using this function, we pass in the size of the buffer to allocate and the address of an ID3DXBuffer interface pointer. If the function is successful, this second parameter will point to a valid ID3DXBuffer interface.

8.6 Mesh Loading Functions

8.6.1 D3DXLoadMeshFromX

The global D3DX function D3DXLoadMeshFromX creates a new D3DXMesh and loads X file data into its vertex, index, and attribute buffers. It basically creates a ready-to-render mesh for our application with a single function call. However, no data optimization will have been performed on the returned mesh, so if you want to optimize the resulting mesh, you will need to do this as a separate step with a call to ID3DXMesh::OptimizeInPlace after the mesh has been loaded. More often than not, you will be loading your meshes from X files. This function does all the hard work of parsing the X file data and creating a new mesh for you. It is shown below along with a description of its parameter list.

```
HRESULT D3DXLoadMeshFromX
(
    LPCTSTR pFilename,
    DWORD Options,
    LPDIRECT3DDEVICE9 pDevice,
    LPD3DXBUFFER* ppAdjacency,
    LPD3DXBUFFER* ppMaterials,
    LPD3DXBUFFER* ppEffectInstances,
    DWORD* pNumMaterials,
    LPD3DXMESH* ppMesh
);
```

LPCTSTR pFilename

This is a string containing the file name of the X file we wish to load. If the compiler settings require Unicode, the data type LPCTSTR resolves to LPCWSTR. Otherwise, the string data type resolves to LPCSTR.

DWORD Options

Here we specify one or more flags from the `D3DXMESH` enumerated type describing how we would like the mesh to be created. This enumerated type contains members that can be used for all mesh types (including ID3DXPatchMesh, which is not covered in this chapter), so not all members will be valid for ID3DXMesh creation. These flags control items like the vertex and index buffer resource pool and whether the buffers are static or dynamic. These are basically wrappers around the standard vertex buffer and index buffer creation flags we discussed in Chapter Three.

D3DXMESH_32BIT

If this flag is specified then the index buffer will be created with 32-bit indices instead of the default 16-bit indices. This is analogous to specifying the `D3DFMT_INDEX32` usage flag when creating an index buffer using the IDirect3DDevice9::CreateIndexBuffer function.

D3DXMESH_DONOTCLIP

This informs the mesh to create its underlying vertex and index buffers such that they will never require clipping by the pipeline. This is analogous to the `D3DUSAGE_DONOTCLIP` flag used when manually creating a vertex buffer with the IDirect3DDevice9::CreateVertexBuffer function. The default state (the absence of this flag) is to create buffers that pass through the clipping process of the pipeline. If you know that your mesh will always be rendered such that it is within the bounds of the render target, this flag can speed up pipeline processing.

D3DXMESH_POINTS

This is a simple wrapper around creating a vertex buffer with the `D3DUSAGE_POINTS` flag. This is used for rendering a special primitive called a point sprite. Point sprites will be discussed in Module III.

D3DXMESH_RTPATCHES
D3DXMESH_NPATCHES

These flags can be used to create the mesh for storage of higher-order primitives and N-patches. These types are beyond the scope of this chapter and will be covered later in this course series. They are analogous to creating vertex buffers and index buffers manually using the `D3DUSAGE_RTPATCHES` and `D3DUSAGE_NPATCHES` flags.

D3DXMESH_VB_SYSTEMMEM
D3DXMESH_VB_MANAGED

These two flags are mutually exclusive. They allow us to specify the resource pool where we would like the mesh vertex buffer stored. By default, if we do not specify one of these flags, the vertex buffer will be created in the default memory pool. The same rules about resource persistence apply here when a device is lost and reset (see Chapter Three). Default pool buffers become invalid when a device is lost. This requires having to release and recreate the mesh from scratch using either the D3DXLoadMesh… or D3DXCreateMesh functions. To avoid this step when using the default pool, a common practice is to store two meshes: one in system memory and one in video memory. When the video memory copy becomes lost, it is released and

recreated by cloning from the system memory mesh. As discussed in Chapter Three, all of this can be avoided through the use of the managed memory pool (`D3DXMESH_VB_MANAGED`). When the device is lost and reset, the DirectX memory manager will automatically handle the release and recreation of the internal buffers.

D3DXMESH_VB_WRITEONLY
This is analogous to specifying the `D3DUSAGE_WRITEONLY` flag during normal vertex buffer creation. In Chapter Three we discussed using this flag for optimal rendering performance. However, we also learned that we should not do this if we intend to read from the vertex buffer since the lock call could potentially fail or return an aliased pointer directly into video memory, resulting in terrible performance.

When using this flag to create a mesh, we have to be very careful because many of the mesh functions (GenerateAdjacency, OptimizeInPlace, and even D3DXLoadMeshFromX) require read access to the vertex and index buffers. Specifying this flag will cause these functions to fail. Note that even though this flag can be specified in the D3DXLoadMeshFromX function, the function will fail if this is the case.

So it would seem as if there is no way to create a mesh with the `D3DXMESH_VB_WRITEONLY` flag and then optimize it, because to optimize a mesh we first need to generate the adjacency information (which will fail if the vertex buffer is write-only). Furthermore, the vertex buffer itself will usually be read from and reordered during an attribute sort (which will also fail if the mesh has a write-only vertex buffer).

To get the benefit of optimized write-only vertex buffers in our meshes, we will load the mesh into a temporary mesh (usually in system memory) created without the `D3DXMESH_VB_WRITEONLY` flag. At this point, adjacency information can be generated and optimization performed. Finally, we will clone the mesh and specify that the clone have the write-only flag set. We will discuss mesh cloning later in this chapter.

D3DXMESH_VB_DYNAMIC
This flag is analogous to specifying `D3DUSAGE_DYNAMIC` when creating a normal vertex buffer. Because dynamic vertex buffers carry some overhead due to a buffer swapping mechanism that allows the buffer to be locked without stalling the pipeline, you should only create a mesh with a dynamic vertex buffer if you intend to lock the and alter the vertex buffer contents in time critical situations. Dynamic vertex buffers were discussed in Chapter Three.

D3DXMESH_VB_SOFTWAREPROCESSING
This flag is analogous to the `D3DUSAGE_SOFTWAREPROCESSING` flag that we can specify when creating a vertex buffer manually. When using a mixed-mode device, we must indicate when a vertex buffer (and therefore a mesh) is created whether we intend to render it when the device is in software or hardware vertex processing mode. By default, the mesh vertex buffer will be created for hardware vertex processing. If we intend to use the mesh in software vertex processing mode on a mixed-mode device, we must specify this flag.

D3DXMESH_IB_SYSTEMMEM
D3DXMESH_IB_MANAGED
D3DXMESH_IB_WRITEONLY
D3DXMESH_IB_DYNAMIC
D3DXMESH_IB_SOFTWAREPROCESSING
The five flags listed above control how the index buffer of the mesh is generated. They are analogous to their vertex buffer counterparts previously discussed. Vertex buffers and index buffers are stored on the same type of memory surface, so the semantics of both are the same.

D3DXMESH_VB_SHARE
Later in the chapter we will discuss mesh cloning using the ID3DXBaseMesh::Clone and ID3DXBaseMesh::CloneFVF functions. By default these functions create a new mesh object and copy the data from the original mesh into its vertex, index, and attribute buffers. When we specify this flag as an option to the ID3DXBaseMesh::Clone function, the result will be a new mesh object that shares the vertex buffer with the original mesh. This is often referred to as *instancing* (see Chapter One). Any modifications made to the master vertex buffer will affect all cloned meshes. It should be noted that this is not a valid mesh creation flag for the D3DXCreateMesh or D3DXLoadMeshFromX functions. It should only be used in a mesh cloning operation.

D3DXMESH_USEHWONLY
This flag is only valid for the ID3DXSkinInfo::ConvertToBlendedMesh function. It creates a mesh that has per-vertex blend weights and a bone combination table from a standard ID3DXMesh. Skinned meshes will be covered later in this course, so we can ignore this flag for now.

The next five members are combinations of the previous flags discussed. They emerge from the concept that we will often create both the index buffer and the vertex buffer in the same resource pools using the same functionality.

D3DXMESH_SYSTEMMEM
Informs the mesh creation functions that we wish both the vertex buffer and the index buffer of the mesh to be created in system memory. Equivalent to specifying both `D3DXMESH_VB_SYSTEMMEM` and `D3DXMESH_IB_SYSTEMMEM`.

D3DXMESH_MANAGED
Informs the mesh creation functions that we wish both the vertex buffer and the index buffer of the mesh to be created in the managed memory pool. Equivalent to specifying both `D3DXMESH_VB_MANAGED` and `D3DXMESH_IB_MANAGED`.

D3DXMESH_WRITEONLY
Specifying this flag will create the mesh index buffer and vertex buffer with the write-only flag. Equivalent to specifying both `D3DXMESH_VB_WRITEONLY` and `D3DXMESH_IB_WRITEONLY`.

D3DXMESH_DYNAMIC
Equivalent to specifying both `D3DXMESH_VB_DYNAMIC` and `D3DXMESH_IB_DYNAMIC`. This will create a mesh that can have both its vertex buffer and index buffer efficiently locked without stalling the pipeline.

D3DXMESH_SOFTWAREPROCESSING
Equivalent to specifying both `D3DXMESH_VB_SOFTWAREPROCESSING` and `D3DXMESH_IB_SOFTWAREPROCESSING`. Used to specify when using a mixed mode device that the mesh will be rendered in software vertex processing mode.

We have not covered all of the flags that can be specified as the second parameter to the D3DXLoadMeshFromX function. However you will usually find yourself using only one or two of the flags we have looked at here. Please consult the SDK documentation if you would like more information on other flag types.

LPDIRECT3DDEVICE9 pDevice
This is a pointer to the device interface. Mesh objects are always owned by the device object because the vertex and index buffers themselves are owned by the device object.

LPD3DXBUFFER * ppAdjacency
This is the address of an ID3DXBuffer pointer. It should *not* point to an already valid buffer interface since the function creates the buffer object when called. If the function is successful and the mesh is successfully created, this pointer will point to a valid ID3DXBuffer interface that contains the face adjacency information for the mesh. There will be three DWORDs in this buffer for every triangle in the mesh. If your application does not require the face adjacency information, you can simply release this buffer.

LPD3DXBUFFER *ppMaterials
This buffer represents an array of D3DXMATERIAL structures. The D3DXMATERIAL structure is a superset of the D3DMATERIAL9 structure and contains both a D3DMATERIAL9 and a texture filename.

```
typedef struct D3DXMATERIAL
{
      D3DMATERIAL9 MatD3D;
      LPSTR pTextureFilename;
} D3DXMATERIAL;
```

There is one structure in the array for each mesh subset. Thus, if the numbers in the attribute buffer range from 0 to 5 (indicating six subsets) then this buffer will store six D3DXMATERIAL structures. The subset ID itself is the index of the D3DXMATERIAL in the array.

The D3DXMATERIAL structure describes a texture/material pair. This information is stored in the X file and describes the texture and material information for each subset. For example, before calling DrawSubset and passing a value of 0 for the first subset of the mesh, we first set the material and texture described in the first element of the D3DXMATERIAL array.

Note that this information will not be maintained by the mesh object after the call. The application must store the material and texture information in its own arrays for correct subset rendering. Also note that while the material information is stored in the X file, only the texture filename is returned. It is the application's responsibility to load the texture.

While the term ‘material’ is actually quite commonly used in 3D graphics programming circles to describe all of the rendering attributes for a surface, it can be somewhat confusing given the limited definition of a material that we have been using since studying lighting in Chapter Five. The D3DXMATERIAL structure might have been more appropriately named something like D3DXATTRIBUTE or D3DXSUBSETATTRIBUTE to more accurately describe what each element in the material buffer holds, and to minimize confusion. As it stands, just try to keep this in mind moving forward. We can see that because each structure holds the texture and material used by a given subset, two separate subsets that have unique material information but share the same texture information will be represented by two unique D3DXMATERIAL structures in the buffer. Therefore, as multiple D3DXMATERIAL structures may reference the same texture, we must make sure that we do not load the texture multiple times.

Something else which is worth noting is that the X file format supports vertices with multiple sets of texture coordinates but supports only a single texture per face. That is, there is no explicit multi-texture support in the default X file format (although you can create custom chunks to support this feature).

Another small note about the X file format is that it does not store a material ambient property. Although the D3DXMATERIAL structure encapsulates a D3DMATERIAL9 structure (which does indeed support an ambient color), it will always be set to 0 for all materials extracted from the X file. This can create some degree of confusion if you are not aware of this limitation, so it might be wise to set the ambient color of the material to (1,1,1,1) when copying the material data out of the buffer. This will allow for controlling the ambient setting with the `D3DRS_AMBIENT` render state.

DWORD *pNumMaterials
This is the address of a DWORD which will contain the number of materials in the D3DXMATERIAL buffer. Consequently, this value also describes the number of subsets in the mesh and informs us that the attribute buffer will contain Attribute IDs in the range [0, NumMaterials-1].

LPD3DXBUFFER* ppEffectInstances
In Module III we will study Effects, which are essentially a high level abstraction that encapsulates rendering concepts like texture states, transforms states, render states, and more. This buffer is an array of D3DXEFFECTINSTANCE structures (one for each subset). Each structure contains the filename of the effect file that should be used for rendering the subset and an array of default values that can be passed into the effect file code. This allows an artist or modeler to store the default parameters for an effect in the X file. It should be noted that the X file does not store the actual effect file. Effect files will need to be loaded by the application as was the case with textures stored in the material buffer.

LPD3DXMESH* ppMesh
The final parameter is the address of a pointer to an ID3DXMesh interface. If the function is successful this will point to a valid mesh interface when the function returns.

The following code snippet demonstrates how we might use this function to load an X file into an ID3DXMesh. In this example it is assumed that the CScene class has an array allocated to store D3DMATERIAL9 structures and an array of TEXTURE_ITEM structures to store the textures and their filenames. We use a structure rather than just storing the texture interface pointers so that we can store the texture filename to make sure we do not load it more than once.

```
typedef struct _TEXTURE_ITEM
{
    LPSTR               FileName;   // File used to create the texture
    LPDIRECT3DTEXTURE9  Texture;    // The texture pointer itself.
} TEXTURE_ITEM;
```

The following code loads the X file and immediately releases the returned adjacency and effect instance buffers because they are not needed in this example. After that, we get a pointer to the returned D3DXMATERIAL buffer and start copying the material information to our CScene class D3DMATERIAL9 array and load the textures and into the CScene::m_pTextureList array.

```
ID3DXBuffer       *pAdjacency;
ID3DXBuffer       *pSubSetAttributes;
ID3DXBuffer       *pEffectInstances;
ID3DXMesh         *pMesh;
DWORD              NumAttributes;

D3DXLoadMeshFromX("Cube.x", D3DXMESH_MANAGED, pDevice , &pAdjacency,
                  &pSubSetAttributes, &pEffectInstances, &NumAttributes, &pMesh);

// We don't need this info in this example so release it
pAdjacency->Release();
pEffectInstances->Release();

// Lets get a pointer to the data in the material buffer
D3DXMATERIAL *pXfileMats = (D3DXMATERIAL*) pSubSetAttributes->GetBufferPointer();
```

At this point we can use the pointer to the D3DXMATERIAL data to step through the material buffer and process the information. The first step copies the D3DMATERIAL9 information into the CScene material array. Since an X file does not contain ambient information, we set the ambient property to opaque white after the copy.

```
// Loop through and store all the materials and load and store all the textures
for ( DWORD  i = 0 ; i < NumAttributes ; i++ )
{
    // first copy the material data into the scenes material array
    pScene->m_Materials[i] = pXFileMats[i].MatD3D;
    pScene->m_Materials[i].Ambient = D3DXCOLOR ( 1.0f , 1.0f , 1.0f , 1.0f );
```

Now we will process the texture for the current attribute. We will check to see whether any of the previous textures we have loaded share the same filename and if so, store a copy of the pointer in the current TEXTURE_ITEM element and increase the texture's reference count.

```
    // Used to track the whether a texture has already been loaded.
    BOOL bTextureFound = FALSE;

   // Next we need to check if the texture filename already exists in our
   // scene. If so, we don't want to load it again. We will just store its
   // pointer in the new array slot.

   for ( ULONG q = 0; q < pScene->m_TextureCount; ++q)
   {
```

```
        if( _tcsicmp( pScene->m_pTextureList[q]->FileName,
                  pXFileMats[i].pTextureFilename ) == 0 )
        {
                pScene->m_pTextureList[i]->Texture=
                                        pScene->m_pTextureList[q]->Texture;

                pScene->m_pTextureList[i]->Filename=
                           strdup(pScene->m_pTextureList[q]->Filename);

                pScene->m_pTextureList[i]->AddRef();

                bTextureFound = TRUE:
        }

    } // Next Texture
```

If the loop ends and bTextureFound is still false, then this is a new texture and must be loaded and the filename stored for future comparisons.

```
     // If the texture did not already exist load it into our array
     if( !bTextureFound )
     {
        D3DXCreateTextureFromFile(pScene->m_pD3DDevice,
                                  pXFileMats[i].pTextureFilename,
                                  &pScene->m_pTextureList[i]->Texture);

        pScene->m_pFilename = strdup(  pXFileMats[i].pTextureFilename );
     }

     // a new texture has been added to our CScene TEXTURE_ITEM array.
     pScene->m_TextureCount++;

} // next material in buffer
```

The code above requires some tighter error checking (for example, a material may not have a valid texture filename) but it gives us a good idea of the basic steps.

At this point, each face in our mesh has an Attribute ID assigned and stored in the attribute buffer. This ID describes the index of the material and texture it should be rendered with. With this in mind, we can render our mesh like so:

```
pDevice->SetFVF( pMesh->GetFVF() );

// render our mesh
for ( DWORD i = 0; i < NumAttributes; i++ )
{
      pDevice->SetMaterial ( &pScene->m_Materials[i] );
      pDevice->SetTexture  ( 0 , pScene->m_pTextureList[i].Texture );
      pMesh->DrawSubset    ( i );
}
```

8.6.2 D3DXLoadMeshFromXInMemory

We can also load the X file data in its entirety into a block of memory and instantiate a mesh object using this stored data. The block of memory should be an exact representation of the X file (headers, etc.). This can be done by inquiring about the size of the file, allocating a block of memory to accommodate it, and then reading every byte of the file into the memory buffer. Once the file is in memory, you can use the following function to create an ID3DXMesh:

```
HRESULT D3DXLoadMeshFromXInMemory
(
    LPCVOID Memory,
    DWORD SizeOfMemory,
    DWORD Options,
    LPDIRECT3DDEVICE9 pDevice,
    LPD3DXBUFFER *ppAdjacency,
    LPD3DXBUFFER* ppMaterials,
    LPD3DXBUFFER* ppEffectInstances,
    DWORD *pNumMaterials,
    LPD3DXMESH *ppMesh
);
```

This function is analogous to the texture loading function D3DXCreateTextureFromFileInMemory (see Chapter Six) in that rather than loading the X file from a file on the hard disk, it loads it from data that is stored in memory. With the exception of the first two parameters, all other parameters are identical to the D3DXLoadMeshFromX function.

LPCVOID Memory
This is a pointer to the first byte in the block of memory containing the X file data that has been loaded.

DWORD SizeOfMemory
This parameter describes the size of the X file data memory block in bytes.

8.6.3 D3DXLoadMeshFromXResource

Sometimes storing models as resources -- which are compiled either inside the application module or an external compiled module -- is preferred since it prevents users from gaining access to your models outside of the application. For smaller applications this is fine, but we will look at better alternatives for keeping our data safe in Module III.

The last seven parameters are identical to those described in the D3DXLoadMeshFromX function. The first three parameters are used to pass information about the module the X file resource is stored in, the name of the resource within the module, and the type of resource that it is.

```
HRESULT D3DXLoadMeshFromXResource
(
    HMODULE Module,
    LPCTSTR Name,
    LPCTSTR Type,
    DWORD Options,
    LPDIRECT3DDEVICE9 pDevice,
    LPD3DXBUFFER *ppAdjacency,
    LPD3DXBUFFER *ppMaterials,
    LPD3DXBUFFER* ppEffectInstances,
    DWORD *pNumMaterials,
    LPD3DXMESH *ppMesh
);
```

HMODULE Module
This is the handle of an already loaded module that contains the resource.

LPCTSTR Name
This is the name that has been given to the X file resource in the module. It is used to extract the correct resource from the specified module.

LPCTSTR Type
This is a string describing the resource type.

8.6.4 D3DXLoadMeshFromXof

```
HRESULT D3DXLoadMeshFromXof
(
    LPDIRECTXFILEDATA pXofObjMesh,
    DWORD Options,
    LPDIRECT3DDEVICE9 pD3DDevice,
    LPD3DXBUFFER *ppAdjacency,
    LPD3DXBUFFER *ppMaterials,
    LPD3DXBUFFER* ppEffectInstances,
    WORD* pNumMaterials,
    LPD3DXMESH *ppMesh
);
```

This function is used to work with lower level X file parsing routines. While DirectX Graphics now provides most of the high level X file loading and creation functions that we should need, many of these functions were not available in earlier versions of DirectX. Even DirectX 8 had no mechanism to automatically load mesh hierarchies (Chapter Nine), so X files had to be loaded at a lower level. Even now, it is possible that you may still need to resort to lower level X file loading -- if you intend to place customized template types in your X files, then this is certainly the case.

From the very early days of DirectX, a set of interfaces has been available to parse X files. Although a complete discussion of these low level interfaces is beyond the scope of this chapter, there is some

coverage included in the next chapter and in the DX9 SDK documentation itself (check the section called 'The X File Reference'). For now, we will briefly explain the basics of how these interfaces work.

The first thing we need to do to load data manually from an X file is call the function DirectXFileCreate. This will create a DirectXFile object and return a pointer to an IDirectXFile interface.

```
IDirectXFile *pXfile;
DirectXFileCreate ( &pXfile );
```

The IDirectXFile interface exposes three methods:

- CreateEnumObject - used for enumerating the memory chunks in the X file (meshes, materials matrices, etc.)

- CreateSaveObject - creates an interface that allows you to save data out to an X file (with custom templates if desired) \

- RegisterTemplates - used to register your own custom templates so that they are recognized by both the enumerator and save objects.

Normally the first thing we would do after creating the interface is register the standard X file templates. The following function call makes sure that the X file interfaces understand all of the common templates found in an X file.

```
pXfile->RegisterTemplates((VOID*) D3DRM_XTEMPLATES, D3DRM_XTEMPLATE_BYTES);
```

We now call the CreateEnumObject function to create an enumeration object for a given file. We will get back an IDirectXFileEnumObject interface, which we can use to step through the file contents.

```
IDirectXFileEnumObject *pEnumObject;
pXfile->CreateEnumObject( "MyXfile.x" , DXFILELOAD_FROMFILE ,&pEnumObject );
```

The first parameter is actually dependant on the second parameter. In this case, because we are specifying `DXFILELOAD_FROMFILE`, the first parameter should be the X file name. The third parameter is the address of an IDirectXFileEnumObject interface that will point to a valid enumeration object on function return.

Once we have the enumeration object, we can use it to step through the *top-level* data chunks in the X file. A top-level object in an X file is an object which has no parent, but may or may not have multiple child objects. (The concept of parent/child hierarchies will be discussed in detail in the next chapter).

We use the IDirectXFileEnumObject::GetNextDataObject function to fetch the next top-level data object from the X file. It will return a pointer to an IDirectXFileData interface representing the retrieved data object. This interface can then be used to inquire about the object's properties. The following code shows how we can retrieve top-level objects in the mesh file using a while loop.

```
while (SUCCEEDED(pEnumObject->GetNextDataObject(&pFileData)))
{
    pFileData->GetType(&pGuid);

    if (*pGuid==TID_D3DRMMesh) ParseMesh ( pFileData );

    pFileData->Release();
}
```

Once we have the data object, we can call the IDirectXFileData::GetType function to return the GUID for the object type. The DirectX SDK provides a list of all object types and their associated GUIDs so that we can use them to make decisions about how and what to parse. In the simple example above, we are ignoring all top-level objects except meshes. Once we locate a mesh, we can extract the data from it using the D3DXLoadMeshFromXof as shown below.

> **Note**: If we load a mesh hierarchy manually using this approach, then we will also want to also process the TIF_D3DTMFrame top-level object and any child objects. Frame objects can contain additional child meshes and matrices describing parent-child spatial relationships. Processing a frame object is a recursive concept where we test for children and create child meshes as needed. These are stored along with their respective matrices. In our example above, child meshes and frames would be ignored and only top-level meshes would be created. In the next chapter, we will discuss scene hierarchies.

```
void ParseMesh ( IDirectXFileData * pFileData )
{
    ID3DXBuffer * pAdjacency;
    ID3DXBuffer * pMaterials;
    ID3DXBuffer * pEffects;

    D3DXLoadMeshFromXof ( pFileData , D3DXMESH_MANAGED , pDevice ,
                          pAdjacency, pglbMaterials[glbMeshCount],pEffects,
                         &pglbNumMaterials[gblMeshCount],
                         &pMeshArray[glbMeshCount] );

    glbMeshCount++;
    pAdjacency->Release();
    pEffects->Release();

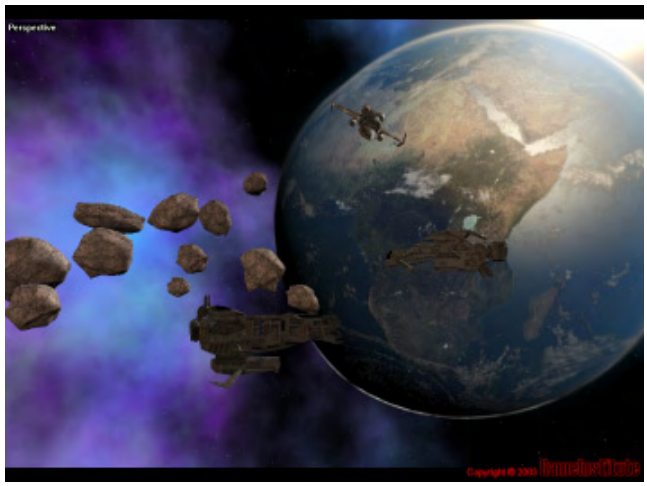
}
```

The above function assumes that pglbMaterials is a global array of ID3DXBuffer interface pointers. For each mesh extracted, we can store its buffer in an array for later processing. The number of materials is stored in a global and this tells us how many materials are in the corresponding materials buffer. The returned ID3DXMesh interface is also stored in a global array. The adjacency and effect buffers are simply released as we are not using them in this example.

> **Note:** D3DXLoadMeshFromX, D3DXLoadMeshFromXInMemory, D3DXLoadMeshFromXof and D3DXLoadMeshFromResource do not support the loading of multiple meshes and arranging them in a hierarchical fashion. It is often the case (as we will see in the next chapter) that an X file may contain a number of mesh objects which may or may not be arranged hierarchically. When an X file is loaded using one of these functions, a single mesh is returned. If the file contained multiple meshes, they will be collapsed into a single mesh. We still get the full geometry set, but we lose the ability to move each sub-mesh independently. If the file contains a mesh hierarchy, such that a mesh can have child meshes and transformation matrices, this function will transform the child meshes using the matrices in the X file

before collapsing it into the returned mesh. This ensures that meshes that are defined relative to parent meshes in the X file correctly collapse into a single mesh with one coordinate space. In Chapter Nine we will examine how to load mesh hierarchies.

8.7 Mesh Creation



Often we will need to create mesh objects manually for the purpose of filling them with data from another file format (IWF for example). In Lab Project 8.1, we will create a simple mesh viewing application that supports X and IWF file loading. Some of our scene meshes will be loaded from X files using the D3DXLoadMeshFromX function and others will be created manually and populated with mesh data from an IWF file.

Creating an empty mesh is done with a call to either the D3DXCreateMeshFVF or D3DXCreateMesh functions.

D3DXCreateMesh allows us to specify a mesh vertex format using something called a *declarator*. Vertex declarators and the D3DXCreateMesh function will be discussed in Module III of this series when we examine vertex shaders. For the rest of this course, we will use the D3DXCreateMeshFVF version of the function. D3DXCreateMeshFVF allows us to describe the desired vertex format using the more familiar flexible vertex format flags.

```
HRESULT D3DXCreateMeshFVF
(
    DWORD NumFaces,
    DWORD NumVertices,
    DWORD Options,
    DWORD FVF,
    LPDIRECT3DDEVICE9 pDevice,
    LPD3DXMESH *ppMesh
);
```

DWORD NumFaces
This parameter tells the function how many triangles the mesh will have. This value will be used to allocate the mesh index buffer and its attribute buffer to ensure enough space to accommodate this many triangles.

DWORD NumVertices
This parameter tells the function how many vertices will be stored in the vertex buffer. The function uses this value to allocate a vertex buffer large enough to hold only this number of vertices.

DWORD Options

The options flag has the same meaning we saw in the D3DXLoadMesh… functions. It informs the function about memory resource pools, static vs. dynamic properties and/or write-only status. Unlike D3DXLoadMeshFromX and its sister functions, you can use the `D3DXMESH_VB_WRITEONLY`, `D3DXMESH_IB_WRITENONLY` and `D3DXMESH_WRITEONLY` flags and the function will not fail. As mentioned previously however, if you do specify any of these flags, then any subsequent calls to optimize the mesh or generate face adjacency information will fail. Thus, only use the write-only flags if you do not plan on touching the buffers that have been created.

DWORD FVF

Since we are creating an empty mesh, we can choose the vertex format we wish the mesh to use. This flag will be used in conjunction with the NumVertices parameter to allocate the appropriate amount of vertex buffer memory. These FVF flags are no different than the FVF flags we have been using throughout this series when creating a vertex buffer.

LPDIRECT3DDEVICE9 pDevice

Because the device object will own the vertex and index buffer memory, we must pass in a pointer to the device interface for mesh creation.

LPD3DXMESH *ppMesh

The final parameter is the address of an ID3DXMesh interface pointer. On successful return, it will point to the newly created mesh object interface.

The following code demonstrates creating an empty mesh object with enough space in its vertex buffer for 24 untransformed and unlit vertices. The index buffer is large enough to contain 12 triangles (12*3 = 36 indices) and an attribute buffer large enough to hold 12 DWORDs -- one for each face.

```
ID3DXMesh *pMyMesh;
DWORD fvfFlags = D3DFVF_XYZ | D3DFVF_NORMAL | D3DFVF_TEX1
D3DXCreateMeshFVF (24, 12, D3DXMESH_MANAGED, fvfFlags, pDevice, &pMesh);
```

At this point we have an empty mesh and we can begin filling it with our required information. This can be done by locking the buffers and copying the vertex, index, and attribute information into them. Check the source code and workbook for Lab Project 8.1 to see how this was done using IWF data exported from GILES™.

8.8 Mesh Cloning

Cloning is basically the process of duplicating mesh data. However, since we can also specify a desired vertex format, cloning is actually a bit more sophisticated than a simple copy operation. Every mesh type that is derived from ID3DXBaseMesh inherits the Clone and CloneFVF functions. Whenever we call a clone function, a new mesh will be generated and the original mesh data will be copied into the new mesh (although vertex buffer sharing is supported as well). The old mesh remains intact and can continue to be used normally.

Before we discuss some important uses for mesh cloning, let us first take a look at the ID3DXBaseMesh::CloneFVF function to see how we can perform a cloning operation. It should be noted that the ID3DXBaseMesh::Clone function (without the FVF) works with declarators rather than FVF flags. We will discuss vertex declarators in Module III of this series.

```
HRESULT ID3DXBaseMesh::CloneMeshFVF
(
    DWORD Options,
    DWORD FVF,
    LPDIRECT3DDEVICE9 pDevice,
    LPD3DXMESH *ppCloneMesh
);
```

DWORD Options

These flags will be a combination or zero or more members from the D3DXMESH enumerated type that will affect the way the cloned mesh is created. We discussed the various members of this enumerated type when we examined D3DXLoadMeshFromX and their meaning is the same. This means that the cloned mesh need not have its vertex buffers allocated in the same resource pools as the original mesh. It may also have dynamic buffers where the original did not. For example, we could create a mesh in the system memory pool, optimize it, and then clone it out to a mesh in the default pool with the `D3DXMESH_WRITEONLY` flag. This would create a video memory based optimized mesh for fast rendering. This is in fact a very common use of cloning.

One member of the D3DXMESH enumerated type is only used when cloning: `D3DXMESH_VB_SHARE`. With this flag, the cloned mesh will share the vertex buffer with the original mesh and the result is a memory savings. This can be very useful for proprietary LOD algorithms or even just simple mesh instancing. Modifying the original vertex buffer will affect all meshes cloned in this way. The default behavior is to create a cloned mesh with its own vertex, index, and attribute buffers.

DWORD FVF

This value allows us to pass FVF flags for the cloned mesh vertices. The result is that we can clone a mesh into a different vertex format. This can be very useful when we load X file meshes and have no direct control over the FVF format stored in the file. By cloning the mesh into a copy that uses a new vertex format, we can create additional room for texture coordinates or vertex normals that may not have been stored in the original X file. Once we have a cloned copy of the mesh, we could release the original mesh and make the clone the final mesh that we use for rendering.

LPDIRECT3DDEVICE9 pDevice
A pointer to the device that will own the mesh resources.

LPD3DXMESH *ppCloneMesh
Provided the function is successful, this will point to a valid interface for the newly cloned mesh.

Cloning Advantages

1. *Removal of unnecessary or extraneous vertex components.* It is easy to strip off vertex components that we do not intend to support in our engine. After loading a mesh (from a file for example) we simply specify the desired FVF and clone it. The new mesh will have only the required data and we can safely release the original mesh. As an example, imagine we load a mesh from an X file which contains vertex normals, but our engine has no use for them (perhaps it is not using the lighting pipeline). We could clone a new mesh which does not have vertex normals and then release the original. Our new mesh is now a streamlined version of the original X file representation containing only the data our application requires.

In the following code, pMesh is a pointer to a mesh that was created using the D3DXLoadMeshFromX function and it contains all of the components loaded from the X file. Assume that in this particular case, the mesh includes three sets of texture coordinates, two of which we do not need. We will create a clone that contains only the vertex components we are interested in.

```
LPD3DXMESH NewMesh;
pMesh->CloneMeshFVF(D3DXMESH_MANAGED, D3DFVF_XYZ | D3DFVF_NORMAL | D3DFVF_TEX1,
                    m_pD3DDevice, &NewMesh);
pMesh->Release();
```

2. *Adding missing vertex components.* We can also add vertex components that may not have been present in the original mesh. For example, if the mesh did not include vertex normals, we can add them by cloning with `D3DFVF_NORMAL` included in the flag. Note that while the clone will now have space for the required vertex components, the data itself will still need to be initialized. The cloning functions do not automatically generate the actual values for these added components. They can only make space for them in the vertices so that they can be later initialized.

In the next example, if the original mesh does not contain vertex normals, then we clone a version that does. Once we have a clone that includes space for vertex normals, we call D3DXComputeNormals (another very useful global D3DX function) to compute the vertex normals for the clone. The code assumes that m_pMesh is a pointer to a mesh that was loaded using D3DXLoadMeshFromX.

```
if(!m_pMesh->GetFVF() & D3DFVF_NORMAL)
{
    LPD3DXMESH NewMesh;

    // Introduce a normal component into our VB
    m_pMesh->CloneMeshFVF(m_pMesh->GetOptions(),
                          m_pMesh->GetFVF() | D3DFVF_NORMAL, m_pD3DDevice, &NewMesh);

    // Generate some new vertex normals
    D3DXComputeNormals( NewMesh, NULL );
```

```
    // Release old mesh and store
    m_pMesh->Release();
    m_pMesh = NewMesh;

} // End if no normals
```

3. *Building a render-ready mesh.* In certain situations, mesh cloning becomes a requirement. In a few cases, such as when working with the utility classes (ID3DXSPMesh/ID3DXPatchMesh), the clone functions exposed by these interfaces are the only way to get the data back out to a render-ready format -- an ID3DXMesh.

4. *Maximum benefit from optimization functions*. Write-only buffers make rendering more efficient, but in order for mesh optimization functions to succeed, they need read access to the buffer data. Write-only vertex buffers will cause these routines to fail. In order to achieve both ends, a common practice is to load the mesh into system memory and perform the geometry optimizations. Since the optimization process is performed by the host CPU and not the graphics card, they will be performed more rapidly on a system memory mesh anyway. Once the mesh has been optimized, we will clone the system memory mesh to a default pool or managed pool mesh. This is where we can specify the write-only flag for the clone's vertex buffer. At this point we can either release the system memory copy or store it for later use (perhaps to re-clone on device loss if using the default pool for the clone).

The following code loads a mesh into system memory and performs the optimization step. The optimized mesh is then cloned out to the default pool with the write-only flag set for both buffers.

```
ID3DXBuffer *pAdj ;
ID3DXBuffer *pMat;
ID3DXBuffer *pEff;
ID3DXMesh *pSysCopyMesh;
ID3DXMesh *pRenderCopyMesh;

// Load the X file into a system memory mesh
D3DXLoadMeshFromX("Cube.x" , D3DXMESH_SYSTEMMEM , pDevice , &pAdj , &pMat,
                  &pEff , &NumMaterials , &pSysCopyMesh );

// Release the effects buffer, we will not use it in this example
pEff->Release();
pEff = NULL;

DWORD *pAdjacency = pAdj->GetBufferPointer();

// Optimize the mesh and pass in the adjacency array
pSysCopyMesh->OptimizeInPlace(D3DXMESHOPT_VERTEXCACHE, pAdjacency, NULL, NULL, NULL);

// Optimization has been done se we no longer need the adjacency info
pAdj->Release();
pAdj = NULL;
pAdjacency = NULL;

// Clone the mesh out to a default pool mesh with write only vertex and index buffers
pSysCopyMesh->CloneFVF(D3DXMESH_WRITEONLY, pSysCopyMesh->GetFVF(),
                       pDevice, &pRenderCopyMesh);

// Release the system memory copy
pSysCopyMesh->Release();
```

To conclude our discussion of the ID3DXMesh interface, there is one more function inherited by all mesh types from the ID3DXBaseMesh interface which we should mention. It is called UpdateSemantics and it is loosely related to the Clone function in that it allows you to alter the format of a mesh vertex buffer without cloning it. However there is a limitation imposed that does not allow us to change to a format that would cause the vertex buffer to change in size. So you might use this function to change the vertex format such that a mesh uses a vertex with a specular color instead of a diffuse color. In that case we are simply changing the meaning of the DWORD stored in each vertex (a semantic difference).

> **Note:** ID3DXBaseMesh::UpdateSemantics function only works with vertex declarators (not FVF flags) so we will examine it in Module III of this series.

8.9 Progressive Meshes

In any given scene, it is probably fair to say that a number of objects will be situated at a distance from the viewer such that their full detail is no longer appreciable. Consider a model of a car that is constructed using 3000 polygons. If the car is far off in the distance, it might only take up a handful of screen space pixels when rendered. In that case the user will no longer be able to clearly see that the car has four doors, or that there is a driver sitting inside the car. Logos or other forms of writing on the car are certainly no longer able to be clearly viewed. In such a case, rendering only a handful of polygons for the car would not noticeably degrade the image presented to the viewer, given the already reduced level of detail present in the few pixels being drawn. Transforming, lighting, and rasterizing 3000 polygons under these circumstances would be inefficient to say the least. Reducing the polygon count of the object provides a significant savings with respect to both GPU processing and bandwidth.

Ideally what we would like to do is perform this process on the fly. As objects move closer to the camera, the polygon count would increase and more model detail would be visible. As objects move further away, the polygon count would be reduced. We would also prefer this detail reduction to take place in such a way that the model does not become noticeably corrupt. That is, the selection of which polygons to remove should be based on a heuristic that understands which ones contribute more than others. Certainly we want to be careful about removing polygons that would clearly distort the overall shape of the object.

What we require is a way to progressively refine the *level of detail* (LOD) of a mesh at runtime so that detail is removed when no longer needed and re-introduced when that detail is once again required.

> **Note:** While LOD is often discussed in the context of geometric manipulation, it applies to other concepts as well where we might need less detail at one time and more at another. For example, we could consider mip-mapping to be an LOD technique for textures. Animations might also be modified to be more or less complex based on factors such as view distance.

Much research in the field of mesh LOD has taken place and there are a variety of different algorithms that have become essential tools in game development. Algorithms that are based on camera distance and sometimes even orientation are called **view dependant**. View Dependant Progressive Meshes (VDPM) is the embodiment of that technique. Other algorithms are not tied directly to the camera, but instead tessellate or simplify geometry based on other criteria. These are called **view independent** algorithms and are implemented as View Independent Progressive Meshes (VIPM).

While VIPM methods do not downgrade/upgrade a mesh based on distance to the viewer per se, that is not to suggest that they cannot be used in that way. When using VIPM methods, we typically pass in a target vertex or face count for the model. This target can certainly be calculated by taking into account camera distance. Thus VIPM is more flexible in this respect and we can progressively alter mesh LOD based on whatever heuristics we choose (model distance from the camera, the capabilities of the end user's machine, a geometry detail setting that the user may choose from a menu, etc.).

VIPM techniques can be especially useful for console development where there is typically a much smaller amount of memory available to store polygons and textures. It can also be useful to achieve a desired frame rate. If the frame rate of the application drops below a certain threshold, meshes can be

simplified to lower resolutions to help achieve a more fluid gaming experience. If the frame rate is very high, more detail can be added back. In the next section we will take a brief look at the VIPM algorithm used by the D3DXPMesh and D3DXSPMesh objects to perform mesh simplification. Please note that you do not have to be aware of how VIPM works in order to use progressive mesh support in D3DX, but many students may find what is going on under the hood interesting. This will also allow you to more intelligently use the mesh interfaces in an efficient way.

8.9.1 View Independent Progressive Meshes (VIPM)

Progressive mesh support was introduced in DirectX 8.0 as part of the D3DX library. The progressive mesh support in D3DX uses a VIPM algorithm to increase/decrease the face count or vertex count to a specified vertex or face count target through requests from the calling application.

When we first create a progressive mesh, a number of calculations are done behind the scenes to build lookup tables. These tables describe how the original mesh data we pass in should be downgraded over a series of different stages. Each stage will typically store the collapse information for two triangles (although this can vary), reducing the face count of the mesh by two. This triangle removal is set in motion by a vertex being removed (i.e. *collapsed* onto a neighboring vertex). This removes an edge from the model and in turn, the triangles that share that edge. As you can imagine, a complex mesh will have many collapse stages pre-calculated for it -- each stage performing one edge collapse, typically removing a single vertex and two triangles from the mesh.

The mesh data is not actually simplified at progressive mesh creation time, but what is stored is a series of edge collapse structures. These structures can be traversed at runtime to simplify the mesh via the requests made by the application (through the ID3DXPMesh interface). With this approach, we can downgrade the mesh one stage at a time to a very low level of detail. Because the simplification stages are pre-computed at mesh creation time and simply have to be traversed at runtime in response to a simplification request, this makes the runtime part of the simplification process more efficient.

> **Note:** This is a unidirectional simplification algorithm. It is not possible to tessellate the mesh beyond the original polygon count using VIPM. Polygon splitting is not a component of the algorithm, so the original model we start with is the highest LOD we can achieve.

When specifying a target face or vertex count, the LOD routine must be able to quickly determine which vertices to remove and which triangles are affected. As mentioned, the removal of a vertex will usually result in the removal of an edge, which in turn usually removes two triangles from the index buffer. Of course, other triangles that share that vertex may also be affected and they will need to have their indices remapped to point to a neighboring vertex instead. This is the *vertex collapsing* process.

In order to go from the highest level of detail down the desired face count, the progressive mesh will step through an ordered series of pre-calculated edge collapse structures (built at mesh creation time). Each structure stores information about which vertex must be removed next, which triangles need to be removed as a result of the collapsed edge, and which remaining triangles index the removed vertex and need to have their indices remapped to a neighboring vertex instead. This very same information also describes how the simplification can be undone. We can reverse an edge collapse (a process known as a

vertex split) to re-introduce vertices and edges that have been removed. Eventually this will bring the mesh back up to its highest LOD. Again, the highest level of detail will be the dataset that the progressive mesh was first created with. While we can remove detail from this dataset and re-introduce the detail we removed, we can never introduce more detail than was contained in the original model.

> **Note:** Progressive meshes cannot add detail to the original dataset used to create the progressive mesh. No surface subdivision is ever done to the input data set. Progressive meshes can only vary the detail of a model from its original polygon count down to a lower polygon count and back up again.

Calculating which vertex to remove each time we need to collapse an edge in the mesh can be a very time-intensive task. It is usually performed by calculating an error metric that determines how much a collapse alters the surface topology of the mesh. Since this can involve testing every vertex in the vertex buffer and finding the vertex that has the lowest error (and removing that vertex), we can rest assured that the least important vertices are removed from the mesh first.

Given the time consuming nature of this task, each collapse step will be pre-calculated when the progressive mesh is first created. In this manner, the progressive mesh knows in advance the exact order that vertices will need to be removed to achieve a certain level of detail. We will see later that when we create a progressive mesh, we can influence the error metric calculation and assign priorities to make some vertices more or less important than others. Lower priority vertices will be candidates for removal early on in the simplification chain. Because the simplification routine knows the exact order that vertices will need to be removed during runtime simplification, the mesh vertex buffer can be built using the exact order of removal. Vertices that will be removed first can be stored at the end of the vertex buffer and vertices to be removed later (or not at all) can be stored at the front of the buffer. This makes LOD changes and subsequent rendering considerably more efficient.

When a simplification step is executed at runtime by our application and a vertex is removed, the D3DX object need only decrement the number of vertices in the vertex buffer for the render call. This means that the vertices currently being used to render the mesh at its current level of detail will always be in a continuous block in the vertex buffer. This is especially important if the progressive mesh is going to perform well on a software vertex processing device. As we know from our discussions in Chapter Three, a linear block of vertices will be transformed (and possibly lit) by the software pipeline.

The same logic extends to the triangles. Since D3DX will pre-calculate the order in which triangles will be removed during edge collapses, the index buffer can also be ordered accordingly. Triangles that will be removed first will be placed at the end of the index buffer and triangles that will be removed later (or not at all) will be placed near the front of the index buffer. A single edge collapse structure will tell the D3DXMesh at render time how many triangles will be taken away. If multiplied by 3, D3DX will know how many indices to ‘remove’ from the index buffer. Again, this is really just a decrement of the total count.

Fig 8.6 depicts a single pre-calculated simplification step. We see the removal of an edge by collapsing vertex 8 onto vertex 4, which causes the blue and orange triangles to be removed from the mesh. In this example, vertex 8 was determined during mesh initialization to be the first candidate for removal because it would have the least impact on the mesh topology. Note its position at the end of the vertex buffer. The current index count is also decreased by six to account for the two triangles lost during the edge collapse. This effectively pops six indices off the end of the currently used portion of the index

buffer. Triangles that were not removed but that referenced vertex 8 are then remapped to point to vertex 4.

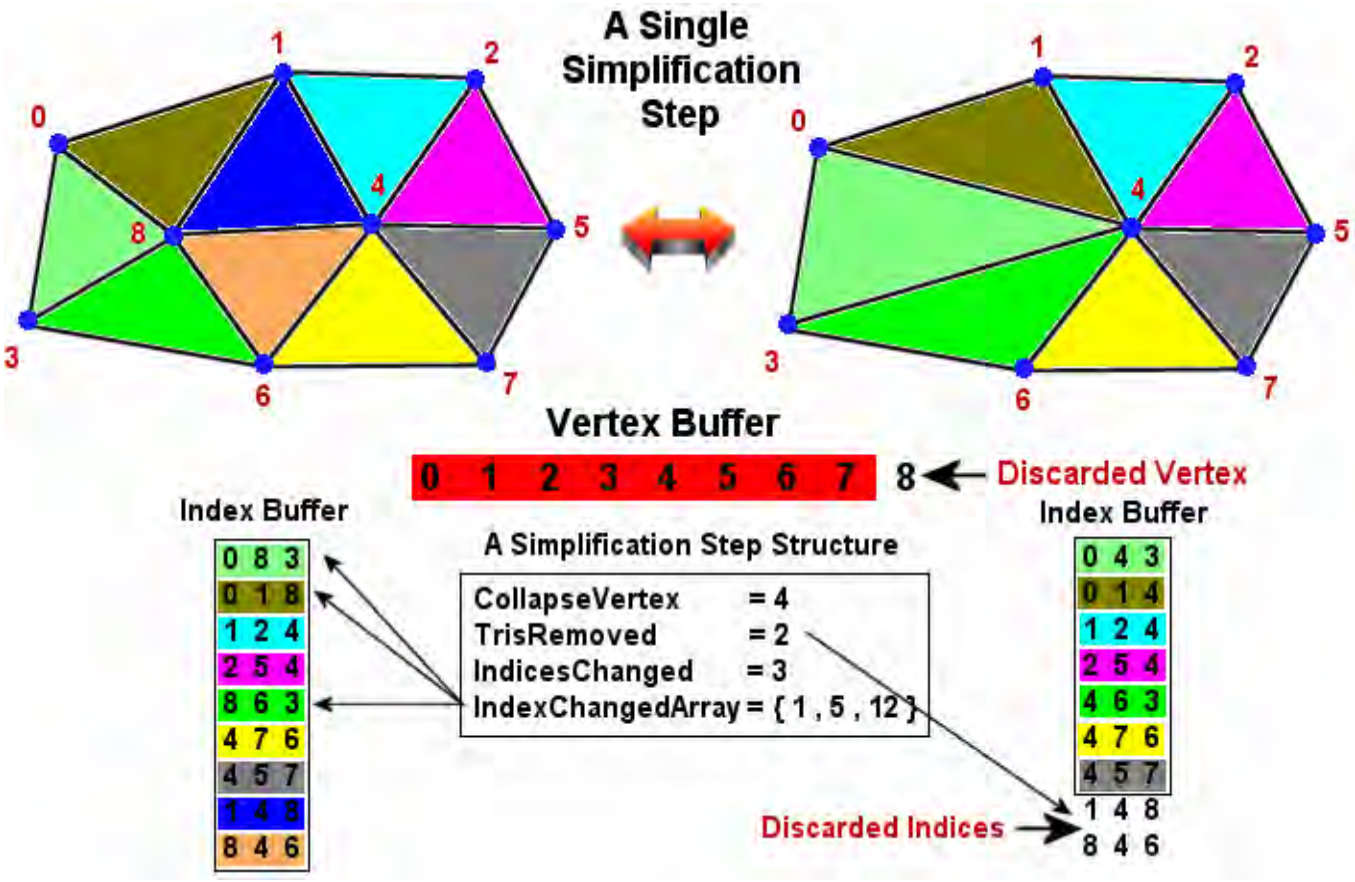


Figure 8.6

While the index remapping for the triangles that are not removed (yet still affected by the edge collapse) is done at runtime by the mesh object, each pre-computed simplification structure contains an array of indices that will need re-mapping when the simplification step is performed. In Fig 8.6 we can see that the IndexChangedArray contains the numbers of all indices in the index buffer that will need to be assigned the new vertex index because they reference the vertex which has just been removed (vertex 8). The six indices that are snipped off the end of the index buffer do not need to be remapped even if they reference the removed vertex because they are not going to be used until we undo the collapse (re-adding vertex 8 to the vertex buffer).

The following pseudo-code shows the use of the pre-compiled simplification step array (generated at mesh creation time) to simplify the mesh down to as close to the requested face count as possible. This is not necessarily the exact process carried out by the D3DX progressive mesh object mind you, but it does give us a theoretical understanding of VIPM.

```
if (CurrentFaceCount > RequestedFaceCount) // we need to process the next simplification step
{
        SimplificationStep *SimpStep = &SimplificationStepArray [CurrentStepIndex++];

        for ( I = 0 ; I < SimpStep->IndicesChanged;  I++)
        {
                pIndices[ SimpStep->IndexChangedArray[I] ] = SimpStep->CollapseVertex;
        }

        CurrentlyUsedVertices --;
        CurrentlyUsedIndices -= SimpStep->TrisRemoved * 3;
}
```

In this example the application has requested a target face count. If it is lower than the current face count then we need to process more of the pre-compiled simplification steps to further simplify the current mesh representation. If the mesh is currently set to the maximum level of detail then the first simplification step we process will be the first one in the pre-compiled array. This tells us the first vertex/edge to remove. Each simplification step tells us the indices that need to be changed to execute the current vertex removal in its IndexChangedArray. It also tells us the new values that these indices have to be set to in the structure's CollapseVertex member. Therefore, all we need to do is loop through each index in this array and change its value from the vertex about to be removed to the collapse vertex. That takes care of the triangles that will survive the collapse that reference the vertex about to be removed. Once done, we simply decrement the number of vertices we are using, effectively dropping the last vertex in the mesh, and decrease the current index count by multiplying the number of triangles dropped by three. Remember, we do not need to manually perform any of these steps, this is all hidden away inside the D3DXPMesh object. All we need to do is call a single function to set a new desired vertex or face count. The D3DXPMesh object will perform the simplification for us using a method similar to that described above.

A key point to understand is that we do not simply jump from one simplification step to another using some arbitrary position in the array. Instead we must process all of the simplification steps in between. If we currently have a face count of A and we want to simplify the mesh to face count D, we must process simplification steps A, B, C, and D to get the desired LOD. This is because a simplification step is computed relative to the one that came before it. This minimizes memory footprint for the simplification data structures.

Fig 8.7 shows that if the maximum face count of our mesh was 100, and we wanted to reduce the face count down to 90, the progressive mesh would need to carry out the first five simplification steps stored in the array. In this example we are assuming that each simplification step removes two triangles, but that may not always be the case with complex mesh topologies.

Figure 8.7

It should also be noted that this process will only be performed when the desired face count or vertex count has been modified. The resulting mesh would be used for rendering until such a time as a new target face or vertex count was specified. Thus, if we had already simplified the mesh down to 96 faces in our example, the internal simplification index would be set to 3 in Fig 8.7 because simplification steps 1 and 2 would have already been executed. If we then decided to simplify the mesh even further by another six faces, and passed in a face count of 90 (from the current 96) the simplification process would start at the current simplification level (3) and execute only simplification steps 3, 4, and 5.

Although it may not be obvious at first, the same information stored in the simplification structures we have been using to collapse edges also tell us everything we need to know to re-add that edge to the mesh and undo the simplification steps. Even at the lowest level of detail, nothing has actually been removed from the vertex or index buffers. The vertices and indices at the end of these buffers are just currently being ignored. Therefore, if we specify a desired face count that is higher than the current level of detail (but not higher than the maximum level of detail the progressive mesh was first created with), the mesh simplification routine can step backwards through the simplification array starting at the current position. Along the way it can restore the indices that were changed in the previous simplification step so that they once again point at the vertex that was removed. It can re-introduce the vertices and indices at the end of the currently unused portions of the vertex and index buffers by incrementing the counters, thereby adding the triangles that were removed in that step.

The following pseudo-code demonstrates how to reverse a simplification step and re-introduce previously deleted triangles and vertices until the desired face count is reached. It is essentially the exact opposite of the simplification code we just looked at.

```
if (CurrentFaceCount < Requested FaceCount && CurrentFaceCount < MaximumFaceCount)
{
        SimplificationStep *SimpStep = &SimplificationStepArray [ --CurrentStepIndex ];

        for ( I = 0 ; I < SimpStep->IndicesChanged; I++)
        {
                pIndices [ SimpStep->IndexChangedArray[I] ] = CurrentlyUsedVertices;
        }

        CurrentlyUsedVertices ++;
        CurrentlyUsedIndices += SimpStep->TrisRemoved * 3;
}
```

This code shows that if we need to re-introduce face detail, then we decrement the CurrentStepIndex and get a pointer to the last simplification step that was performed. The mesh has an array of indices that were changed and stored in each simplification step's IndexChangedArray. At first it might seem that we have no way of knowing which vertex those indices were re-mapped from when the collapse was performed. However, remember that for each simplification step we perform, the vertex removed is the one at the end of the currently used section of the vertex buffer. So when we are about to undo a simplification step, the next vertex just outside the currently used portion of the buffer *is* the vertex those indices were mapped to before that simplification step occurred. Therefore, we loop through each of the indices changed by that simplification step and reset their values to the CurrentlyUsedVertices number. If we currently have 10 vertices in use, then the 11^{th} vertex (i.e. Vertex[10]) will be the vertex we need to reset these indices to reference. Once we have remapped these indices to the original vertex, we simply increment the current vertex count by 1. This extends the size of the usable section of the vertex buffer to re-introduce the deleted vertex that these updated indices have now been reset to reference. Finally, we know that the triangles removed by the simplification step are still in the index buffer, but just outside the section currently being used. Therefore we increase the count of currently used indices to re-introduce the triangles that were removed.

While we do not need to know the details of VIPM and its various implementations to use the D3DX provided mesh class, it is certainly interesting material to study and may come in handy if you ever have to create your own simplification or LOD routines. This basic understanding of VIPM will also help us to properly use the D3DX supplied interface and give us some insight for decision making when it comes to issues of performance and efficiency.

> **Note:** Progressive mesh rendering, despite its potential for reduced polygon count, does not always outperform brute-force mesh rendering. This is because the algorithm requires that the vertex and index buffers be arranged in a manner such that the technique executes quickly. The buffer rearrangement will often be to the detriment of some of the optimization techniques discussed earlier (attribute sorting, vertex cache performance, etc.). Index buffer updates also hurt performance, so keep these ideas in mind as you experiment with the technique.

8.9.2 ID3DXPMesh

The ID3DXPMesh interface (derived from ID3DXBaseMesh) contains functionality that encapsulates dynamic mesh LOD. Based on our discussion in the last section, we now have a fairly good theoretical understanding of what this interface will do for us behind the scenes when we wish a mesh to be dynamically simplified.

Since its introduction in DirectX 8.0, the ID3DXPMesh has been based on the VIPM method introduced by Hughes Hoppe in a 1996 ACM SIGGRAPH paper. While the VIPM method used by the D3DX progressive mesh is not necessarily the most optimal reduction scheme, it is simple to implement, easy to use and is relatively hardware friendly. Unfortunately, it suffers from poor utilization of the vertex cache on hardware vertex processing devices given the vertex buffer ordering requirements we discussed in the last section.

It is also worth noting that the VIPM technique discussed requires the use of a dynamic index buffer to handle LOD changes. Because simplification is performed by the host CPU and involves a good deal of index buffer touching, the progressive mesh index buffer will typically be allocated in system memory. This allows the CPU to write to the buffer as quickly as possible. Although this means that we are rendering from a system memory index buffer, it is generally not as expensive as passing 2-byte indices over the bus (or 4 byte indices if 32-bit indices are used) given large sections of index data on a hardware vertex processing device. Fortunately the VIPM method used by the D3DX progressive mesh does not need to modify the vertex buffer contents once data has been properly ordered. Therefore, the vertex buffer will typically be created in video memory (local/non-local) by default on a hardware vertex processing device.

While ID3DXPMesh does introduce many additional functions beyond those inherited from ID3DXBaseMesh, most are simple ‘Get’ functions used for inquiring about the current settings or state of the mesh. Fortunately, there are surprisingly few methods that are required to use the LOD features.

8.9.3 Progressive Mesh Generation

D3DX provides no functions to load a progressive mesh from a file or even to create an empty progressive mesh. A progressive mesh is created via a standard ID3DXMesh which determines how the progressive mesh looks at its highest level of detail. D3DX exposes the D3DXGeneratePMesh function to convert a standard mesh to a progressive mesh. This provides the indirect means for creating a progressive mesh using data stored in an X file: we call D3DXLoadMeshFromX to create a normal ID3DXMesh and then feed it into the D3DXGeneratePMesh function to create a progressive mesh. Once the progressive mesh has been initialized, the ID3DXMesh interface is no longer needed and can be released. It is at this stage (when the progressive mesh is first created), that D3DX will analyze the topology of the mesh and will determine the order in which vertices and edges should be removed from the mesh. The progressive mesh will have its vertices and indices arranged in its index and vertex buffers so that triangles that will be removed first will have their vertices and indices placed at the rear of their respective buffers. After this step has been performed, the function will then pre-compute and

store all the edge collapse structures and arrange them in a list that can be traversed at runtime to perform efficient simplification in response to application requests. At this point, the function returns to the calling application a newly created progressive mesh interface ready to be simplified using a few simple ID3DXPMesh interface function calls.

```
HRESULT D3DXGeneratePMesh
(
    LPD3DXMESH pMesh,
    CONST DWORD *pAdjacency,
    CONST LPD3DXATTRIBUTEWEIGHTS pVertexAttributeWeights,
    CONST FLOAT *pVertexWeights,
    DWORD MinValue,
    DWORD Options,
    LPD3DXPMESH *ppPMesh
);
```

LPD3DXMESH pMesh

This is the input mesh from which the progressive mesh will be built. It defines the progressive mesh dataset at its highest possible level of detail. Note that this mesh is a standard ID3DXMesh which can be created manually using D3DXCreateMesh or loaded from an X file using D3DXLoadMeshFromX.

CONST DWORD *pAdjacency

Since pre-computing edge collapses relies on information describing how triangles and vertices are connected, this function requires us to pass in the adjacency information for the input mesh. This array will contain three DWORDs per-triangle and is used to compile a table of edge collapse information. The mesh will also reorganize its vertex and index buffers according to collapse order and will use this adjacency information to build a new adjacency buffer for the reorganized data. Unlike the D3DXMesh object which does not maintain adjacency information, progressive meshes will maintain their own internal face adjacency information. So once the mesh has been created, we can discard the input adjacency information of the input mesh along with the input mesh itself.

CONST LPD3DXATTRIBUTEWEIGHTS pVertexAttributeWeights

When the progressive mesh is first created, a pre-compiled simplification step lookup table will be built. It is used to order the data in the vertex and index buffers. To ensure that the mesh transitions as smoothly as possible between detail levels, each vertex receives an error value which describes how dramatic the change to the mesh topology will be if the vertex is removed. When calculating each simplification step, the vertex with the lowest error will be marked as the next to be collapsed. By default (or if we pass NULL as this parameter) the vertex position, normal, and blend weight contribute equally to the error produced for each vertex. For each vertex, a comparison is made between it and neighboring vertices to see which of the neighboring vertices is most similar to the current vertex being processed. This tells us which neighbor makes the best target for collapsing the vertex onto while keeping mesh distortion to a minimum. We would then compare various components of the two vertices and record the error value which is generated by summing the difference in the two vertex components. After doing this for each vertex, we will have a per-vertex error value describing the level of distortion that will be caused if this vertex is removed. At this point, the vertex list can be ordered such that vertices with lower error values are stored at the back of the vertex buffer and the triangles they remove pushed to the back of the index buffer.

Be default, the blend weight, vertex position, and vertex normal are used to build the error value for a vertex, and they are used in equal measure. By passing in a `D3DXATTRIBUTEWEIGHTS` structure, we can force the simplification step compiler to consider additional vertex components when generating the error for each vertex. If we pass in NULL as this parameter, a `D3DXATTRIBUTEWEIGHTS` structure with the following values is used (and is usually acceptable for most situations):

```
D3DXATTRIBUTEWEIGHTS AttributeWeights;

AttributeWeights.Position =  1.0;
AttributeWeights.Boundary =  1.0;
AttributeWeights.Normal   =  1.0;
AttributeWeights.Diffuse  =  0.0;
AttributeWeights.Specular =  0.0;
AttributeWeights.Tex[8]   =  {0.0, 0.0, 0.0, 0.0, 0.0, 0.0, 0.0, 0.0};
```

By default, the vertex colors and texture coordinates are not taken into account. Note that this can lead to distortion that is not topological but instead color based. If the texture coordinates or colors of a vertex that was collapsed onto another are very different, the visual results may certainly be noticeable.

This structure allows the application to change this default behavior by adding weights to additional vertex components or increase/decrease the weight of a default component such that it is considered more/less important in the comparison function and generates a larger/smaller error value, respectively. For example, the default values above show that the position, the boundary, and the normal of the vertex each contribute to the vertex error calculation equally. If we were to set the vertex normal to 2.0 instead of 1.0, we would double its importance and any error produced by differing vertex normals would be doubled. This would make vertices with different normals much less likely candidates for removal. If we were to set the normal member to 0.0, then when calculating the error of collapsing vertex A onto vertex B, the normals of vertex A and B would be ignored and would not influence the error calculation in any way.

The default values generally work pretty well most of the time and you will probably be able to pass NULL as this parameter and live with the results. However, if you discover that one of your simplified meshes is suffering severe texture distortion for example, you can weight the relevant texture coordinate set into the error calculation by using a larger value. Setting the structure's Tex[0] member to 4.0 for example, would quadruple the error caused by different texture coordinates. The result would be that two vertices with different texture coordinates are much less likely to be collapsed onto one another.

CONST FLOAT *pVertexWeights

This parameter is used to pass an array of per-vertex weights for the mesh. If NULL is passed, each vertex is assumed to have an equal weight of 1.0. Once the error for a vertex is calculated, its error is multiplied by its weight in this array, allowing the user to increase/decrease the importance of a particular vertex in a mesh.

Total Vertex Error = Vertex Error x Vertex Weight

Let us consider a mesh of a human face as an example. The nose vertices are likely to be very close together and thus may be removed from the mesh very early on in the simplification chain. Of course, the nose is a pretty important feature, so using this array we could set the weight of the nose vertices to a

larger value to ensure that they will be removed very late in the process (if at all). This allows us to retain the basic outline of the face even at a distance.

Another example might be rendering a section of terrain as a progressive mesh. As the terrain shifted to a lower LOD, a hill might disappear which currently has the mesh of a building sitting on top of it. When the hill polygons were simplified away, the building would be left floating in mid-air. Therefore, it is common practice in terrain engines that use such forms of dynamic LOD to be able to specify certain portions of the terrain mesh (such as those under buildings for example) as being non-removable.

If you do not pass NULL as this parameter, the array you pass in should hold a floating point weight value for every vertex in the input mesh. The higher the vertex weight, the less likely that vertex is to be removed. Passing NULL simply means that all vertices will be weighed equally (1.0).

DWORD MinValue

When the progressive mesh is generated, a number of simplification steps are pre-computed (one for each edge collapse). As you can imagine, a large number of edge collapse structures will be required to take a highly detailed mesh down to a handful of polygons. This value specifies a minimum number of vertices or faces (depending on the Options parameter to this function that will be discussed next) and simplification information will only be generated down to this level. This allows us to save memory and speed up the mesh creation process by instructing it not to compile and store information beyond a level of detail that we have no intention of using.

Once the mesh has been created and its simplification information pre-compiled, there is no way to simplify the mesh any lower than this number of faces or vertices. If you set the minimum number of faces to 100 for example, the edge collapse information would be generated at mesh creation time to take the mesh from its original polygon count to 100 faces and back up again. If during the render loop you called the ID3DXPMesh::SetNumFaces function and specified a value of 10, the edge collapse information for this LOD would not be available in the lookup table and the mesh would be simplified to its minimum number of faces (100 in this example).

It is worth noting that this value is not always achievable, since the mesh distortion caused by simplifying down to the requested minimum might be too extreme. However, if we do specify a minimum number that cannot be reached, the collapse information will be generated down to the lowest possible level of detail. Thus, passing zero as this parameter will always guarantee that we can simplify the mesh down to the lowest resolution considered possible by the progressive mesh object.

DWORD Options

The ***MinValue*** parameter just discussed allows us to specify the minimum requested resolution for the progressive mesh as either a minimum vertex count or a minimum face count. The ***Options*** parameter allows us to specify one member of the D3DXMESHSIMP enumerated type to tell the progressive mesh object how to interpret the ***MinValue*** parameter. The enumerated type has two members:

```
typedef enum _D3DXMESHSIMP
{
        D3DXMESHSIMP_VERTEX = 1,
        D3DXMESHSIMP_FACE = 2
} D3DXMESHSIMP;
```

LPD3DXPMESH *ppPMesh
The final parameter is the address of an ID3DXPMesh interface pointer. If the function is successful and the progressive mesh is successfully created, this will point to a valid interface for that progressive mesh object.

8.9.3.1 Data Validation and Cleaning

Certain types of geometric data may fail to be converted into a progressive mesh because the dataset is considered invalid. Common problems include twisted or invalid faces or adjacency loops that make the simplification table building process impossible. While this is generally caused by the input data being corrupt or erroneous to begin with, there is a way for us to validate whether a mesh that we have just loaded or created will make an appropriate progressive mesh. The D3DX library contains a function called D3DXValidMesh that will validate an ID3DXMesh object and return information describing whether it is suitable for progressive mesh generation or has geometric problems that will cause the progressive mesh generation process to fail.

```
HRESULT D3DXValidMesh
(
    LPD3DXMESH pMeshIn,
    CONST DWORD *pAdjacency,
    LPD3DXBUFFER *ppErrorsAndWarnings
);
```

LPD3DXMESH pMeshIn
This is the ID3DXMesh interface that we wish to test for progressive mesh compliance. If the function returns D3D_OK, then this mesh data is suitable for progressive mesh generation.

CONST DWORD *pAdjacency
This is a pointer to an array of DWORDs (3 for each triangle in the input mesh) describing the adjacency information for each triangle in the mesh. This information is generated automatically by the D3DXLoadMeshFromX function or can be requested from the input mesh using the ID3DXMesh::GenerateAdjacency function.

LPD3DXBUFFER *ppErrorsAndWarnings
If the function returns D3DERR_INVALIDMESH, this buffer will contain a *string* of errors and warnings describing where and why the mesh data contains errors. This will be useful for debugging the mesh.

If the mesh is not suitable for progressive mesh generation, the D3DX library provides a function called D3DXCleanMesh which can be used to try to repair the invalid geometry. So before we generate a progressive mesh from an ID3DXMesh, we should call the D3DXValidMesh function to test for compliance, and if the standards are not met, call D3DXCleanMesh to repair the data.

D3DXCleanMesh actually creates a new mesh along with new adjacency information. The original mesh and adjacency information buffer are not altered by the function so you can keep them if you wish. However you will generally want to release them and use the new data this function produces.

```
HRESULT D3DXCleanMesh
(
    D3DXCLEANTYPE CleanType,
    LPD3DXMESH    pMeshIn,
    const DWORD  *pAdjacencyIn,
    LPD3DXMESH   *ppMeshOut,
    DWORD        *pAdjacencyOut,
    LPD3DXBUFFER *ppErrorsAndWarnings
);
```

D3DXCLEANTYPE CleanType

This first method allows you to control how aggressively the cleanup is performed and control exactly what is considered for cleaning. It can be one of the following enumeration members. Note that although there are actually five cleaning options, there are only really two cleaning techniques you can switch on and off: the merging of back faces and front faces that share the same space, and the removal of bowties.

```
typedef enum _D3DXCLEANTYPE
 {
    D3DXCLEAN_BACKFACING = 1,
    D3DXCLEAN_BOWTIES    = 2,
    D3DXCLEAN_SKINNING   = D3DXCLEAN_BACKFACING,
    D3DXCLEAN_OPTIMIZATION   = D3DXCLEAN_BACKFACING,
    D3DXCLEAN_SIMPLIFICATION = D3DXCLEAN_BACKFACING|D3DXCLEAN_BOWTIES
} D3DXCLEANTYPE;
```

D3DXCLEAN_BACKFACING

Merge triangles that share the same vertex indices but have face normals pointing in opposite directions (back-facing triangles). Unless the triangles are not split by adding a replicated vertex, mesh adjacency data from the two triangles may conflict. This is something you will usually want to do before performing optimization on a mesh or converting that mesh to a skin (skins will be discussed later in the course).

D3DXCLEAN_BOWTIES

If a vertex is the apex of two triangle fans (a bowtie) and mesh operations will affect one of the fans, then split the shared vertex into two new vertices. Bowties can cause problems for operations such as mesh simplification that remove vertices, because removing one vertex will affect two distinct sets of triangles.

D3DXCLEAN_SKINNING

Use this flag to prevent infinite loops during skinning setup mesh operations. It is the same as specifying D3DXCLEAN_BACKFACING.

D3DXCLEAN_OPTIMIZATION

Use this flag to prevent infinite loops during mesh optimization operations. It is the same as specifying D3DXCLEAN_BACKFACING

D3DXCLEAN_SIMPLIFICATION
Use this flag to prevent infinite loops during mesh simplification operations. Performs back face merging and bowtie removal.

LPD3DXMESH pMeshIn
This is the interface pointer to the ID3DXMesh that you would like to try to repair before progressive mesh generation. It will typically be a mesh that failed the validation test. This mesh is not affected by the operation and the clean data is output in a separate mesh. After the mesh has been cleaned, this input mesh can be released.

CONST DWORD *pAdjacencyIn
This is where you pass in the pointer to the input mesh's adjacency information. This array should contain 3 DWORDs per triangle in the input mesh. This adjacency buffer can be released after the function returns and a new cleaned mesh has been generated as it may no longer describe the adjacency information of the output mesh correctly. It is merely used for the cleaning process and can be safely discarded on function return.

> **Note:** For virtually all functions and methods that expect adjacency input information, we can specify NULL for this parameter. If we do, the function will internally generate the mesh adjacency information by calling the mesh's GenerateAdjacency method behind the scenes.

LPD3DXMESH *ppMeshOut
This is the address of an ID3DXMesh pointer that will point to a new mesh containing the cleaned mesh data. If the input mesh did not require cleaning, then this interface will simply be another interface to the input mesh object. The input mesh interface can still be safely released as the reference count mechanism will prevent the underlying mesh object from being destroyed.

DWORD *pAdjacencyOut
This is a pointer to a pre-allocated buffer that the function will fill with the cleaned mesh's adjacency information. It should be large enough to store three DWORDs for each triangle in the cleaned mesh. It is worth noting that the adjacency input buffer can also be used as the adjacency output buffer (i.e. you can pass in the same pointer for both pAdjacencyIn and pAdjacencyOut). The input adjacency information will be overwritten with the new adjacency information for the cleaned mesh in that case.

LPD3DXBUFFER *ErrorsAndWarnings
This is the address of an ID3DXBuffer pointer that will be used to allocate a buffer of error information if the mesh cleaning fails.

Generating a progressive mesh in our code might look as follows:

```
HRESULT      hRet;
LPD3DXMESH   pStandardMesh;
LPD3DXPMESH  pProgressiveMesh;
ID3DXBuffer *pAdj;
ID3DXBuffer *pEff;
ID3DXBuffer *pMat;
DWORD        NumMaterials;
DWORD       *pAdjacency;
```

```
// Load our standard mesh
hRet = D3DXLoadMeshFromX("Factory.x" ,D3DXMESH_MANAGED, pDevice, &pAdj, &pMat,
                         &pEff, &NumMaterials , &pStandardMesh);

if (FAILED(hRet)) return false;

// We wont use the effects buffer so release it
pEff->Release();

pAdjacency = (DWORD*) pAdj->GetBufferPointer();

// Check to see if mesh is valid
hRet = D3DXValidMesh( pStandardMesh, pAdjacency, NULL );

if (FAILED(hRet))
{
    LPD3DXMESH pCleanedMesh;
    // Attempt to repair the mesh
    hRet = D3DXCleanMesh( pStandardMesh, pAdjacency, &pCleanedMesh, pAdjacency );

            if (FAILED(hRet))
            {
                pMat->Release();
                pStandardMesh->Release();
                pAdj->Release();
                return false;
            }

    // We repaired ok, let's store pointer
    pStandardMesh->Release();
    pStandardMesh = pCleanedMesh;

} // End if invalid mesh

// Generate our progressive mesh and request simplification down to potentially
// 10 faces
hRet = D3DXGeneratePMesh(pStandardMesh, pAdjacency, NULL, NULL, 10,
                         D3DXMESHSIMP_FACE, &pProgressiveMesh );

            if (FAILED(hRet))
            {
                pMat->Release();
                pStandardMesh->Release();
                pAdj->Release();
                return false;
            }

// We're done, release our original mesh
pStandardMesh->Release();
```

In the code above we loaded X file data into a standard ID3DXMesh and then validated it. If it passed validation then we generated a progressive mesh with the requested minimum level of detail of 10 faces.

If the mesh failed the validation, then we cleaned it, and if the mesh was cleaned successfully, went on to generate the progressive mesh from the newly cleaned mesh.

> **Note:** When a progressive mesh is first generated, its current level of detail is initially set to its lowest level of detail.

8.9.4 Setting LOD

Because ID3DXPMesh is derived from ID3DXBaseMesh, all of the same rendering functionality is available. To render the progressive mesh, we loop through each of its subsets and call ID3DXPMesh::DrawSubset in exactly the same way that we rendered a standard mesh. This call will render the mesh at its currently set level of detail.

To increase/decrease the current level of detail is quite simple: we just specify a desired vertex count or a desired face count. Given what we have learned thus far, we cannot specify a face or vertex count that is lower than the minimum value specified during progressive mesh creation because precompiled information will not be available down past that level. We also cannot specify a vertex or face count that is higher than the vertex or face count of the original model since this describes the maximum level of detail for the mesh. Specifying counts outside the allowed range will result in clamping to the minimum or maximum level of detail allowed by the mesh.

ID3DXPMesh exposes two functions to allow for current LOD configuration of either the vertex or face counts: ID3DXPMesh::SetNumFaces and ID3DXPMesh::SetNumVertices.

```
HRESULT SetNumFaces( DWORD Faces );
```

DWORD Faces
The only parameter to this function is the number of faces we would like for the current LOD. Clamping will occur if the value is outside the min/max ranges discussed previously. It should also be noted that this value is a request only. While the progressive mesh will try to achieve the requested face count, the exact face count may not be able to be reached. The final LOD may have more or fewer faces than the requested value.

```
HRESULT SetNumVertices( DWORD Vertices );
```

DWORD Vertices
This parameter tells the function the desired number of vertices for the current LOD. As with the previous function, clamping will occur if the value is outside the min/max ranges and the value is a request only.

These two functions are all we need to perform dynamic LOD on our meshes (we will usually use one or the other). In the following pseudo code, we see how we might subtract detail from the object based on whether the current frame rate has dropped below a target threshold.

```
// If the frame rate has dropped unacceptably low, reduce the mesh face count in increments of
// 10 until (hopefully) it becomes acceptable
if ( CurrentFrameRate < MinimumFrameRate )
{
        pMesh->SetNumFaces( pMesh->GetNumFaces() – 10 );
}
else
// If the current frame rate is some way over an acceptable frame rate, we can introduce more
// detail if available, making sure we create a richer environment on higher powered machines.
if ( CurrentFrameRate > AcceptableFrameRate + 10 )
{
       pMesh->SetNumFaces( pMesh->GetNumFaces() +10 );
}

// Render the mesh
for ( int I = 0; I < NumOfAttributes; I++)
{
          pMesh->DrawSubset (I);
}
```

8.9.5 Retrieving LOD

As discussed in the last section, there are min/max face and vertex counts that define the extreme LOD ranges in a progressive mesh. It is useful to know these thresholds when performing runtime simplification so that you do not waste time calling ID3DXPMesh::SetNumFaces function to add/reduce the face/vertex count of a mesh that is already at its maximum or minimum level of detail. ID3DXPMesh exposes four functions to retrieve these values.

`DWORD GetMaxFaces(VOID)`
This function returns the maximum number of faces the mesh can be set to. Any calls to ID3DXPMesh::SetNumFaces that pass a value larger than the value returned by this function will be clamped to this value. The mesh can never have more faces than the value returned by this function.

`DWORD GetMaxVertices(VOID)`
This function returns the maximum number of vertices the mesh can be set to with the ID3DXPMesh::SetNumVertices function. If we specify a value to the ID3DXPMesh::SetNumVertices function that is larger than the value returned from this function, the value will be clamped to this max vertex value.

`DWORD GetMinFaces(VOID)`
This function returns the minimum number of faces the mesh can be set to. Any calls to ID3DXPMesh::SetNumFaces that pass a value smaller than the value returned by this function will be clamped to this value. The mesh can never have fewer faces than the value returned by this function.

`DWORD GetMinVertices(VOID)`
This function returns the minimum number of vertices the mesh can be set to with the ID3DXPMesh::SetNumVertices function. If we specify a value to the ID3DXPMesh::SetNumVertices

function that is smaller than the value returned from this function, the value will be clamped to this minimum vertex value.

It is also useful to know the current LOD the progressive mesh is using, so ID3DXPMesh exposes two functions that return the current number of vertices used by the mesh and the current number of triangles. As mentioned in the last section, when we set the LOD using SetNumFaces or SetNumVertices, the exact face or vertex count requested may not actually be achievable and the mesh will be simplified as near as possible to the value requested. Therefore, after we call SetNumFaces or SetNumVertices we can use GetNumFaces and GetNumVertices to retrieve the exact face or vertex count the mesh was simplified to.

`DWORD GetNumFaces(VOID)`
Returns the current number of triangles used to render the mesh at its current level of detail.

`DWORD GetNumVertices(VOID)`
Returns the current number of vertices used to render the mesh at its current level of detail.

8.9.6 LOD Trimming

When we set the current level of detail using either SetNumVertices or SetNumFaces, we know that no vertices or triangles are physically being deleted from the vertex and index buffers. Only count values are being incremented and decremented to determine which sections of our buffers are used to render the mesh. However, at some point we may want to physically and persistently reduce the dynamic simplification range of the mesh by *trimming* the mesh. Trimming allows us to lower the maximum level of detail and increase the minimum level of detail that the mesh can be set to. Trimming is much more than simply setting a new minimum and maximum value. Instead, memory is physically freed as a result of this process.

Trimming is useful if you decide that you do not need the mesh to ever use its maximum LOD -- in which case you can set a new lower maximum. The mesh can free the vertices and indices at the end of its buffers as well as the memory taken up by the pre-compiled simplification steps that process the edge collapses at these higher LODs.

While it is clear that reducing the maximum level of detail will free up memory and result in a persistent change, it might not be immediately obvious why setting a new (higher) minimum level of detail would be beneficial. The reason is that when we specify a minimum LOD at mesh creation time, a series of edge collapse information structures have to be stored (one for each edge collapse) describing the step-by-step simplification (edge-by-edge) down to the minimum LOD. If we decide that we do not wish to simplify the mesh beyond a certain point, then we can release the memory used by the simplification steps at the bottom of the edge collapse chain. So ‘trimming’ is an appropriate description of what is occurring. We are contracting the dynamic range of the mesh and making it more memory efficient.

> **Note:** Trimming is a permanent change. Once you trim the maximum level of detail for example, you can never increase that maximum value. Likewise, once you increase the minimum level of detail, the edge

collapse information at the bottom of the simplification chain is discarded and you can never decrease that minimum value. The data is gone for good.

ID3DXPMesh exposes two trimming functions to alter the dynamic simplification range of the progressive mesh:

```
HRESULT TrimByFaces
(
    DWORD NewFacesMin, DWORD NewFacesMax,
    DWORD *rgiFaceRemap, DWORD *rgiVertRemap
);

HRESULT TrimByVertices
(
    DWORD NewVerticesMin, DWORD NewVerticessMax,
    DWORD *rgiFaceRemap,  DWORD *rgiVertRemap
);
```

The first two parameters to each function are the new dynamic range of the progressive mesh. In the case of TrimByFaces, these are the new minimum and maximum face count. NewFacesMin must be greater than or equal to the current minimum number of faces and NewFacesMax must be less than or equal to the current maximum number of faces. The same logic holds true for TrimByVertices for vertex counts instead of face counts.

Both functions accept two pointers to two pre-allocated DWORD buffers which return the vertex and face re-mapping information caused by the trimming function. The trimming function may cause vertices and indices to be shuffled about inside the index and vertex buffers and this could be problematic if you have external objects or structures linked to vertices or faces by index. Although both of these parameters can be set to NULL (and probably will be most of the time), if you need to know where vertices or faces have moved, you can supply these buffers and the function will fill them.

The rgiFaceRemap parameter should be large enough to hold one DWORD for every face in the pre-trimmed mesh's maximum LOD (its maximum face count). When the function returns, each element in the array will describe how that face has been mapped to another. If rgiFaceRemap[5] equals 10 for example, then this means the face that was originally 6^{th} in the index buffer has now been moved to the 11^{th} slot in the buffer.

The rgiVertexRemap parameter should either be set to NULL or it should point to a buffer large enough to hold one DWORD for every vertex in the pre-trimmed mesh's maximum vertex count. When the function returns, this buffer will describe the new location of a vertex in the vertex buffer. If rgiVertexRemap[200] equals 10 for example, it means that the 201^{st} vertex in the vertex buffer has now been moved to the 11^{th} position in the vertex buffer.

The following code snippet shows how we might trim a progressive mesh to subtract 200 triangles from its dynamic range. To do so we decrease maximum face count by 100 triangles and increase the minimum face count by 100 triangles.

```
pMesh->TrimByFaces(pMesh->GetMinFaces()+100,pMesh->GetMaxFaces()-100, NULL, NULL);
```

8.9.7 Progressive Mesh to Standard Mesh Cloning

The ID3DXPMesh interface is derived from ID3DXBaseMesh and as such, inherits ID3DXBaseMesh::CloneMeshFVF (and the declarator version not discussed in this course). This function will allow us to create an ID3DXMesh clone of the progressive mesh at its *current* level of detail. This function is identical to the ID3DXMesh::CloneMeshFVF function covered earlier in the chapter.

This presents an interesting use of the progressive mesh as a one-off simplification utility class for meshes that will not use dynamic LOD in the run-time engine and therefore do not require the rather large simplification step chain to be computed and stored in memory. We can load a standard ID3DXMesh, use it to generate a progressive mesh using the D3DXGeneratePMesh function, set the level of detail to a desired face or vertex count, and then clone the progressive mesh using CloneMeshFVF back out into a vanilla ID3DXMesh. The clone would be a standard ID3DXMesh with a lower level of detail than the original dataset and the progressive mesh interface could be released as we no longer need its simplification abilities.

While there is nothing wrong with using ID3DXPMesh to perform one-off standard mesh simplifications in this way, this is exactly what the ID3DXSPMesh interface is designed to do. It simplifies the mesh in the same way but does not incur any of the memory overhead of the progressive mesh caused by the progressive mesh's runtime simplification system. We will discuss simplification meshes shortly.

The code snippet below demonstrates progressive mesh cloning for mesh simplification. The code assumes that the input mesh has already been validated and has more than 1000 faces to start.

```
ID3DXMesh  *pStandardMesh; // Assume this mesh already contains data
ID3DXPMesh *pPMesh;

D3DXGeneratePMesh(pStandardMesh , pAdjacency , NULL , NULL , 1 ,
                  D3DMESHSIMP_FACE , &pPMesh);

pStandardMesh->Release();
pPMesh->SetNumFaces( 1000 );

pPMesh->CloneMeshFVF( D3DXMESH_MANAGED , pPMesh->GetFVF  ,
                      pDevice , &pStandardMesh);

pPMesh->Release();
```

The result of the above example is a regular ID3DXMesh which has had its face count reduced using a temporary ID3DXPMesh to carry out the simplification task.

8.9.8 Progressive Mesh to Progressive Mesh Cloning

ID3DXPMesh also includes a cloning function (two functions if you count the declarator version) that allows us to clone a progressive mesh to a new progressive mesh. This is useful if we need to make a copy of the progressive mesh and have it remain progressive, or if we would like to change the vertex format of an already progressive mesh, perhaps to make room for a new component.

```
HRESULT ClonePMeshFVF
(
    DWORD Options,
    DWORD FVF,
    LPDIRECT3DDEVICE9 pDevice,
    LPD3DXPMESH *ppCloneMesh
);
```

The parameter list is identical to the standard cloning function except for the fact that the last parameter must be the address of a pointer to an ID3DXPMesh rather than an ID3DXMesh interface. If the function is successful, the new progressive mesh will contain all of the mesh geometry and collapse structures as the original and it will share the same current LOD state. That is, if we have a 1000 face progressive mesh, reduce its current face count to 100 and then clone it, the clone will also be set to render using 100 faces. Of course, the identical collapse structures and geometry are stored within the clone, so it can always adjust its LOD independently after it is created and can also be adjusted back up to a 1000 face mesh (the maximum detail level of the progressive mesh from which it was cloned).

8.9.9 Progressive Mesh Optimization

The progressive mesh interface exposes two optimization functions, much like the ID3DXMesh. The first, ID3DXPMesh::Optimize creates an optimized standard (non-progressive) mesh whose dataset contains the faces and vertices of the progressive mesh's *current* level of detail. This is exactly like cloning the progressive mesh using the ID3DXPMesh::CloneMeshFVF function to create a standard output mesh and then performing an OptimizeInPlace on it. The original progressive mesh is not altered by this method. This can be a useful way for generating optimized low-poly representations of complex meshes. The function is identical to the ID3DXMesh::Optimize function and as such the parameter list will not be explained again. The function is shown below for your reference.

```
HRESULT ID3DXPMesh::Optimize
(
    DWORD Flags,
    DWORD *pAdjacencyOut,
    DWORD *pFaceRemap,
    LPD3DXBUFFER *ppVertexRemap,
    LPD3DXMESH *ppOptMesh
);
```

ID3DXPMesh does not expose the OptimizeInPlace function for optimization of the current mesh data. This is due in part to the fact that the optimizations that can be performed on the progressive mesh base geometry data are limited by the fact that triangles and vertices have to be in a precise order so that edges can be correctly and speedily collapsed and split. It is still possible for triangles to be reordered in the progressive mesh index buffer in a limited way to optimize for attribute sorting or higher vertex cache hit rates, but the vertex data itself will not be touched. To make this distinction clear, the ID3DXPMesh interface exposes a function to perform an in-place optimization of the progressive mesh base geometry. The name of this function is ID3DXPMesh::OptimizeBaseLOD and it accepts a much smaller parameter list than the ID3DXMesh::OptimizeInPlace function.

```
HRESULT OptimizeBaseLOD
(
    DWORD Flags,
    DWORD *pFaceMap
);
```

DWORD Flags
This is one of the D3DXMESHOPT flags discussed earlier in the chapter (see ID3DXMesh::Optimize or the ID3DXMesh::OptimizeInPlace function). The efficiency of the optimization is limited by the requirements of the progressive mesh system where collapse order takes precedence.

DWORD *pFaceMap
This is a pointer to an array large enough to hold one DWORD for each face in the pre-optimized mesh. When the function returns, it will be filled with information describing how triangles may have moved. This allows us to correct external references if necessary.

8.9.10 Vertex History

Edge collapsing and splitting can result in a visible popping effect as the mesh topology changes suddenly between detail levels. To solve this problem, many 3D engines use a morphing technique to gradually perform the collapse in a controlled fashion over time. As long as the vertex to be collapsed and the neighbor it will collapse onto are known, this is a relatively easy thing to do.

While ID3DXPMesh does not support morphing directly, it does expose a function that can be used to assist us if we want to do it on the application side. ID3DXPMesh::GenerateVertexHistory will fill an application supplied DWORD array (one DWORD per max vertices in the mesh) describing the new index for a vertex collapse.

```
HRESULT GenerateVertexHistory(DWORD *pVertexHistory);
```

For example, if pVertexHistory[500] equals 2 and pVertexHistory[505] equals 2, this tells is that at the current level of detail, vertices 500 and 505 have both been collapsed onto vertex 2.

Morphing techniques are beyond the scope of this chapter, but there are plenty of references in books and on the web if you are interested in researching it. We will examine morphing concepts later in this course series.

8.10 ID3DXSPMesh

The last mesh interface that we will cover in this chapter is the simplification mesh: ID3DXSPMesh. Fortunately, we will be able to cover this interface very quickly since nearly all of the progressive mesh concepts apply to simplification meshes. In fact, we can think of a simplification mesh as a progressive mesh with no dynamic LOD or rendering functionality. In this sense, it is a utility object that is used to apply polygon reduction methods to a standard input mesh to produce a lower detail result. For performance reasons we would not want to use this class for real-time work, but it is quite useful for performing a one-time simplification offline in a tool or at application startup. Perhaps you would use this interface to tailor mesh LOD according to the capabilities of the end user's machine.

Unlike the ID3DXMesh interface and the ID3DXPMesh interface, the ID3DXSPMesh interface is not derived from the ID3DXBaseMesh interface; it is derived directly from IUnknown. This means that the simplification mesh object does not inherit DrawSubset and as such, is not explicitly renderable.

ID3DXSPMesh exposes the ReduceFaces and ReduceVertices functions to simplify the mesh which, once done, are irreversible. Once the mesh is reduced, it must be cloned for rendering. ID3DXSPMesh has two cloning functions (four if you include declarator versions): CloneMeshFVF which clones the simplified data out to a standard output mesh and ClonePMeshFVF which clones the simplified data out to a progressive mesh. In the latter case, the simplified data will serve as the base geometry (maximum LOD) for the progressive mesh. Once cloned, the simplification mesh can be released. It is faster and more memory efficient to use a simplification mesh for one-time reduction because the overhead of building the runtime edge collapse structures for a progressive mesh is avoided.

8.10.1 Simplification Mesh Creation

We create a simplification mesh object using the global D3DX function D3DXCreateSPMesh. Like the progressive mesh, a simplification mesh needs to be created from a standard ID3DXMesh and cannot be loaded from a file or created manually. The parameter list is almost identical to the GeneratePMesh function used to generate progressive meshes.

```
HRESULT D3DXCreateSPMesh
(
    LPD3DXMESH pMesh,
    CONST DWORD *pAdjacency,
    CONST LPD3DXATTRIBUTEWEIGHTS pVertexAttributeWeights,
    CONST FLOAT *pVertexWeights,
    LPD3DXSPMESH *ppSMesh
);
```

The function accepts a standard ID3DXMesh containing the dataset to simplify. The second parameter points to the input mesh adjacency information. The third and fourth parameters allow us to pass in priorities for vertex component types and for the individual vertices themselves.

The final parameter is the address of a pointer to an ID3DXSPMesh interface to be created on success. As with the generation of a progressive mesh, illegal geometry will cause the function to fail, so we should call D3DXValidMesh and D3DXCleanMesh to repair the mesh in such cases.

The code below shows how we might create a simplification mesh.

```
HRESULT      hRet;
LPD3DXMESH   pStandardMesh;
LPD3DXSPMESH pSimpMesh;
ID3DXBuffer *pAdj;
ID3DXBuffer *pEff;
ID3DXBuffer *pMat;
DWORD        NumMaterials;
DWORD       *pAdjacency;

// Load our standard mesh
hRet = D3DXLoadMeshFromX("Factory.x" ,D3DXMESH_MANAGED, pDevice, &pAdj, &pMat,
                         &pEff, &NumMaterials , &pStandardMesh);

if (FAILED(hRet)) return false;

// We wont use the effects buffer so release it
pEff->Release();

pAdjacency = (DWORD*) pAdj->GetBufferPointer();

// Check to see if mesh is valid
hRet = D3DXValidMesh( pStandardMesh, pAdjacency, NULL );

if (FAILED(hRet))
{
    LPD3DXMESH pCleanedMesh;

    // Attempt to repair the mesh
    hRet = D3DXCleanMesh( pStandardMesh, pAdjacency, &pCleanedMesh, pAdjacency );

    if (FAILED(hRet))
    {
        pMat->Release();
        pStandardMesh->Release();
        pAdj->Release();
        return false;
    }

    // We repaired ok, let's store pointer
    pStandardMesh->Release();
    pStandardMesh = pCleanedMesh;

} // End if invalid mesh

// Generate our simplification mesh object
hRet = D3DXCreateSPMesh( pStandardMesh, pAdjacency, NULL, NULL, &pSimpMesh );
if (FAILED(hRet))
{
    pMat->Release();
```

```
    pStandardMesh->Release();
    pAdj->Release();
    return false;
}

// We're done, release our original mesh
pStandardMesh->Release();
```

8.10.2 Simplification Mesh Usage

We can simplify the mesh data by calling ReduceFaces or ReduceVertices. Both calls accept a single DWORD that describes the target face or vertex count, respectively. This count must be less than or equal to the face or vertex count in the original input mesh.

```
HRESULT ID3DXSPMesh::ReduceFaces( DWORD Faces );
HRESULT ID3DXSPMesh::ReduceVertices( DWORD Vertices );
```

In the case of both of these functions, the exact target face count or vertex count requested may not be able to be met due to certain restrictions.

Continuing the previous code listing, we could request a simplification of the mesh data down to 10 faces using the following code:

```
pSimpMesh->ReduceFaces ( 10 );
```

ID3DXSPMesh also exposes the GetNumFaces and GetNumVertices functions so that we can inquire about the exact face or vertex count after simplification.

```
DWORD ActualNumberOfFaces = pSimpMesh->GetNumFaces();
```

Since ID3DXSPMesh supports no rendering functions, we will need to clone the simplified data out to another mesh type. ID3DXSPMesh::CloneMeshFVF clones the simplified dataset into a standard ID3DXMesh which can then be used for render operations and is identical to this same call in other mesh interfaces.

```
HRESULT ID3DXSPMesh::CloneMeshFVF
(
    DWORD Options,
    DWORD FVF,
    LPDIRECT3DDEVICE9 pDevice,
    DWORD *pAdjacencyOut,
    DWORD *pVertexRemapOut,
    LPD3DXMESH *ppCloneMesh
);
```

ID3DXSPMesh::ClonePMesh is identical to the previous function with the only difference being the final parameter changes to LPD3DXPMESH (a progressive mesh). The maximum level of detail (the base LOD) of the newly created progressive mesh will be the same as the current simplified mesh.

8.10.3 ID3DXSPMesh Misc. Methods

Before we finish up our discussion of the simplification mesh, let us briefly look at the remaining functions exposed by the interface.

HRESULT GetDevice(LPDIRECT3DDEVICE9 *ppDevice)
This function returns a pointer to the device to which the simplification mesh is bound. Notice that we never passed in a pointer to an IDirect3DDevice9 interface when we created the simplification mesh. That is because the owner device is inherited from the standard input mesh.

DWORD GetFVF(VOID)
Allows us to retrieve the FVF flags of the simplification mesh.

DWORD GetMaxFaces(VOID)
Returns the number of faces that exist in the input mesh.

DWORD GetMaxVertices(VOID)
Returns the number of vertices that exist in the input mesh.

DWORD GetOptions(VOID)
Returns a DWORD describing the creation flags for the simplification mesh. What we are really getting here are the creation options for the input mesh since we never explicitly specify creation options when generating a simplification mesh.

HRESULT GetVertexAttributeWeights(LPD3DXATTRIBUTEWEIGHTS *pAttributeWeights*)
Returns the D3DXATTRIBUTEWEIGHTS structure used to perform simplification. This structure describes how much weight each vertex component has when calculating the error metric between two vertices. It will contain either the same values that you passed into the D3DXCreateSPMesh function or a structure containing the default values if you passed NULL. The default values use only the position, weight, and normal of the vertex when calculating vertex collapse errors.

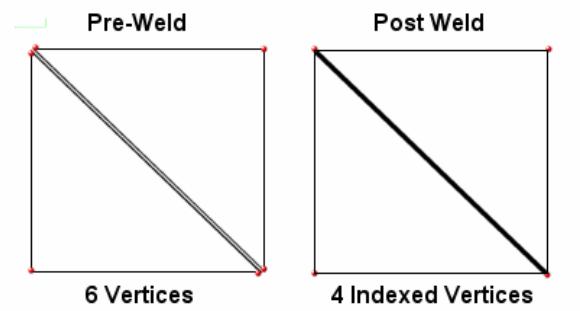
HRESULT GetVertexWeights(FLOAT *pVertexWeights)
Allows you to retrieve the weight of each vertex used to bias the error metric for collapses. If you passed in a per-vertex weights array when you called D3DXCreateSPMesh, then this buffer will be returned with the weight information of each vertex that you passed in. If you passed NULL, then the buffer will be filled with the default weights for each vertex (which is 1.0). This parameter should point to a pre-allocated array that is large enough to hold one DWORD for every vertex in the original/input mesh.

8.11 Global Utility Functions

Before wrapping up this chapter, let us briefly examine some global D3DX functions that can be used with the mesh types we have discussed.

8.11.1 D3DXWeldVertices

This function allows us to weld vertices together in the mesh's vertex buffer. It is essentially another function that can clean and optimize the data for a mesh. This is very useful if the level editor you are using does not generate indices and provides each triangle with its own unique (three) vertices. Consider a quad for example that is stored using 6 vertices (3 for each triangle).



In the case of a D3DX mesh, where all data is stored as indexed triangle lists, the two duplicated vertices at the bottom right and top left corners of the quad could be represented by one vertex (the other discarded) and the indices remapped. Of course, if the two triangles are not supposed to be two halves of the same quad surface and instead had unique textures or colors applied, we definitely would not want to force a vertex weld, as fusing the two vertices into one would cause mesh color/texture distortion.

If two vertices are very close together and share similar or identical properties however, we can use the D3DXWeldVertices function to collapse them into one vertex and reduce the size of our mesh. What this function essentially does is look for vertices that are duplicated and collapse them into a single vertex. This involves removing one of the redundant vertices and changing all indices that reference that vertex to point at the one that remained instead. The function is shown below along with a description of its parameter list.

```
HRESULT D3DXWeldVertices
(
    const LPD3DXMESH pMesh,
    DWORD Flags,
    CONST D3DXWELDEPSILONS* pEpsilon,
    CONST DWORD* pAdjacencyIn,
    DWORD* pAdjacencyOut,
    DWORD* pFaceRemap,
    LPD3DXBUFFER* ppVertexRemap
);
```

const LPD3DXMESH pMesh
This is a standard ID3DXMesh interface pointer to a mesh you want to have welded.

DWORD Flags
A combination of zero or more D3DXMESH flags. Recall that we used these to create a mesh and specify which resource pool the mesh is created in. Since this function does not explicitly generate an output mesh, we can assume that the vertex and index buffers are destroyed and rebuilt because we are able to change resource pools.

CONST D3DXWELDEPSILONS *pEpsilon
To determine whether two vertices should be welded (if they are considered so alike that collapsing them into a single vertex would not significantly alter the appearance of the mesh), a comparison is made between vertex components. If the components match, then the vertices should be welded. To provide tolerance for floating point inaccuracy (ex. 0.998 vs. 0.997), we pass the address of a D3DXWELDEPSILONS structure. It contains a floating point epsilon member for every possible vertex component. This allows us to fine tune exactly how fuzzy the comparisons are when searching for like vertices.

```
typedef struct _D3DXWELDEPSILONS
{
        FLOAT Position;
        FLOAT BlendWeights;
        FLOAT Normal;
        FLOAT PSize;
        FLOAT Specular;
        FLOAT Diffuse;
        FLOAT Texcoord[8];
        FLOAT Tangent;
        FLOAT Binormal;
        FLOAT TessFactor;
} D3DXWELDEPSILONS;
```

Do not concern yourself with the unfamiliar vertex components for now. The vertex structures we will use for the time being require only the components we have seen thus far in the course series.

If we set the Position member to 0.005 and the distance between two vertices is less than 0.005, they will be considered a match (for position). Since we can set tolerance values for each vertex component individually, we might specify a bigger tolerance for the vertex normal test than for the diffuse color. Alternatively, setting the TexCoord[0] member to 0.0 for example means that vertices will only be welded if their first set of texture coordinates are an exact match.

The following code shows how we might fill this structure to perform a weld when each existing vertex component is compared using a tolerance of 0.001.

```
D3DXWELDEPSILONS Epsilons;

 // Set all epsilons to 0.001;
 float *pFloats = (float*)&Epsilons;

 for ( ULONG i = 0; i < sizeof(D3DXWELDEPSILONS) / sizeof(float); i++ )
      *pFloats++ = 1e-3f;
```

CONST DWORD *pAdjacencyIn
This is the adjacency information for the pre-welded mesh.

DWORD* pAdjacencyOut
If we require adjacency information after the mesh has been welded, we can pass a pointer to a DWORD buffer here. It should be large enough to hold 3 DWORDs for every triangle in the pre-optimized mesh.

DWORD* pFaceRemap
LPD3DXBUFFER* ppVertexRemap
These parameters can store face and vertex remapping information to reflect the changes that took place during the operation.

Weld Example:

```
D3DXWELDEPSILONS Epsilons;

// Set all epsilons to 0.001;
float * pFloats = (float*)&Epsilons;
for (ULONG i = 0; i < sizeof(D3DXWELDEPSILONS)/sizeof(float); i++)
     *pFloats++ = 1e-3f;

// Optimize the data
m_Mesh.OptimizeInPlace( D3DXMESHOPT_VERTEXCACHE );

// Weld the Data
m_Mesh.WeldVertices( 0, &Epsilons );
```

8.11.2 D3DXComputeNormals

D3DXComputeNormals calculates vertex normals for D3DX mesh objects. Since the function accepts an ID3DXBaseMesh pointer, we can use it to compute the normals for any derived mesh (ID3DXMesh or ID3DXPMesh).

```
HRESULT D3DXComputeNormals
{
    LPD3DXBASEMESH pMesh,
    const DWORD *pAdjacency
);
```

The mesh must have a vertex buffer created with the D3DFVF_NORMAL flag. The per-vertex normal is generated by averaging face normals for faces that share the vertex. If adjacency is provided, replicated vertices are ignored and "smoothed" over. If adjacency is not provided, replicated vertices will have normals averaged only from the faces explicitly referencing them.

This function is extremely useful, especially if you have loaded an X file without vertex normals and would like to add them to the mesh. Simply clone the mesh with the D3DFVF_NORMAL flag set to create room for vertex normals, and then call D3DXComputeNormals to calculate their values.

8.11.3 D3DXSplitMesh

This function is used to split a mesh into multiple meshes. We pass in a source mesh (ID3DXMesh) and the maximum number of vertices allowed per mesh. If the input mesh is larger than the specified maximum size, it will be split into multiple (current / max) ID3DXMesh objects. The new meshes are returned in an ID3DXBuffer as an array of ID3DXMesh pointers.

```
void D3DXSplitMesh
(
    const LPD3DXMESH pMeshIn,
    const DWORD *pAdjacencyIn,
    const DWORD MaxSize,
    const DWORD Options,
    DWORD *pMeshesOut,
    LPD3DXBUFFER *ppMeshArrayOut,
    LPD3DXBUFFER *ppAdjacencyArrayOut,
    LPD3DXBUFFER *ppFaceRemapArrayOut,
    LPD3DXBUFFER *ppVertRemapArrayOut
);
```

const LPD3DXMESH pMeshIn
This is a pointer to the ID3DXMesh interface that will be split into multiple meshes.

const DWORD *pAdjacencyIn
This is a pointer to a buffer containing the input mesh face adjacency information

const DWORD MaxSize
This is the maximum vertex buffer size per mesh.

const DWORD Options
Here we specify zero or more D3DXMESH flags describing concepts like the resource pool for the smaller meshes that are created by this function.

DWORD *pMeshesOut
This DWORD will contain the number of smaller meshes that were created when the function returns. It tells us the number of ID3DXMesh interface pointers in the ppMeshArrayOut buffer.

LPD3DXBUFFER *ppMeshArrayOut
This is the address of an ID3DXBuffer interface pointer that will contain one or more ID3DXMesh interface pointers for the smaller meshes.

LPD3DXBUFFER *ppAdjacencyArrayOut
This buffer will contain face adjacency information for the meshes created. It is an array of N DWORD pointers (one per mesh) that is followed immediately by the actual data (3 DWORDS per face) referenced by these pointers. For example, if we wanted to find the third adjacency DWORD for the fifth mesh we would do the following:

```
DWORD **pAdjacency = (DWORD**)(ppAdjacencyArrayOut->GetBufferPointer());
DWORD   Adjacency = pAdjacency[4][2];
```

LPD3DXBUFFER *ppFaceRemapArrayOut
If we require the face re-map information for each mesh, we can pass the address of an ID3DXBuffer pointer. When the function returns, the buffer will contain the face re-map information (1 DWORD per face) for each mesh created. This is stored in the same way as the adjacency out information described previously. We could retrieve re-map information for the 10^{th} face in the 4^{th} mesh using the following code:

```
DWORD **FaceRemap = (DWORD**)(ppFaceRemapArrayOut->GetBufferPointer());
DWORD   Remap = FaceRemap[3][9];
```

LPD3DXBUFFER *ppVertRemapArrayOut
If we require the vertex re-map information for each mesh, we can pass in the address of an ID3DXBuffer interface pointer. On function return it will contain 1 DWORD per vertex for each mesh created. This information is also stored in the same way as the adjacency and face remap data. We could retrieve the re-map information for the 100^{th} vertex in the 2^{nd} mesh using the following code:

```
DWORD **VRemap = (DWORD**)(ppVRemapArrayOut->GetBufferPointer());
DWORD   Remap  = VRemap[1][99];
```

8.11.4 D3DXSimplifyMesh

As it turns out, there is also a global function to perform one-time mesh simplification. It is an alternative to using the ID3DXSPMesh interface to simplify a standard mesh.

```
HRESULT D3DXSimplifyMesh
(
    LPD3DXMESH pMesh,
    CONST DWORD *pAdjacency,
    CONST LPD3DXATTRIBUTEWEIGHTS pVertexAttributeWeights,
    CONST FLOAT *pVertexWeights,
    DWORD MinValue,
    DWORD Options,
    LPD3DXMESH *ppMesh
);
```

Most of these parameters should be familiar to you by now. The MinValue parameter is where we pass in the number of vertices or the number of faces we would like the input mesh to be simplified to. This value is interpreted based on the Options parameter, as we saw earlier in the chapter.

The final parameter is the address of a D3DXMesh pointer to store the simplified data. At this point we can release the input mesh and use the output mesh for rendering. This is a quick and easy way to perform one-time simplification at application startup with a single function call.

While this function is very convenient, it does perform the simplification from scratch every time it is called. Therefore, if you wish to clone multiple copies of a simplified mesh, it would be more efficient to use ID3DXSPMesh to perform the simplification once, and then use the interface to clone out the copies.

8.11.5 D3DXIntersect

The D3DXIntersect function determines whether a ray intersects any of the faces in a mesh. This is useful for any number of intersection tasks (collision detection, object picking, etc.). Simply pass in a source mesh and a ray start position and direction vector.

```
HRESULT D3DXIntersect
(
    LPD3DXBASEMESH pMesh,
    CONST D3DXVECTOR3 *pRayPos,
    CONST D3DXVECTOR3 *pRayDir,
    BOOL *pHit,
    DWORD *pFaceIndex,
    FLOAT *pU,
    FLOAT *pV,
    FLOAT *pDist,
    LPD3DXBUFFER *ppAllHits,
    DWORD *pCountOfHits
);
```

LPD3DXBASEMESH pMesh
This is a pointer to the mesh that will be tested for intersection. Since this is a pointer to an ID3DXBaseMesh, we can use this function with both ID3DXMesh and ID3DXPMesh meshes.

CONST D3DXVECTOR *pRayPos
This is a 3D vector describing the model space position of the origin of the ray. For example, if you wanted to test whether a ray from a laser gun has hit a mesh, this vector may initially describe the world position of the gun from which the laser is originating. Since the ray origin must be in the mesh model space, we need to multiply it by the inverse world matrix of the input mesh. If the mesh is already defined in world space, then this step is not necessary since both spaces are the same.

CONST D3DXVECTOR3 *pRayDir
This is a unit length model space direction vector describing the direction the ray is heading with respect to the starting position. If the player look vector was aligned with the world X axis when they fired a laser gun, you might want the laser beam to travel along this same direction. Therefore, you would take the player look vector, multiply it by the inverse of the mesh world matrix to convert it to model space, and then pass it into the function.

BOOL *pHit
If the ray intersects any of the triangles in the mesh, this Boolean will be set to true when the function returns (false otherwise).

DWORD *pFaceIndex
If any faces have been intersected by the ray, this value will contain the zero-based index of the closest triangle that was intersected by the ray. The closest triangle is the triangle that was intersected closest to the ray origin (pRayPos).

FLOAT *pU
If a face has been intersected, this float will contain the barycentric U coordinate for the closest triangle. Barycentric coordinates have two components (U, V) much like texture coordinates. They are also in the range [0, 1]. You can use them to calculate the exact texture coordinate, or diffuse/specular color at the point of intersection because they describe the intersection as how much each vertex is weighted in that intersection. If we have a triangle (v1,v2,v3) then the U coordinate tells us how much v2 is weighted into the result and V tells us how much v3 gets weighted into the result. To find the weight for v1 we simply subtract (v1 = 1.0 – U – V). With these three weights we can interpolate the exact color, texture coordinate, or normal at the exact point of intersection within the face.

FLOAT *pV
If a face has been intersected, this float will contain the barycentric V coordinate for the closest triangle (see previous).

FLOAT *pDist
This is the distance from the ray origin to the intersection point on the closest intersected triangle. Perhaps you would use this distance value to check whether the laser gun in our previous example has hit a face that is considered out of range.

LPD3DXBUFFER *ppAllHits
Because the ray used for intersection testing is infinitely long, it is possible that many faces may be intersected. While the last four parameters return only details for the closest triangle intersected, we can also pass a buffer pointer to be filled with all hits. The function will fill an array of D3DXINTERSECTINFO structures. The D3DXINTERSECTINFO structure contains the face index, barycentric hit coordinates, and a distance from the intersection point to the ray origin. There will be one of these structures in the buffer for each face intersected by the ray.

```
typedef struct _D3DXINTERSECTINFO
{
    DWORD FaceIndex;
    FLOAT U;
    FLOAT V;
    FLOAT Dist;
} D3DXINTERSECTINFO, *LPD3DXINTERSECTINFO;
```

DWORD *pCountOfHits
This parameter will tell us how many faces were hit by the ray (i.e. the number of D3DXINTERSECTINFO structures in the ppAllHits buffer).

8.11.6 D3DXIntersectSubset

We can also run a ray intersection test on specified mesh subsets. This can be used for a wide variety of interesting features. For example, perhaps certain mesh subsets are more vulnerable to attack than others or require a different AI response to collisions. This function is identical to D3DXIntersect except for the fact that it takes the subset attribute ID as an additional parameter.

```
HRESULT D3DXIntersectSubset
(
    LPD3DXBASEMESH pMesh,
    DWORD AttribId,
    const D3DXVECTOR3 *pRayPos,
    const D3DXVECTOR3 *pRayDir,
    BOOL *pHit,
    DWORD *pFaceIndex,
    FLOAT *pU,
    FLOAT *pV,
    FLOAT *pDist,
    LPD3DXBUFFER *ppAllHits,
    DWORD *pCountOfHits
);
```

8.11.7 D3DXIntersectTri

This is a generic ray/triangle intersection function (it does not take a mesh as input). We pass three vectors describing the positions of the triangle vertices and a ray position and direction vector. The triangle is tested against the ray and returns TRUE if the ray intersects, FALSE if not. We can also pass variables for barycentric hit coordinates and distance from the ray origin.

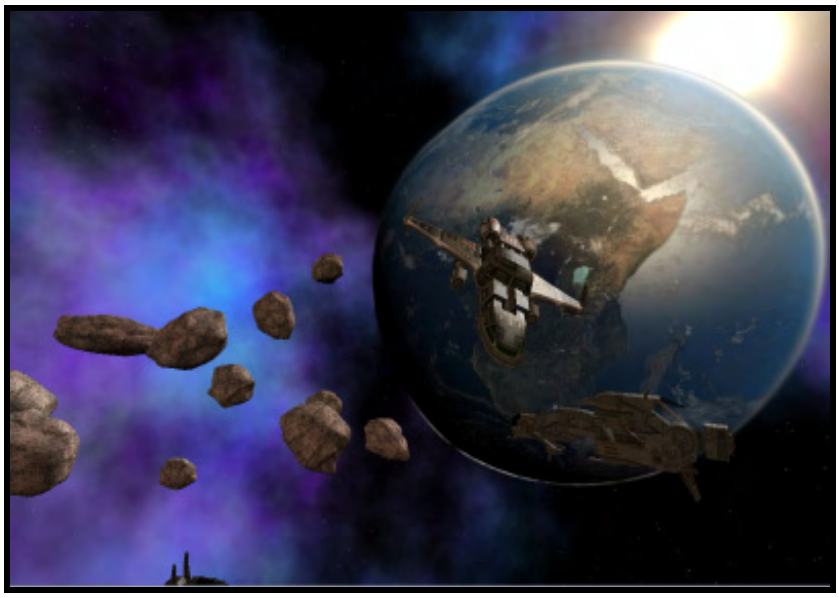
```
BOOL D3DXIntersectTri
(
    const D3DXVECTOR3 *p0,
    const D3DXVECTOR3 *p1,
    const D3DXVECTOR3 *p2,
    const D3DXVECTOR3 *pRayPos,
    const D3DXVECTOR3 *pRayDir,
    FLOAT *pU, FLOAT *pV,
    FLOAT *pDist
);
```

D3DX also provides functions for generating bounding volumes such as spheres and boxes for D3DX mesh objects. These bounding volumes can be used for quick collision detection and frustum culling. We will look at bounding volumes and intersection testing in much more detail a little later in this course.

Conclusion

That wraps up coverage of the three mesh types we wanted to discuss in this chapter. We have certainly seen how D3DX makes what would otherwise be complex coding tasks very simple. In the next chapter we will look at loading mesh hierarchies, which allow us to deal with our scenes in a more organized and flexible fashion. We will also spend a good deal of time exploring the details of the X file format so that we are comfortable with manually parsing such files and creating our own custom templates when needed. This will set the stage for our detailed examination of the D3DX interfaces that support scene animation.

Workbook Eight:
Meshes



Lab Project 8.1: Using ID3DXMesh

The two lab projects in this workbook will be dedicated to the construction of a reusable mesh class. This class will wrap D3DX mesh functionality and employ a sub-system to conveniently handle resource management (the loading and storing of textures and materials). The D3DX library does provide us with an easy means for loading geometry from X files with a single function call, but the burden of loading textures still remains with the application. Our aim is to make this task as easy as possible while avoiding textures being loaded more than once, when they are referenced by more than one mesh.

A mechanism for the efficient rendering of multi-mesh scenes will also need to be put in place. We can not always allow meshes to render themselves independently from the rest of the scene if proper batch rendering is to be achieved. If multiple meshes have subsets that share the same properties, then the scene should be able to intelligently render all subsets from all meshes that share the same device states with a single render call. This will minimize device state changes, an ingredient that is crucial for good performance.

While the D3DX library greatly assists in the loading of X files, if you wish to import your geometry from another source, this has to be accomplished at a lower level. Vertex buffers, index buffers and attribute buffers will need to be locked and manually filled with the data that the application has parsed from a custom file format. An IWF file is an example of such a custom format that we may wish to load and store in a D3DXMesh. This will ensure that the data can benefit from its optimization features. Our wrapper class should expose an interface so that the adding of vertices, indices and attributes is done in as painless a manner as possible. We will expose functions such as AddVertex, AddIndex and AddAttribute which will allow us to build a mesh gradually from data imported from external resources. The vertex buffer, index buffer and attribute buffer will only be constructed internally by the mesh object once all data has been added. This will ensure that we are not locking and unlocking the buffers every time we add a small amount of data (which is highly inefficient).

Finally, as our mesh class is essentially wrapping the underlying ID3DXMesh interface, geometry loaded into our mesh will automatically benefit from the collection of optimization features provided by D3DX.

After the construction of our mesh class you will be able to do the following:

- Populate meshes manually with geometry and attribute data
- Load X files and/or IWF files created by the GILES™ level editor
- Optimize mesh data for rendering
- Create a reusable mesh container class for future applications
- Deal with key aspects of scene state management
    - Texture/material sharing across multiple meshes and their subsets
    - Elimination of redundant texture loading

The CTriMesh Class

The CTriMesh class will be employed as a means for wrapping D3DX mesh functionality. The management of multiple mesh objects and the resources they use will be handled at the scene level. This is made possible by the way each CTriMesh object registers its required resources with the scene texture/material database. To understand this fully, it makes sense for us to look at the CTriMesh class first and later examine the code to the CScene class.

Implementation Goals:

The first design issue to be tackled is texture loading. It does not make sense for the mesh object to manage the loading of textures as the scene or application class is typically the object aware of the limitations of the device. In our demo applications, the scene class is aware of the available texture formats compiled from the device enumeration process. The scene class will therefore be responsible for loading and storing any textures that our mesh objects will use.

Allowing the scene to store and manage the textures used by the mesh is not a trivial design decision. The D3DXLoadMeshFromX function, which our wrapper class will use internally, does not perform any texture loading on our behalf. It returns an array of D3DXMATERIAL structures describing the texture filename and material properties used by each subset in the mesh. We know for example, that the first element in this array contains the texture filename and the material that should be used to render subset 0. The second element in this array contains the attribute properties for subset 1 and so on.

A naive first approach might be to place some code in the mesh wrapper class that, on return from the D3DXLoadMeshFromX function, simply loads all textures referenced in this array. While it is true that every subset in a mesh uses a different texture/material pair, it is probable that multiple subsets in the mesh will use the same texture. In this instance, multiple D3DXMATERIAL structures would contain the same texture filename. Blindly loading the texture referenced by each attribute in this array would cause the same texture to be loaded multiple times. Video memory is a precious resource and we certainly cannot accept this wasteful outcome.

To solve this problem we will expose a function in our mesh class that will allow an external object (our scene class in particular) to register a texture loading callback function. After the scene has instantiated a CTriMesh (but before it has loaded any data into it), it will register a texture loading function with the mesh. The mesh will store a pointer to this function for use when loading data from an X file. When the application calls the CTriMesh::LoadFromX function, the function will first load the geometry using the D3DXLoadMeshFromX function. Then, the mesh object will loop through each of the attributes returned from D3DXLoadMeshFromX and pass each texture filename to the texture loading callback function. The callback (which in our application is a static method of the CScene class), will then check its internal texture list to see if the texture has been previously loaded. If it has, then the function will simply return the texture pointer back to the mesh class for storage. If it has not been loaded, then the CScene class will load the texture using a suitable format and add it to its internal texture database. This pointer is then returned back to the mesh object for storage. After the loading process, a mesh object will thus maintain an attribute array internally which contains one element for each subset in the mesh. Each

element will contain a D3DMATERIAL9 structure and a pointer to an IDirect3DTexture9 interface. The original textures are managed and stored at the scene level.

Using this mechanism, we will solve our redundant texture problem. If multiple subsets use the same texture, their corresponding elements in the internal attribute array will simply contain the same pointer to a texture in the scene texture list. This is true even if multiple meshes use the same texture. They will all contain pointers to the same scene owned texture.

This system provides us with a way to make the mesh essentially self-managed when it comes to rendering since it maintains an internal list of attributes (texture pointer and material) for each subset. This means the mesh object has all the information it needs to render all of its subsets without intervention from the application. The CTriMesh::Draw function will be simple to write. It will loop through each attribute in the attribute array, set the texture and material contained therein, and then use the ID3DXMesh::DrawSubset function to render the appropriate subset in the underlying ID3DXMesh.

This system of self-management makes the mesh class very easy to use. Meshes can be loaded without wasting memory on redundant textures. And, with a single function call, the mesh can be batch rendereded efficiently with mesh triangles that are optimized and sorted by attribute.

This type of self-contained object that requires little external intervention is great for rapid prototyping. It allows an application (such as a mesh viewer) to load and render the mesh with only a few function calls. Each mesh is a self-contained object which will manage its own rendering and therefore is unaware of other mesh objects in the scene. Of course, while easy and intuitive, this approach is not always ideal for all situations, so our mesh class will need to expose an additional mode of operation. The purpose of this additional mode will be to make the mesh more state change friendly when the scene contains multiple meshes.

The importance of batch rendering to minimize state changes has been discussed many times in our studies together. The problem with the self-contained rendering system discussed thus far is that it fails to account for other objects in the scene which may share the same states. It is certainly not uncommon for two or more unique meshes to have cases of identical texture and/or material information at the subset level. For optimal performace, we might want to render all subsets from all meshes which share the same attributes together, to minimize texture and material state changes. This would allow us to batch render across mesh boundaries.

In order for this additional mode (non-managed mode) to allow for state batching across mesh boundaries, the task of rendering the mesh can no longer reside in the mesh class itself. It must now be handled by a higher level object, such as the scene, which can maintain a global list of all attributes (texture and material pairs) used by all meshes in the scene. In this mode, the texture loading callback mechanism will be disabled in favor of another callback function. The new function will also belong to the scene class and will be registered with the mesh. It will accept the complete set of attribute data returned from the D3DXLoadMeshFromX function; not just the texture filename. In this case, the mesh object will not maintain the list of attributes used by each of its subsets; the scene will maintain a global list of attributes used by all meshes.

In order for all meshes to reference the same shared list of attributes, a little remapping of mesh attribute buffers is necessary. This will occur after the mesh is loaded and its textures and materials are registered with the scene. To understand why this is required we must remember that each mesh has its own zero based attribute buffer. While two meshes might each have a subset that both use the same texture and material pair, in the first mesh it may be subset 0 and in the second mesh it may be subset 10.

So we need a way for all of the meshes in the scene to have their attributes remapped. If any meshes have subsets that share the exact same attributes, then we should make sure that both of these subsets use the same attribute ID. An attribute ID will then have global meaning across the entire scene. It is fortunate that attribute IDs within a given mesh do not have to be zero based, or even consecutive, otherwise we would be forced to work with local attributes. If we know that after the remapping process, subset 5 describes the same set of attributes across all meshes, the scene can render the matching subset in all meshes together to reduce state changes. The scene will not loop through each mesh and then render each subset as before, as this would require setting the texture and material states for every subset for every mesh. Instead, the scene will loop through each attribute ID in its internal array and then render any subsets from any mesh that share that attribute together. This way, we set the texture and material for a given scene attribute only once.

The task of remapping the attribute buffer to a global list of attributes is performed when the mesh is first loaded. Our mesh object will pass the attribute data (texture filename and material) returned from the D3DXLoadMeshFromX function to the attribute callback function. This function will search an array of attributes to see if the texture/material data passed in already exists. If so, then its index in the array is returned to the mesh class and becomes the new attribute ID for the subset in question. If a matching attribute cannot be found in the scene attribute array, a new texture/material pair is added to the attribute list and the index of this new element is returned to the mesh. As before, the mesh object can then lock its attribute buffer and alter its contents so that the subset now uses this global attribute ID instead.

To better visualize this process, think of a freshly loaded mesh just about to process the attribute for subset 5. The texture and material used by subset 5 is passed by the mesh into the scene's attribute callback function, where the scene object determines that a matching texture and material already exists in its attribute array at element 35. This means that at least one mesh that was previously loaded used this same attribute combination for one of its subsets. The value of 35 would be returned from this function back to the mesh object. The mesh can now lock the attribute buffer and search for all entries with a value of 5 and replace them with the new global attribute value of 35. Using this method, we can rest assured that all meshes sharing the same attribute data, now share the same global attribute ID for the subsets that reference it.

To summarize, we have achieved some important design goals for our mesh class by envisioning a class that supports two different operational modes:

- ***Managed Mode***: In this mode the mesh object manages its own rendering and setting of states. The mesh maintains an internal attribute array which contains a texture and material pointer for each subset in the mesh. An external texture callback function is used for the loading of texture

filenames returned from the D3DXLoadMeshFromX function. The mesh can be rendered in its entirety with a single function call from the application.

***Pros** : With the exception of the texture callback function, the mesh is self contained. This makes it very easy to setup and render. This mode is ideal for simple applications and prototyping. In this mode the mesh is very easy to plug into existing applications, requiring virtually no support code to be written to access its features. The obvious exception to this is the texture callback function which will need to be implemented and registered with the mesh object if we wish textures to be loaded from the X file.*

***Cons** : The mesh object is not aware of other meshes in the scene and therefore batch rendering across mesh boundaries is not possible. This results in ineffiecient rendering practices when many meshes are in the scene which share matching attributes. This mode is not ideal for using meshes in a typical multi-mesh game environment. Essentially, this mode's greatest strength is in many ways its greatest weakness. By completely encapsulating the rendering of the mesh, the supporting application is denied the chance to use a mesh rendering strategy that it considers optimal.*

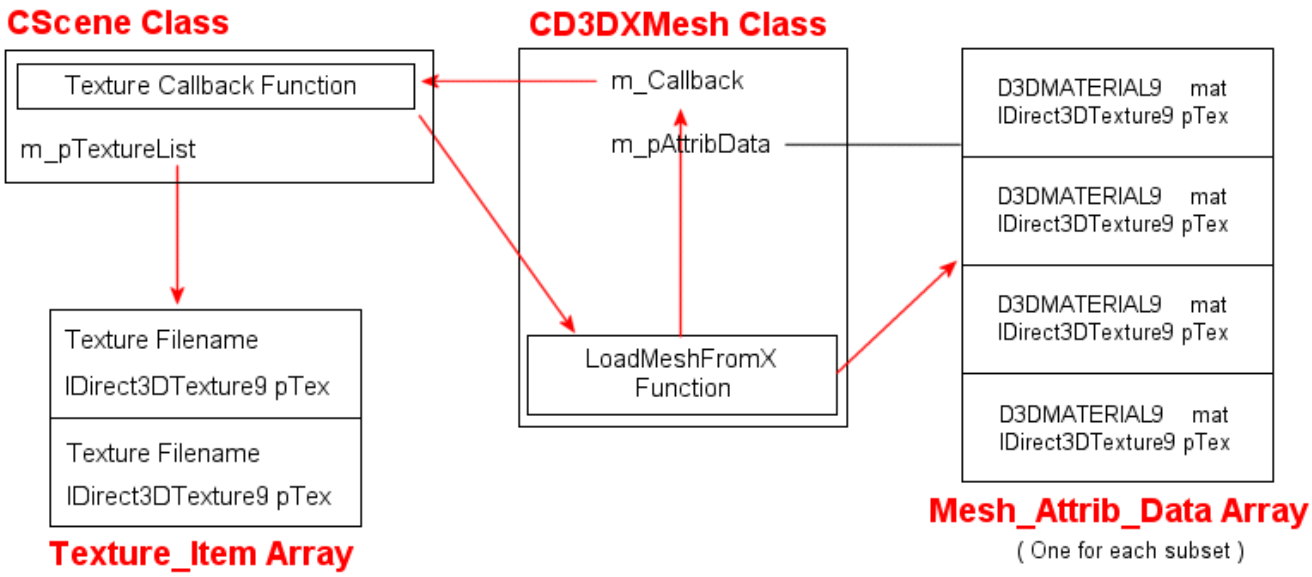
- ***Non-Managed Mode***: In this mode the mesh object no longer maintains an internal list of attributes used by each of its subsets, and is thus incapable of rendering itself. Instead, the meshes pass all attribute data loaded from an X file to an external object (such as our scene class) via an attribute callback function. The scene maintains the attribute list and is responsible for rendering each of the mesh subsets individually. The scene will also be responsible for setting device states before rendering any subset of a given mesh. Attribute data is passed to the scene for registration during X file loading via a callback which returns a global attribute ID for that subset. The mesh will then remap its attribute buffer so that any triangles belonging to the old subset now have attribute IDs matching the newly returned global ID.

***Pros** : Multiple meshes in the scene can have subsets that share the same attribute ID. This attribute ID is actually the index of the texture and material pair stored in the scene's attribute array. The scene can batch render across mesh boundaries. All subsets across all meshes that share the same global attribute ID can be rendered together, minimizing state changes between each render call. This mode is much more efficient for a game scene that contains multiple meshes indexing into a global list of attributes. The mesh object itself is ultimately more flexible in this mode because it does not force any rendering semantics on the application. The application is free to render the various subsets of all meshes in the scene how it sees fit.*

***Cons** : The only real downside for this mode is that more support code must be implemented in the application. This can make integration of the object into new or existing applications a more time consuming affair. The application must supply the rendering logic and maintain and manage the internal attribute list.*

To better visualize the two modes of operation discussed, some diagrams are presented in the next section. They should aid us in seeing the implementations for the mesh in each of these modes.

Managed Mode



Managed mode is the default mode for the class. As seen above, the CScene class maintains an array of Texture_Items. Each texture item contains the filename and texture pointer for a texture that has already been loaded by a mesh in the scene. This array will be empty prior to any meshes having been instantiated.

The CScene class also has a texture callback function which will be registered with the mesh object. This function pointer will be stored in the mesh so that it can be called by the mesh object during X file loading. The CTriMesh::LoadMeshFromX function is exposed to facilitate the loading of X files. This function will initially use the D3DXLoadMeshFromX function to create the underlying D3DXMesh object and initialize its geometry. The mesh object will then loop though each D3DXMATERIAL structure returned from the D3DXLoadMeshFromX function and will pass the texture filename stored there to the texture callback function. If the texture is not already loaded then it will be and added to the end of the scene's Texture_Item array.

The texture callback function will return a texture pointer back to the mesh object to be stored in the mesh's Mesh_Attrib_Data array. Each element in this array contains a material and a texture pointer for a subset in the mesh. The material data is simply copied straight over from the properties returned from D3DX in the D3DXMATERIAL array. The texture pointer is issued to the mesh by the scene object's texture loading callback.

The diagram shows the core components for the mesh in managed mode so we can see that, because the mesh contains its own attribute list, it has everything it needs to render itself. In order for the mesh to render itself in its entirety, simple code can be employed:

```
void CTriMesh::Draw()
{
    // This function is invalid if there is no managed data
    if ( !m_pAttribData ) return;

    // Render the subsets
    for ( ULONG i = 0; i < m_nAttribCount; ++i )
    {
        // Set the attribute data

        pD3DDevice->SetMaterial( &m_pAttribData[i].Material );
        pD3DDevice->SetTexture( 0, m_pAttribData[i].Texture );

        // Otherwise simply render the subset(s)
        m_pMesh->DrawSubset( i );

    } // Next attribute
}
```

The CTriMesh::Draw function will loop through each subset contained in the mesh and manage the setting of the states stored in its attribute array. Then it calls the ID3DXMesh::DrawSubset function, passing in the number of the subset we wish to render. The ID3DXMesh::DrawSubset function renders all triangles in the underlying D3DXMesh with a matching attribute ID.

In this self-contained mode, any burden for rendering the mesh is largely removed from the application. We might imagine that if a scene has many meshes that are all set to operate in managed mode, the code to render those meshes would be a single call to the CTriMesh::Draw method for each mesh in the scene.

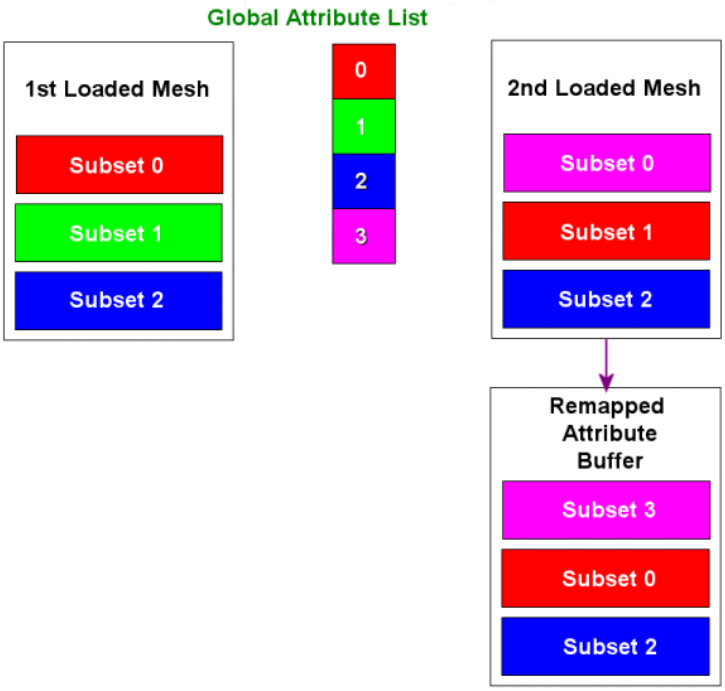
```
for(int i = 0; i < m_NumberOfMeshes; i++)
{
  Meshes[i]->Draw();
}
```

It is the self-contained nature of the managed mode mesh that makes it so quick and easy to plug in and use in existing applications.

Non-Managed Mode

To batch by state across mesh boundaries, we give more rendering control to the scene. In non-managed mode, the mesh does not store an attribute array (this pointer is set to NULL) -- it simply passes the texture/material information loaded from the file to the scene and forgets about it. Subsets will be rendered by the scene using the CTriMesh::DrawSubset function. This function does not update texture or material states and the scene class render method will assume this responsibility. The mesh subset attribute IDs will be remapped to reference a global set of attributes maintained by the scene. This means

that two different meshes that contain matching subset attributes (same texture, same material) can both be remapped to reference the same attribute IDs in the global attribute table. This is demonstrated in the following diagram.

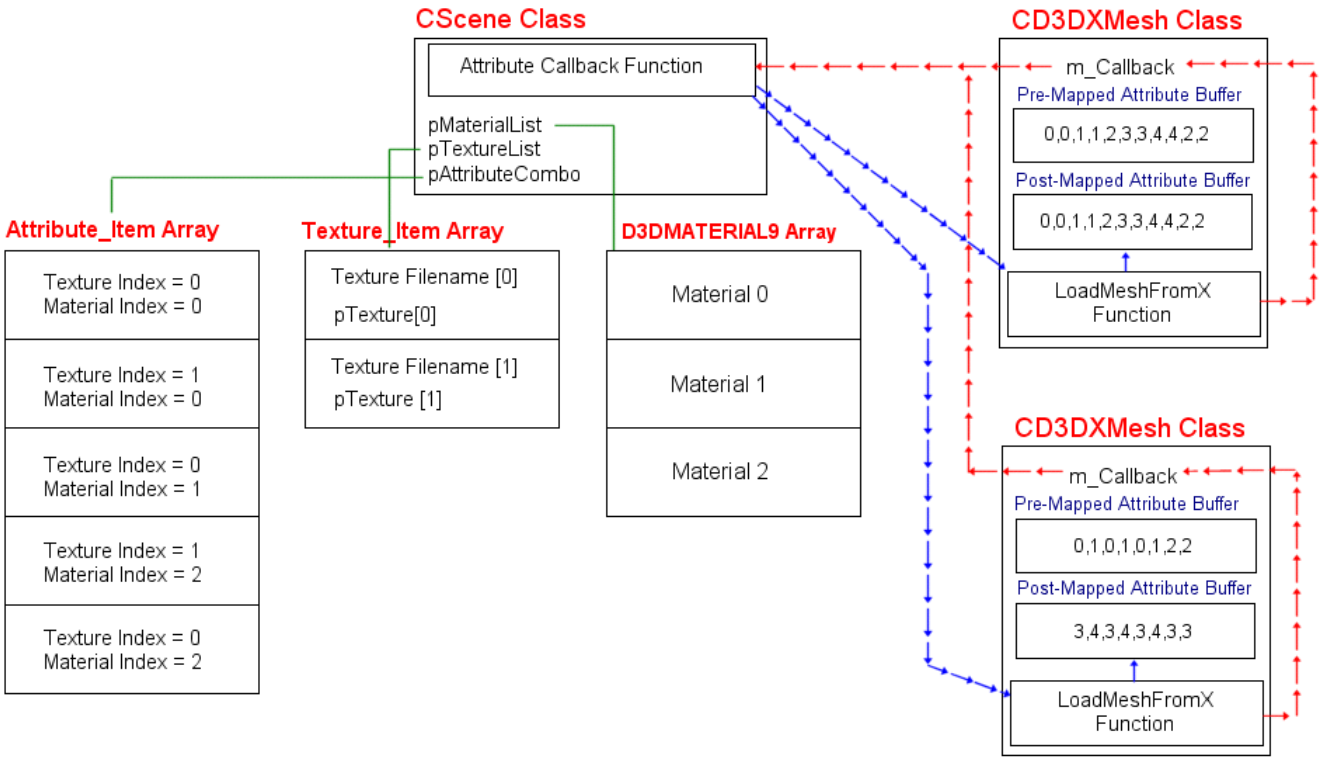


The above image shows how two meshes might initially be loaded. The first and second mesh both have three subsets each. Between both meshes, there are four unique attributes being used. We can see that (using color coding for this example) both the first and second mesh have a red attribute and both also have a blue attribute. The green subset is unique to the first mesh and the purple is unique to the second. We also see that the global attribute list, managed by the scene object, contains those four unique attributes in an ordered array.

While both the first and second mesh contain a red subset, each mesh has a zero based attribute buffer. The attribute buffer values returned from the D3DXLoadMeshFromX function have been assigned differently for the red subset in both meshes. The red material has an attribute ID of 0 in the first mesh and 1 in the second. In order for the scene to render these two subsets together they must both be assigned the same attribute ID. It makes sense to use the index at which the attribute is stored in the global attribute array for this purpose. We can see that the red attribute is stored in this array in position 0. This means any meshes which reference this attribute must use an attribute ID of 0.

The first mesh is basically unaffected because it initially used attribute ID 0 for its red subset. The second mesh however will need to have its attribute buffer locked and altered. Any faces in the red subset of this mesh must have their corresponding attribute ID mapped from 1 (original value when loaded by D3DX) to 0 (the global ID).

The following diagram shows how this model is implemented in our CTriMesh class.



This diagram shows the interaction between the scene and the mesh objects in non-managed mode. The scene class now has to maintain all attribute information used by meshes in the scene; not just textures. The CScene class therefore contains a material array, a texture item array and an attribute combo array. The Texture_Item array is the same one used when dealing with meshes in managed mode. It contans a texture filename, used for testing whether a requested texture has been loaded already, and its accompanying texture pointer. The scene also contains an array of D3DMATERIAL9 structures which will contain all the materials used by all meshes in the scene. These two arrays are maintained by the scene class and logic is put in place to assure that multiple copies of the same texture or material are not loaded more than once. The Attribute_Item_Data array contains what is essentially a scene attribute.

When a non-managed mesh has a subset with an attribute ID of 5 for example, it means the texture and material contained in the 6th element in this array should be used to render that subset. Each element in the scene's attribute array contains a material index and a texture index. These indices are lookups into the Texture_Item array and the D3DMATERIAL9 array. The scene attribute array is analogous to the attribute array that is maintained internally by the mesh object when placed in managed mode. The difference is that this contains the global attribute array for all meshes used in the scene.

In order to place a mesh in non-managed mode we must register an attribute callback function with the mesh, much as we do in managed mode when we register a texture callback function. Registration of this attribute function informs the mesh that it is to be used in non-managed mode. If an attribute callback

has not been registered, the mesh will operate in managed mode and will try to use the texture callback function instead (if one has been registered). The attribute callback function must be registered with the mesh *before* geometry is loaded.

Pay special attention to the two mesh objects shown in the previous diagram as you can see both the pre- and post-mapped attribute buffers. The pre-mapped attribute buffer represents what the mesh looked like just after the D3DXLoadMeshFromX function had been called. Each item is zero based as expected. After the mesh data has been loaded, the mesh object then loops through each attribute and calls the attribute callback function, passing in both the texture and material of each subset. The scene will add the texture and material to its internal arrays and return the index of the corresponding Attribute_Item for that texture/material pair. The attribute buffer of the mesh is then remapped using this information.

Notice how the first mesh that is loaded is also the first to add attributes to the scene. Therefore, the global indices returned for each subset from the callback are the same as the original attribute IDs in the attribute buffer. The second mesh loaded however, has its attribute buffer changed significantly. This is because the attributes it requires were also required by the first mesh and already exist in the scene attribute array.

Once all meshes have been loaded and are known to reference the same global list of attributes, the scene object can render the meshes using whatever method it considers efficient. In the following example we see some code that might be employed by the scene's render function to draw all meshes with minimized texture and material state changes. Batching across mesh boundaries in this fashion is not possible in managed mode.

```
for ( i = 0 ; i < m_TotalNumberOfSceneAttributes; i ++)
{
        pDevice->SetTexture(0, pTextureList[pAttributeCombo[i].TextureIndex]);
        pDevice->SetMaterial(&pMaterialList[pAttributeCombo[i].MaterialIndex]);

        for ( t = 0 ; t < m_NumberOfMeshes ; t ++ )
        {
              m_pMeshes->DrawSubset( i );
        }
}
```

Note that one thing missing from the above code is any mention of the world transform. This is also a device state that must be set.

Often, batching by attribute across mesh boundaries will provide an increase in performance, but this is not always guaranteed. In fact, it is possible that the opposite will happen. If meshes are defined in world space and do not need to be transformed, then batching by attribute across mesh boundaries will provide an increase in performance and is certainly a worthy goal. It is probable however that many of your meshes will be defined in model space and will need to have a world matrix set for them before rendering any of their subsets. If we continue to batch by attribute when this is the case, we are actually increasing the number of times the world matrix has to be set for a mesh. Under normal circumstances, the world matrix would need to be set only once and then the entire mesh rendered. But since attribute

batch rendering requires that we no longer render complete meshes in isolation, the total number of SetTransform calls made per mesh will be equal to its number of subsets:

```
for ( int i=0 ; i<NumberOfAttributes; i ++ )
{
        pDevice->SetTexture ( 0 , pTextureList [ pAttributeCombo[i].TextureIndex]  );
        pDevice->SetMaterial( &pMaterialList  [ pAttributeCombo[i].MaterialIndex] );

        for ( int t =0 ; t < NumberOfMeshes ; t++ )
        {
               pDevice->SetTransform ( D3DTS_WORLD , &pMeshes[t]->Matrix );
               pMeshes[t]->DrawSubset[i];
        }
}
```

SetTransform is a very costly operation and it should not be called superfluously. Usually, the 3D pipeline will try to intelligently predict what information the 3D hardware will need next in its buffers. As a result, the pipeline will often have one or more frames beyond the one you are currently rendering cued up in advance. When the application alters any of its state transform matrices, the pipeline has to flush its buffers. This causes a wait state or stall in the pipeline. In some tests we conducted here in the Game Institute labs, frame rates actually decreased by as much as 50% when batching by attribute on certain scenes because each mesh required multiple world transform sets. This will not always be the case and our non-managed mode mesh provides total flexibility by allowing the scene to choose its preferred rendering strategy. The scene has the ability now to choose how it wishes to batch, by attribute or by transform state.

The scene could choose to render its meshes in the following manner which would assure transform batching over attribute batching. This method would most likely perform better in a scene containing many dynamic meshes.

```
for ( int t = 0 ; t < NumberOfMeshes ; t++ )
{
        pDevice->SetTransform ( D3DTS_WORLD , &pMeshes[t]->Matrix );

        for ( int i=0 ; i<NumberOfAttributes; i ++ )
        {
               pDevice->SetTexture ( 0 , pTextureList [ pAttributeCombo[i].TextureIndex]  );
               pDevice->SetMaterial( &pMaterialList  [ pAttributeCombo[i].MaterialIndex] );

               pMeshes[t]->DrawSubset[i];
        }
}
```

If your scene has many static meshes (which typically lend themselves to being pre-defined in world space), then it would be quicker to batch across mesh boundaries. When a scene consists of both world space meshes and meshes that need a world transform set, you could batch them into two groups and use a different rendering strategey for each group in your core rendering routine.

In our demo applcation we provide the ability for batch render either by attribute or by transform when the mesh objects are in non-managed mode (using a pre-compiler define directive). The scene class

rendering function will test if this define has been set and if so, batch by attribute. Otherwise, batching by transform will be employed.

Source Code Walkthrough

The class declaration for the CTriMesh class is contained in the CObject.h header file. In this listing we have left out the member functions and only show the member variables to improve readability. The class is shown below followed by a description of some of its important member variables.

```
class CTriMesh
{
public:
//-----------------------------------------------------------------------------
// Public Enumerators for This Class.
//-----------------------------------------------------------------------------
 enum CALLBACK_TYPE { CALLBACK_TEXTURE = 0, CALLBACK_EFFECT = 1,
                      CALLBACK_ATTRIBUTEID = 2, CALLBACK_COUNT = 3 };

private:
 //-----------------------------------------------------------------------------
 // Private Variables for This Class
 //-----------------------------------------------------------------------------
    LPD3DXBUFFER  m_pAdjacency;                // Stores adjacency information
    CALLBACK_FUNC m_CallBack[CALLBACK_COUNT];  // References the various callbacks
    LPD3DXMESH    m_pMesh;                     // Physical mesh object
    TCHAR         m_strMeshName[MAX_PATH];       // The filename used to load the mesh

 // Managed Attribute Data
    MESH_ATTRIB_DATA  *m_pAttribData;  // Individual mesh attribute data.
    ULONG              m_nAttribCount; // Number of items in the attribute data array.

 // Mesh creation data.
    ULONG          m_nVertexStride;    // Stride of the vertices
    ULONG          m_nVertexFVF;         // FVF
    ULONG          m_nIndexStride;     // Stride of the indices
    ULONG          m_nVertexCount;     // Number of vertices to use during BuildMesh
    ULONG          m_nFaceCount;       // Number of faces to use during BuildMesh
    ULONG          m_nVertexCapacity;  // We are currently capable of holding this many
                                       // before a grow
    ULONG          m_nFaceCapacity;    // We are currently capable of holding this many
                                       // before a grow
    ULONG          *m_pAttribute;      // Attribute ID's for all faces
    UCHAR          *m_pIndex;          // The face index data
    UCHAR          *m_pVertex;         // The physical vertices.

};
```

LPD3DXBUFFER m_pAdjacency

Unlike ID3DXMesh, the CTriMesh object always maintains a copy of the adjacency information. We use an ID3DXBuffer to store the adjacency data in a uniform and consistent way. Recall that some D3DX functions expect adjacency information as a DWORD array and others expect it as an

ID3DXBuffer. Because the pointer obtained when locking the buffer can be cast to a DWORD pointer, storing it in an ID3DXBuffer makes sure that we account for both cases.

CALLBACK_FUNC m_CallBack[CALLBACK_COUNT]
This is an array which will hold pointers to callback functions. The type CALLBACK_FUNC is a structure defined in the header file Main.h. It contains a void pointer to a function and a void pointer to a context. This second pointer is used to pass arbitrary information to the callback.

```
typedef struct _CALLBACK_FUNC   // Stores details for a callback
{
    LPVOID  pFunction;          // Function Pointer
    LPVOID  pContext;           // Context to pass to the function
} CALLBACK_FUNC;
```

A CTriMesh can hold up to three callback functions for use when loading X files. The first callback (m_CallBack[0]) is used only in managed mode for texture registration. It is where the texture loading callback function pointer will be stored if it has been registered by the application. When the X file is loaded in managed mode, the texture filenames used by each of the mesh attributes will be passed to this function, if it exists. The object that registered the callback with the mesh should make sure that it creates the texture if it does not exist and return a pointer to the texture interface back to the mesh. The returned texture pointer is stored in the mesh MESH_ATTRIB_DATA member. If this callback function is not registered, then no textures will be loaded for the managed mesh. This callback function is not used if the mesh is in non-managed mode and therefore does not need to be registered.

The second array entry (m_CallBack[1]) should contain a pointer to an effect file callback function. X files contain effect file references which the application can use to load the effect file. Effect files are not used in this demo and will be covered in Module III of this series. This callback is only used in managed mode and effect files contained within the X file will be ignored if it is not registered.

The third array entry (m_Callback[2]) essentially switches the mesh into non-managed mode if it contains a function pointer. When this element is not NULL, it should point to an externally defined attribute callback function. For each attribute returned from the D3DXLoadMeshFromX function, the mesh passes in the texture and material to this callback function, if it is defined. The owner of this function should add the material and texture information to its own texture and material lists if they do not already exist and return a new Attribute ID that the mesh class can use to re-map its attribute buffer to point to the global stores. Attribute IDs will then take on global meaning across mesh boundaries and allow for resource sharing. If this function is not registered, then the mesh is assumed to be in managed mode. Registering this function places the mesh in non-managed mode.

There is an enumerated type in the CTriMesh namespace that indexes these callbacks for easy registration:

```
enum CALLBACK_TYPE { CALLBACK_TEXTURE = 0, CALLBACK_EFFECT = 1,
                     CALLBACK_ATTRIBUTEID = 2, CALLBACK_COUNT = 3 };
```

The last member (CALLBACK_COUNT) indicates the total number of callbacks available to the mesh class at present (i.e., it defines the size of the callback array). This allows us to add more callbacks in the future by inserting them into the enum (before the last element) and incrementing CALLBACK_COUNT.

An external object or function that creates a mesh can set the callback function using the CTriMesh::RegisterCallback function:

```
bool   RegisterCallback ( CALLBACK_TYPE Type, LPVOID pFunction, LPVOID pContext );
```

In Lab Project 8.1, the CScene class is responsible for loading the geometry and creating the CTriMesh objects. After a new CTriMesh has been created (but before the data is loaded) the scene registers its callback function as follows:

```
// Create the Mesh
CTriMesh * pNewMesh = new CTriMesh;

// Load in the specified X file
pNewMesh->RegisterCallback(CTriMesh::CALLBACK_ATTRIBUTEID,CollectAttributeID,this);

// Load the X file into the CTriMesh object
pNewMesh->LoadMeshFromX( strFileName, D3DXMESH_MANAGED, m_pD3DDevice );
```

In this example, after we have created the mesh, the scene registers the CALLBACK_ATTRIBUTEID callback function. This places the mesh into non-managed mode. The second parameter is the address of the function that will be called by the mesh for each texture/material combo returned when the X file is loaded. The CScene class includes a function called CScene::CollectAttributeID which accepts a texture and a material and returns a global attribute ID which the mesh can then use to re-map its attribute buffer. This is the also function that is responsible for both creating the texture and adding the texture and the material to the scene database. In this example we do not have to register the texture or effect callback functions since they are only used with managed meshes. Note that the scene passes the ‘this’ pointer so that it is stored in the context and can be passed to the callback function when called from the mesh. We need to do this because the callback function is a static function shared by all instances of the CScene class. As such, the function can only access static variables. The ‘this’ pointer allows us to circumvent that problem as we saw in earlier lessons and access the non-static member variables of the instance of the CScene object being used.

The three callback functions each take different parameter lists and return different values. The function signatures are typedef’d at the top of the file CObject.h and are shown below. If you register any of these callback functions, you must make sure the functions you write have the the exact signatures that the mesh expects.

```
typedef LPDIRECT3DTEXTURE9    (*COLLECTTEXTURE )( LPVOID pContext, LPCSTR FileName );

typedef LPD3DXEFFECT          (*COLLECTEFFECT)(LPVOID pContext,
                                               const D3DXEFFECTINSTANCE & EffectInstance );
```

```
typedef ULONG                (*COLLECTATTRIBUTEID)( LPVOID pContext,
                                                    LPCSTR strTextureFile,
                                                    const D3DMATERIAL9 *pMaterial,
                                                    const D3DXEFFECTINSTANCE * pEffectInstance);
```

Continuing our discussion of the CTriMesh member variable…….

LPD3DXMESH m_pMesh
This is a pointer to the ID3DXMesh wrapped by this class.

TCHAR m_strMeshName[MAX_PATH]
This member will hold the filename of the X file used to load the mesh data.

MESH_ATTRIB_DATA *m_pAttribData
When the mesh is in managed mode (i.e. the attribute callback function has not been registered) the mesh will maintain an array of MESH_ATTRIB_DATA structures -- one for each subset. Each structure describes the texture and material used by the corresponding subset. The structure is defined in the header file CObject.h and is shown below for convenience.

```
typedef struct _MESH_ATTRIB_DATA
{
    D3DMATERIAL9        Material;
    LPDIRECT3DTEXTURE9  Texture;
    LPD3DXEFFECT        Effect;
} MESH_ATTRIB_DATA;
```

When the mesh is in non-managed mode, this pointer will be NULL and no texture and material information will be managed by the mesh.

There are two ways that this array can be populated in managed mode. When using the CTriMesh::LoadMeshFromX function, this array will automatically be populated with the material information in the X file and the texture pointers returned from the texture callback function. If we are building the mesh ourselves, then we use the AddVertex, AddFace and AddAttributeData functions to populate the mesh buffers. The AddAttributeData function makes new space at the end of the MESH_ATTRIB_DATA array (in managed mode) which we can then populate with the material and texture information we desire. When rendering the mesh in managed mode (CTriMesh::Draw), this array is used to set the texture and the material for each subset.

ULONG m_nAttribCount
This value describes how many attributes are in the MESH_ATTRIB_ARRAY. This is only used in managed mode and should always be equal to the number of subsets in the mesh.

ULONG m_nVertexStride
ULONG m_nVertexFVF
ULONG m_nIndexStride
These three members store vertex stride, FVF, and index stride (16 vs. 32-bit) information. Our application will set these as soon as it creates a mesh (before calling any loading functions). We set this information by calling CTriMesh::SetDataFormat:

```
void   SetDataFormat ( ULONG VertexFVF,  ULONG IndexStride);
```

SetDataFormat copies over the information into the internal class variables and uses the specified FVF flags to calculate the vertex stride. This function is only used when creating a mesh from scratch. You must make sure you call it before adding any data to the mesh, otherwise mesh creation will fail. We do not call this function when we create the mesh using CTriMesh::LoadMeshFromX because the vertex and index formats will be taken from the X file. Recall that the D3DXLoadMeshFromX function will set the FVF of our vertices when the mesh is created based on the vertex components available in the X file.

UCHAR *m_pVertex
ULONG m_nVertexCount
We simplify the manual creation of mesh data by maintaining temporary system memory vertex, index, and attribute arrays. This allows an application to accumulate data in these arrays and only build the actual ID3DXMesh once all arrays are finalized. Once the mesh is created, these arrays can be freed since the data is no longer needed. The m_nVertexCount member describes the current number of vertices in the temporary array and does not necessarily describe the number of vertices in the underlying mesh. This is especially true after the underlying mesh has been optimized. These variables are not used at all if we create the mesh data using CTriMesh::LoadMeshFromX.

UCHAR *m_pIndex
ULONG *m_pAttribute
ULONG m_nFaceCount
These are also temporary storage bins that will be used during manual mesh filling. m_pIndex will contain three indices per face (m_nFaceCount*3) and the m_pAttribute array will hold m_nFaceCount DWORD values. These are the per-face attribute IDs. These members are not used if the mesh data is created using the CTriMesh::LoadMeshFromX function. When we manually add faces to the mesh we also specify the attribute ID of the face about to be added. The indices and attributes passed for each face are stored in these temporary bins and later used to populate the actual index and attribute buffers of the ID3DXMesh.

ULONG m_nVertexCapacity
ULONG m_nFaceCapacity
These member variables are only used during manual mesh creation. When we use the AddVertex method to add a vertex to the m_pVertex array, the array will need to be resized to accommodate the new addition. Array resizing can be slow, so to avoid doing it for single vertex additions, we use the m_nVertexCapacity member to define a resize threshold. For example, the array will be resized only

after every 100 vertices have been added. If we start with a vertex capacity of 100, we only need to resize the array when we add the 101st vertex. We then resize again by 100 and increase m_nVertexCapacity by 100 also. We can then once again add another 100 vertices before the new vertex capacity of 200 is reached. The vertex array is resized again by 100, and so on. While it might seem wasteful to resize the array by 100 when we may only need to add 1 vertex, this memory is freed as soon as the underlying ID3DXMesh object is created. Thus the memory footprint is only temporary and it does greatly speed up manual mesh creation. m_nFaceCapacity works in precisely the same way but with the index and attribute arrays. These member variables are not used once the underlying ID3DXMesh has been created.

The Methods

Many of the CTriMesh functions are just wrappers around their ID3DXMesh counterparts (e.g., the functions which optimize and render the underlying mesh data). Some may be slightly more complex than others due to the management modes the class supports. This is certainly true in the managed mode code sections where asset management code is introduced to cater for its self-contained design. We will look at the list of the methods next, but only discuss source code for non-wrapper functions where the code inside the function is new or significant.

CTriMesh::CTriMesh()

The mesh class has a default constructor that takes no parameters and initializes all internal variables to NULL or zero.

```
CTriMesh::CTriMesh()
{
    // Reset Variables
    m_pAdjacency      = NULL;
    m_pMesh           = NULL;
    m_pAttribData     = NULL;
    m_nAttribCount    = 0;
    m_nVertexCount    = 0;
    m_nFaceCount      = 0;
    m_pAttribute      = NULL;
    m_pIndex          = NULL;
    m_pVertex         = NULL;
    m_nVertexStride   = 0;
    m_nIndexStride    = 0;
    m_nVertexFVF      = 0;
    m_nVertexCapacity = 0;
    m_nFaceCapacity   = 0;

    ZeroMemory( m_strMeshName, MAX_PATH * sizeof(TCHAR));

    // Clear structures
    for(ULONG i = 0; i < CALLBACK_COUNT; ++i )
        ZeroMemory( &m_CallBack[i], sizeof(CALLBACK_FUNC) );
}
```

Notice how CALLBACK_COUNT is being used to initially clear the function callback array. Initially no callback functions are registered so the mesh is assumed to be in managed mode at this point. However, textures and effect files would be ignored during loading unless a callback is given.

CTriMesh::~CTriMesh()

The destructor calls CTriMesh::Release to free the internal memory used by the object.

```
CTriMesh::~CTriMesh()
{
    Release();
}
```

CTriMesh::Release

The Release function manages the freeing of memory resources used by the mesh. This allows us to release the underlying data and reuse the same CTriMesh object to create another CTriMesh object if desired. This function calls Release for any COM objects it is currently managing so that reference counts are decremented as expected. This allows the COM layer to unload those objects from memory if no other references to those objects remain outstanding.

If the mesh has an internal attribute array defined (which is only the case if the mesh is operating in managed mode), then the reference count of any textures and effect files contained therein are decremented and the attribute array deleted. It is likely that the texture objects will not be released from memory at this point since the scene object will also have a reference to this object. The same texture resource may also be referenced by other meshes in the scene. Only when all meshes have released their claim to a texture and the scene itself releases it, will the reference count hit zero and the texture be unloaded from memory. It is especially important that our mesh class abides by the COM reference counting convention and is well behaved in this regard. If we did not make sure that the reference count of a texture was increased and decreased correctly when a mesh object gains or releases its claim to a texture resource, we might end up with a scenario where meshes in the scene still have pointers to textures which no longer exist.

```
void CTriMesh::Release( )
{
    // Release objects
    if ( m_pAdjacency ) m_pAdjacency->Release();
    if ( m_pMesh      ) m_pMesh->Release();

    // Release attribute data.
    if ( m_pAttribData )
    {
        for ( ULONG i = 0; i < m_nAttribCount; i++ )
        {
            // First release the texture object (addref was called earlier)
            if ( m_pAttribData[i].Texture ) m_pAttribData[i].Texture->Release();
```

```
            // And also the effect object
            if ( m_pAttribData[i].Effect  ) m_pAttribData[i].Effect->Release();

        } // Next Subset

        delete []m_pAttribData;

    } // End if subset data exists

    // Release flat arrays
    if ( m_pVertex    ) delete []m_pVertex;
    if ( m_pIndex     ) delete []m_pIndex;
    if ( m_pAttribute ) delete []m_pAttribute;

    // Clear out variables
    m_pAdjacency      = NULL;
    m_pMesh           = NULL;
    m_pAttribData     = NULL;
    m_nAttribCount    = 0;
    m_nVertexCount    = 0;
    m_nFaceCount      = 0;
    m_pAttribute      = NULL;
    m_pIndex          = NULL;
    m_pVertex         = NULL;
    m_nVertexStride   = 0;
    m_nIndexStride    = 0;
    m_nVertexFVF      = 0;
    m_nVertexCapacity = 0;
    m_nFaceCapacity   = 0;

    ZeroMemory( m_strMeshName, MAX_PATH * sizeof(TCHAR));
}
```

Note that we do not reset the callback array to zero. It may well be the case that you want to free the internal data but re-use the class to create another mesh. In this case, you will probably want to use the previously registered callback functions to load a new mesh.

Loading Mesh Data

Once we have a new CTriMesh object, there are two ways to populate it. We can either load the data from an X file using CTriMesh::LoadMeshFromX or we can use the AddVertex, AddFace, and AddAttributes functions to add the data to the mesh manually. In the latter case we would call CTriMesh::BuildMesh to create the final ID3DXMesh. Because the two methods of mesh population are quite different, we will cover them in two sections.

A. Loading Data from X Files

If we intend to load the mesh from an X file, then before calling CTriMesh::LoadMeshFromX we will want to register one or more callback functions to handle asset management. The following example demonstrates texture callback registration for a managed mode mesh. Registering this function will have no effect for a non-managed mode mesh since the attribute callback function will be called instead in that case.

```
CTriMesh MyMesh;
MyMesh.RegisterCallback ( CTriMesh::CALLBACK_TEXTURE , MyFunction ,  pSomeInfo );
```

pSomeInfo is a pointer to arbitrary data (or NULL) that we wish the mesh class to pass to the callback function when it is called. We will look at the code to this function next.

CTriMesh::RegisterCallback

The mesh class allows for registration of three types of callback functions to handle asset management requirements. When instructed to load an X file, the mesh can use these functions to pass texture names and material properties to the external object that registered the callback. In our application, the CScene class is responsible for loading and storing textures and making sure that we do not load redundant texture copies.

```
bool CTriMesh::RegisterCallback( CALLBACK_TYPE Type, LPVOID pFunction, LPVOID pContext )
{
    // Validate Parameters
    if ( Type > CALLBACK_COUNT ) return false;

    // You cannot set the functions to anything other than NULL
    // if mesh data already exists (i.e. it's too late to change your mind :)
    if ( pFunction != NULL && m_pAttribData ) return false;

    // Store function pointer and context
    m_CallBack[ Type ].pFunction = pFunction;
    m_CallBack[ Type ].pContext  = pContext;

    // Success!!
    return true;
}
```

This function is passed a member of the CALLBACK_TYPE enumerated type (CALLBACK_TEXTURE, CALLBACK_EFFECT or CALLBACK_ATTRIBUTEID) indicating the callback function being set. The first two types are used if the mesh is in managed mode. Registering the CALLBACK_ATTRIBUTEID function places the mesh object into non-managed mode. When in non-managed mode we do not need to register the texture or effect callback functions as they will never be called. Note that CALLBACK_TYPE also serves as the callback array index of each function pointer.

The second parameter is a pointer to the callback function. It will be stored in the callback array. The third parameter allows the external object that is registering the callback to store arbitrary data that it wants passed to the callback function on execution. Because our callback functions are static, the CScene class will pass the ‘this’ pointer as the context to ensure access to non-static members.

CTriMesh::LoadMeshFromX

Once we have registered our callback functions, we call LoadMeshFromX to populate the mesh with data from an X file. The following example shows how this function might be called. Again, it is important to call this function only after callback registration so that attribute data is handled properly.

```
MyMesh.LoadMeshFromX( strFileName, D3DXMESH_MANAGED, m_pD3DDevice );
```

The function takes three parameters: a string containing the filename of the X file, a DWORD containing our desired mesh creation flags, and a pointer to the device that will own the mesh resources. The mesh creation flags are a combination of zero or more D3DXMESH flags that we use when creating an ID3DXMesh. These flags are passed straight to the D3DXLoadMeshFromX function to control properties such as the memory pools used for the vertex and index buffers.

Note as well that we do not need to specify vertex stride, FVF, or index size since the X file will provide that information. If the end result is not to our liking, we can always clone the CTriMesh to a different format after it has been loaded.

> **Note:** Due to the lengthy nature of this function, we will leave out error checking to compact the listing. The complete version can be found in the source code that accompanies this lesson.

```
HRESULT CTriMesh::LoadMeshFromX( LPCSTR pFileName, DWORD Options, LPDIRECT3DDEVICE9 pD3D )
{
    HRESULT      hRet;
    LPD3DXBUFFER pMatBuffer;
    LPD3DXBUFFER pEffectBuffer;
    ULONG        AttribID, i;
    ULONG        AttribCount;
    ULONG       *pAttribRemap  = NULL;
    bool         ManageAttribs  = false;
    bool         RemapAttribs   = false;
```

The first thing the function does is allocate some local variables. It initially assumes the mesh is in non-managed mode by setting the ManageAttribs Boolean to false. We also declare two ID3DXBuffer interface pointers that will passed into D3DXLoadMeshFromX to be filled with material and effect data from the X file.

Since it is possible that the user may have called this function for an object that already has mesh data defined, we call the Release member function (shown earlier) to free up any potential old data.

```
    // Release any old data
    Release();
```

Next we call D3DXLoadMeshFromX with the appropriate parameters (filename, options, etc.). Since we will maintain adjacency data, we pass in the module level CTriMesh::m_pAdjacency member. If the call is successful, the final mesh will be stored in the class variable CTriMesh::m_pMesh.

```
    // Attempt to load the mesh
    D3DXLoadMeshFromX( pFileName, Options, pD3D, &m_pAdjacency, &pMatBuffer,
                       &pEffectBuffer, &AttribCount, &m_pMesh );
```

At this point the mesh has been created and it contains the geometry from the X file. The remainder of the function processes the material and texture information loaded from the file and returned from the D3DXLoadMeshFromX function. In the above code, we can see that it is the pMatBuffer variable which will contain an array of D3DXMATERIAL structures, one for each subset in the mesh. The AttributeCount local variable will contain the number of subsets in the mesh. How we process and store this returned attribute data from this point on depends on whether the mesh is in managed or non-managed mode.

The first thing we do is test wheter the CALLBACK_ATTRIBUTEID callback function is NULL. If it is, then the non-managed mode callback function has not been registered, and this is a managed mesh. In this instance we set the ManageAttribs Boolean to true. Next we store the number of subsets in this mesh in the m_nAttribCount member variable.

```
    // Are we managing our own attributes ?
    ManageAttribs = (m_CallBack[ CALLBACK_ATTRIBUTEID ].pFunction == NULL);
    m_nAttribCount = AttribCount;
```

If this is a managed mesh, then we need to allocate an array of MESH_ATTRIB_DATA structures -- one for each subset. They will be filled with the texture and material information for each subset so that the mesh can render itself using the CTriMesh::Draw function. Once the array is allocated, we initialize it to zero as shown below.

```
    // Allocate the attribute data if this is a manager mesh
    if ( ManageAttribs == true && AttribCount > 0 )
    {
        m_pAttribData  = new MESH_ATTRIB_DATA[ m_nAttribCount ];
        ZeroMemory( m_pAttribData, m_nAttribCount * sizeof(MESH_ATTRIB_DATA));
    } // End if managing attributes
```

If this is a **non**-managed mesh then we will not need to allocate an attribute array as no textures or materials will be stored in the mesh itself. We will however, potentially need to re-map the attribute IDs in the D3DXMesh attribute buffer so that they index into a global pool of resources at the scene level. Therefore, we will allocate a temporary array that will hold new attribute IDs for each mesh subset.

```
    else
    {
        // Allocate attribute remap array
        pAttribRemap = new ULONG[ AttribCount ];

        // Default remap to their initial values.
        for ( i = 0; i < AttribCount; ++i ) pAttribRemap[ i ] = i;
    }
```

By default we initialize each new attribute ID so that it matches the original attribute ID. If the mesh had five subsets for example, this array will be five DWORDS long and each element will initially contain 0

to 4 respectively. This array will be used to store the new values that each ID will have to be mapped to, which will be determined momentarily. Thus if pAttribRemap[2] = 90 after the attribute callback function has been called, this means that the third subset of this mesh uses the texture and material combination that is stored in the 91st position in the scene's global attribute list. We would then loop through the attribute buffer of the ID3DXMesh and change all attribute ID's that currently equal 2 to the new value 90.

Next we retrieve pointers to the material and effects buffers returned from the D3DXLoadMeshFromX function. Although this mesh supports effect instance parsing, we will not be using it in this lesson and effects can be ignored for the time being. Notice how we lock the buffers and cast the pointers to the correct type to step through the data in each buffer.

```
    // Retrieve data pointers
    D3DXMATERIAL       *pMaterials = (D3DXMATERIAL*)pMatBuffer->GetBufferPointer();
    D3DXEFFECTINSTANCE *pEffects   = (D3DXEFFECTINSTANCE*)pEffectBuffer->GetBufferPointer();
```

Now we can loop through each subset/attribute and parse the material data. This is handled differently depending on whether the mesh is in managed or non-managed mode. We will look at the managed case first.

```
    // Loop through and process the attribute data
    for ( i = 0; i < AttribCount; ++i )
    {
```

The material buffer contains D3DXMATERIAL structures that store a D3DMATERIAL9 structure and a texture filename. First we copy the D3DMATERIAL9 into the correct slot in our MESH_ATTRIB_DATA array. For example, if we are currently processing subset 5 in the loop, then we will copy the material into m_pAttribData[4].Material. Since the material information in an X file does not contain an ambient property, we manually set the ambient member to full reflectance (1.0f, 1.0f, 1.0f, 1.0f) after the copy. You should feel free to change this default behavior.

```
        if ( ManageAttribs == true )
        {
            // Store material
            m_pAttribData[i].Material = pMaterials[i].MatD3D;

            // Note : The X File specification contains no ambient material property.
            //        We should ideally set this to full intensity to allow us to
            //        control ambient brightness via the D3DRS_AMBIENT renderstate.
            m_pAttribData[i].Material.Ambient = D3DXCOLOR( 1.0f, 1.0f, 1.0f, 1.0f );
```

To process the texture filename stored in the D3DXMATERIAL buffer for this subset we will use the registered texture callback function. The following code shows how we define a function pointer called CollectTexture to point at the texture callback function in the mesh's callback function pointer array.The CollectTexture variable is a pointer of type COLLECTTEXTURE which we saw defined earlier as a pointer to a function with the desired function signature.

```
            // Request texture pointer via callback
            if ( m_CallBack[ CALLBACK_TEXTURE ].pFunction )
            {
                COLLECTTEXTURE CollectTexture =
                                (COLLECTTEXTURE) m_CallBack[ CALLBACK_TEXTURE ].pFunction;
```

We now call the function using this pointer, passing in the context data that was set for this callback when it was registered. In our case this will be a pointer to the instance of the CScene class that registered the function. We also pass the texture filename for the current subset being processed. The function should return a pointer to an IDirect3DTexture9 interface that will be copied into the Texture member of the mesh attribute array for this subset. In keeping with proper COM standards, we increase the interface reference count of this texture pointer as we make a copy of it.

```
               m_pAttribData[i].Texture = CollectTexture(
                                                m_CallBack[ CALLBACK_TEXTURE ].pContext,
                                                pMaterials[i].pTextureFilename );

                // Add reference. We are now using this
                if ( m_pAttribData[i].Texture ) m_pAttribData[i].Texture->AddRef();

            } // End if callback available
```

Next we need to process the CALLBACK_EFFECT callback function using the same process. We will not register an effect callback function in our application, but we have included the code for future use. When the effect callback function is registered, we pass the context and the D3DXEFFECTINSTANCE structure for this subset. This information was returned from the D3DXLoadMeshFromX function in the pEffects buffer. The effect callback function returns a pointer to an ID3DXEffect interface which is stored in the mesh attribute data array for the current subset. You can feel free to ignore the code that deals with effects until we get to Module III.

```
            // Request effect pointer via callback
            if ( m_CallBack[ CALLBACK_EFFECT ].pFunction )
            {
                COLLECTEFFECT CollectEffect =
                                (COLLECTEFFECT)m_CallBack[ CALLBACK_EFFECT ].pFunction;
                m_pAttribData[i].Effect =
                      CollectEffect( m_CallBack[ CALLBACK_EFFECT ].pContext, pEffects[i] );

                // Add reference. We are now using this
                if ( m_pAttribData[i].Effect ) m_pAttribData[i].Effect->AddRef();

            } // End if callback available

        } // End if attributes are managed
```

At the end of this loop, the managed mesh will have all texture and material information used by each subset stored in the mesh attribute data array. Thus, it can render each of its subsets (including state setting) in a self-contained manner.

If this is not a managed mesh then the chain of events is quite different. We no longer have to allocate a mesh attribute data array and we will not store the texture and material information inside the object.

Management of textures and materials is left to the caller. In order to do this, we must pass the texture filename, the material, and the effect instance to the CALLBACK_ATTRIBUTEID callback function. This function will belong to the CScene class, which maintains a list of all texture and material combinations used by all meshes in the scene. The callback will search its list for a matching attribute (i.e. texture and material combination) and if found, will return the index of this attribute set in its attribute list. If the attribute does not exist in the global list, it will be created and appended. The result is the same from the mesh's perspective -- an index is returned. We store this index in our temporary re-map array so that we can update the subset attribute ID to this new index. After the loop is complete, a non-managed mesh will have an array of re-map values describing what each attribute ID in the mesh attribute buffer should be re-mapped to.

```
        else
        {
            // Request attribute ID via callback
            if ( m_CallBack[ CALLBACK_ATTRIBUTEID ].pFunction )
            {
                COLLECTATTRIBUTEID CollectAttributeID =
                          (COLLECTATTRIBUTEID)m_CallBack[ CALLBACK_ATTRIBUTEID ].pFunction;

                AttribID = CollectAttributeID( m_CallBack[ CALLBACK_ATTRIBUTEID ].pContext,
                                               pMaterials[i].pTextureFilename,
                                               &pMaterials[i].MatD3D,
                                               &pEffects[i] );

                // Store this in our attribute remap table
                pAttribRemap[i] = AttribID;

                // Determine if any changes are required so far
                if ( AttribID != i ) RemapAttribs = true;

            } // End if callback available

        } // End if we don't manage attributes

    } // Next Material
```

We no longer need the material and effect buffers that were returned by D3DXLoadMeshFromX because the callbacks have taken care of loading and storing the resources. Therefore, they can be released.

```
    // Clean up buffers
    if ( pMatBuffer    ) pMatBuffer->Release();
    if ( pEffectBuffer ) pEffectBuffer->Release();
```

If this is a non-managed mesh and attributes require remapping, then we lock the attribute buffer, update it with the new information, and unlock. We can release the remapping data when we are finished because the modifications have now been made to the attribute buffer of the D3DXMesh.. Remember that this buffer contains an attribute ID for each triangle in the mesh.

```
    // Remap attributes if required
    if ( pAttribRemap != NULL && RemapAttribs == true )
    {
        ULONG * pAttributes = NULL;
```

```
        // Lock the attribute buffer
        m_pMesh->LockAttributeBuffer( 0, &pAttributes );

        // Loop through all faces
        for ( i = 0; i < m_pMesh->GetNumFaces(); ++i )
        {
            // Retrieve the current attribute ID for this face
            AttribID = pAttributes[i];

            // Replace it with the remap value
            pAttributes[i] = pAttribRemap[AttribID];

        } // Next Face

        // Finish up
        m_pMesh->UnlockAttributeBuffer( );

    } // End if remap attributes

    // Release remap data
    if ( pAttribRemap ) delete []pAttribRemap;
```

Finally, we store the filename of the X file that was loaded in the m_strMeshName string and return success.

```
    // Copy the filename over
    _tcscpy( m_strMeshName, pFileName );

    // Success!!
    return S_OK;
}
```

The overview of the loading process is not complete until we look at the code for the CScene class callback functions. However, the above function is all that is needed to handle resource management from the perspective of the mesh object. We will look at the CScene callback functions after we have finished examining the methods of CTriMesh.

B. Loading Mesh Data Manually

We have covered the basic loading operations involved for managed and non-managed meshes extracted from X files. Let us now examine the member functions used to manually populate a CTriMesh with vertex, index, and attribute data. An application would need to do this when the mesh data is being created programmatically. More importantly, manual mesh creation will be necessary when the application is loading data from an alternative file format (e.g., IWF, 3DS, etc.). In this section, we will discuss the manual creation methods in the order in which they are normally used so that we get a better feel for the flow of operations.

CTriMesh::SetDataFormat

When we load a mesh from an X file, D3DXLoadMeshFromX chooses the format of our vertices and indices based on the matching data stored in the X file. When creating a mesh manually, before we add any vertex or index data, we must inform the CTriMesh object of the vertex and index formats we will be using. This is the only way it will know how to create the ID3DXMesh. To do this, we call the CTriMesh::SetDataFormat function. This is usually the first function we will call after we have instantiated a mesh object.

```
void CTriMesh::SetDataFormat( ULONG VertexFVF, ULONG IndexStride )
{
    // Store the values
    m_nVertexFVF    = VertexFVF;
    m_nVertexStride = D3DXGetFVFVertexSize( VertexFVF );
    m_nIndexStride  = IndexStride;
}
```

The first parameter is the FVF flag, describing the vertex format for the mesh. The second parameter is the size of the indices (in bytes) we wish to use. This will either be 2 or 4 depending on whether we wish to use 16-bit or 32-bit indices. This function calls the global D3DX helper function D3DXGetFVFVertexSize which returns the size (stride) of a single vertex given the FVF flag passed in.

The following code snippet demonstrates how we might instantiate a mesh which we intend to use for manual data population and set its vertex and index formats:

```
CTriMesh MyMesh;
DWORD  FVFFlags = D3DFVF_XYZ  | D3DFVF_TEX1;
MyMesh.SetDataFormat ( FVFFlags , 2 );
```

Here we are creating a mesh that will have room for a 3D position vector and a single set of 2D texture coordinates stored in each vertex. We also inform the mesh object that we intend to use 16-bit indices.

CTriMesh::AddVertex

This function is used to add vertices to a temporary vertex array maintained by the mesh. It is very much like the functions we have studied in previous lessons that manage array allocation and resizing. In our application, the vertex capacity for the array is initially set to 100 and is increased by 100 every time the limit is reached. This speeds up adding the vertex data to the array and minimizes memory fragmentation. This function adds no data to the ID3DXMesh, as it has not even been created yet. All we are doing is adding vertices to a temporary vertex array which will later be used to create and populate the vertex buffer of the ID3DXMesh. Once the actual ID3DXMesh has been created, this array will no longer be used and may be released.

The first parameter describes the number of vertices we wish to add and the second parameter is a pointer to one or more vertices. We use a void pointer for the vertex data because it must be able to handle arbitrary vertex formats with varying sizes.

```
long CTriMesh::AddVertex( ULONG Count , LPVOID pVertices   )
{
    UCHAR * pVertexBuffer = NULL;

    if ( m_nVertexCount + Count > m_nVertexCapacity )
    {
        // Adjust our vertex capacity (resize 100 at a time)
        for ( ; m_nVertexCapacity < (m_nVertexCount + Count) ; ) m_nVertexCapacity += 100;

        // Allocate new resized array
        if (!(pVertexBuffer = new UCHAR[(m_nVertexCapacity) * m_nVertexStride])) return -1;

        // Existing Data?
        if ( m_pVertex )
        {
            // Copy old data into new buffer
            memcpy( pVertexBuffer, m_pVertex, m_nVertexCount * m_nVertexStride );

            // Release old buffer
            delete []m_pVertex;

        } // End if

        // Store pointer for new buffer
        m_pVertex = pVertexBuffer;

    } // End if a resize is required
```

First we check to see whether the number of vertices passed in will exceed the current capacity of the vertex array. If so, then we need to resize the array. We grow the array by 100 vertices every time the capacity is reached so we will not need to resize again until we have added another 100 vertices.

Note the use of the loop rather than a simple conditional test for the resize. This handles the cases where a user adds large numbers of vertices in one go. If a user wanted to add 500 vertices, we would need to resize the array by 500, not 100. The loop incrementally adds 100 to the current m_nVertexCapcity variable until it is large enough to hold all the vertices required.

Next we use the local temporary pointer pVertexBuffer to allocate a new BYTE array large enough to hold the required number of vertices. Notice that we multiply the vertex capacity by the stride (m_nVertexStride) to get the total number of bytes needed. This is a clear example of why it is important to call SetDataFormat prior to adding vertex data.

If the vertex array currently contains vertex data, then we copy it into the newly allocated buffer and delete the original array because we no longer need it. Finally, we reassign the m_pVertex variable to point to the new vertex array which now contains any previous vertex data and enough room on the end to store the input vertex data. Next we copy over the vertex data passed into this function (it will be appended to the current contents of the buffer). Because we have not yet increased the internal vertex count variable, this tells us exactly where to start adding the new vertices.

```
    // Copy over vertex data if provided
    if ( pVertices )
       memcpy(&m_pVertex[m_nVertexCount*m_nVertexStride],pVertices,Count*m_nVertexStride);
```

Finally, we update the vertex count and return the index of the first newly added vertex in the array. This allows the calling function to retrieve a pointer to the vertex data and use it to start placing vertex data in the correct position.

```
    // Increase Vertex Count
    m_nVertexCount += Count;

    // Return first vertex
    return m_nVertexCount - Count;
}
```

CTriMesh::AddFace

The AddFace function is the second part of the geometry creation functionality. Since the ID3DXMesh object always represents its data as indexed triangle lists, we will follow the same rules when adding mesh indices.

The AddFace function is similar to the AddVertex function in the sense that it is used to temporarily store face data until the ID3DXMesh is created. But there is one important difference -- in addition to the face data (the indices), we must also specify an attribute ID describing the subset the face belongs to. These attribute IDs will be arbitrary values that are used by the application to group faces that have like properties. Therefore, the function must resize the temporary index array as well as the attribute array to allow for one attribute per index buffer triangle.

The first parameter is the number of triangles we wish to add and the second parameter is a void pointer to the index data for the triangles. This buffer should contain Count * 3 indices. The final parameter is the attribute ID we would like associated with the face(s) we are adding. This means that we can add multiple triangles with the same attribute ID in a single call. If we add N faces to the mesh, we will also need to add N attribute ID’s to the temporary pAttribute buffer.

```
long CTriMesh::AddFace( ULONG Count, LPVOID pIndices , ULONG AttribID  )
{
    UCHAR * pIndexBuffer = NULL;
    ULONG * pAttributeBuffer = NULL;
```

First we allocate two pointers that can be used to resize the index and attribute arrays. Because the index buffer contains faces and the attribute array holds an attribute ID for each face, these two arrays will always be resized together so that they stay in sync.

Resizing the arrays is identical to the vertex array resize. The default capacity and resize values are both 100.

```
    if ( m_nFaceCount + Count > m_nFaceCapacity )
    {
        // Adjust our face capacity (resize 100 at a time)
        for ( ; m_nFaceCapacity < (m_nFaceCount + Count) ; ) m_nFaceCapacity += 100;
```

We use the local pIndexBuffer pointer to allocate enough memory to hold the required indices. We multiply the desired face count by three to get the desired index count, and then multiply that value by the size of an index (2 or 4 bytes) to get the total number of bytes needed for the new temporary index buffer.

```
        // Allocate new resized array
        if (!( pIndexBuffer = new UCHAR[(m_nFaceCapacity * 3)*m_nIndexStride])) return -1;
```

If there is currently data in the index array then we will copy it into the new index array and release the old array. We reassign m_pIndex to the newly created array.

```
        // Existing Data?
        if ( m_pIndex )
        {
            // Copy old data into new buffer
            memcpy( pIndexBuffer, m_pIndex, (m_nFaceCount * 3) * m_nIndexStride );

            // Release old buffer
            delete []m_pIndex;
        }

        // Reassign pointer to new buffer
        m_pIndex = pIndexBuffer;
```

We do similar resizing to the attribute array.

```
        // Allocate new resized attribute array
        pAttributeBuffer = new ULONG[ m_nFaceCapacity ];
```

If the current attribute array (m_pAttribute) holds any data, then we copy it into the new array. Finally we release the old array and ressign the member variable m_pAttribute.

```
        // Existing Data?
        if ( m_pAttribute )
        {
            // Copy old data into new buffer
            memcpy( pAttributeBuffer, m_pAttribute, m_nFaceCount * sizeof(ULONG) );

            // Release old buffer
            delete []m_pAttribute;
        }

        // Store pointer for new buffer
        m_pAttribute = pAttributeBuffer;

    } // End if a resize is required
```

Next we append the index data passed into the function into the index array.

```
    // Copy over index and attribute data if provided
    if ( pIndices )
      memcpy(&m_pIndex[(m_nFaceCount*3)*m_nIndexStride],pIndices,(Count*3)*m_nIndexStride);
```

Finally, we loop through the new elements added to the attribute array (one for each new face) and set the attribute ID to the value passed into the function. We then increment the mesh face count and return the index of the first newly added face.

```
    for ( ULONG i = m_nFaceCount; i < m_nFaceCount + Count; ++i) m_pAttribute[i] = AttribID;

    // Increase Face Count
    m_nFaceCount += Count;

    // Return first face
    return m_nFaceCount - Count;
}
```

CTriMesh::AddAttributeData

As discussed earlier, a managed mesh maintains an array of MESH_ATTRIB_DATA structures describing the texture and material used by each subset. This allows the mesh to render itself. We use the CTriMesh::AddAttributeData function to add MESH_ATTRIB_DATA information to this array. This function is necessary if we manually create a mesh which is intended for use in managed mode. It allows us to specify the texture and material properties used by each subset to manually build the mesh's internal attribute array. This function serves no purpose for non-managed mode meshes.

The function takes one parameter which describes how many MESH_ATTRIB_DATA structures to make room for in the m_pAttribData array. If the array already contains mesh attribute data then the array will be resized to store the requested number of elements plus the elements already in the array. Array resizing works in exactly the same way as we saw in the last two functions discussed.

```
long CTriMesh::AddAttributeData( ULONG Count  )
{
    MESH_ATTRIB_DATA * pAttribBuffer = NULL;

    // Allocate new resized array
     pAttribBuffer = new MESH_ATTRIB_DATA[ m_nAttribCount + Count ] ;

    // Existing Data?
    if ( m_pAttribData )
    {
        // Copy old data into new buffer
        memcpy( pAttribBuffer, m_pAttribData, m_nAttribCount * sizeof(MESH_ATTRIB_DATA) );

        // Release old buffer
        delete []m_pAttribData;
    }
```

```
    // Store pointer for new buffer
    m_pAttribData = pAttribBuffer;

    // Clear the new items
    ZeroMemory( &m_pAttribData[m_nAttribCount], Count * sizeof(MESH_ATTRIB_DATA) );

    // Increase Attrib Count
    m_nAttribCount += Count;

    // Return first Attrib
    return m_nAttribCount - Count;
}
```

The function returns the index of the first attribute added by the call. The calling function can use the returned value to index into the m_pAttribData function and fill out the required attribute information. Keep in mind that the number of mesh attribute data elements in this array should match the number of subsets in the managed mesh. There is a one-to-one mapping between subsets in the mesh and this array, therefore, the first element you add to this array will be used to describe the texture and material information for the first subset, and so on.

One thing is not immediately clear. The above function allows us to add space in the internal attribute array of the mesh and returns the index of the newly added attribute element. How do we use this to place texture and material information into that array element? The mesh object also exposes a function called GetAttributeData which returns a pointer to the underlying attribute array. You can use this pointer along with the index returned from the above function to access the newly added attribute elements and populate them with texture and material data.

> **Note:** You should not call the AddAttributeData function if you intend to use the mesh in non-managed mode, since this array will only be used in managed mode. In non-managed mode, the application or scene class is responsible for setting a subset's texture and material before rendering it.

Example: Creating a cube using CTriMesh

We have now covered the basic functions we need to add data to the mesh. For illustration, the following code snippet will demonstrate how we might create a simple cube mesh using these functions. This next section is like an instruction manual for how to use the wrapper (as opposed to an examination of the code), and should be helpful in providing insight into the manual creation process.
First the application must allocate a new CTriMesh. In this example we will be using vertices with a 3D position and one set of 2D texture coordinates. After the mesh is created, the SetDataFormat function is called to inform the mesh object of the vertex and index formats intended for use:

```
CTriMesh  CubeMesh;
CubeMesh.SetDataFormat(  D3DFVF_XYZ | D3DFVF_TEX1 , 2 );
```

Because we will be adding one quad at a time in this example (a cube face is two triangles), we will use temporary arrays of 4 vertices and 6 indices to store the information for each face. We will pass this data into the CTriMesh::AddVertex and CTriMesh::AddFace functions respectively:

```
USHORT   Indices[6];
CVertex  Vertices[4];

// Build Front quad ( all quads point inwards in this example)
Vertices[0] = CVertex( -10.0f,  10.0f,  10.0f, 0.0f, 0.0f );
Vertices[1] = CVertex(  10.0f,  10.0f,  10.0f, 1.0f, 0.0f );
Vertices[2] = CVertex(  10.0f, -10.0f,  10.0f, 1.0f, 1.0f );
Vertices[3] = CVertex( -10.0f, -10.0f,  10.0f,, 0.0f, 1.0f );

// Build the front face indices
Indices[0] = 0; Indices[1] = 1; Indices[2] = 3;
Indices[3] = 1; Indices[4] = 2; Indices[5] = 3;
```

We assign the two triangles of this face to attribute 0 using the AddFace function:

```
// Add the vertices and indices to this mesh for front face
CubeMesh.AddVertex( 4, &Vertices );
CubeMesh.AddFace( 2, Indices, 0 );
```

We have now added the indices and the vertices to the mesh. The two triangles we have added belong to subset 0 and describe the front quad of the cube. Now we can re-use our local arrays to store the information for the back quad before adding it to the mesh. These vertices will be added to the mesh as vertices 4 through 7, so we must set the indices with this in mind.

```
// Back Quad
Vertices[0] = CVertex(  10.0f,  10.0f, -10.0f, 0.0f, 0.0f );
Vertices[1] = CVertex( -10.0f,  10.0f, -10.0f, 1.0f, 0.0f );
Vertices[2] = CVertex( -10.0f, -10.0f, -10.0f, 1.0f, 1.0f );
Vertices[3] = CVertex(  10.0f, -10.0f, -10.0f, 0.0f, 1.0f );

// Build the back quad indices
Indices[0] = 4; Indices[1] = 5; Indices[2] = 7;
Indices[3] = 5; Indices[4] = 6; Indices[5] = 7;

// Add the vertices and indices to this mesh
CubeMesh.AddVertex( 4, &Vertices );
CubeMesh.AddFace( 2, Indices, 0 );
```

This face has also been assigned an attribute ID of 0. Thus the two front triangles and the two back triangles of the cube belong to subset 0. As a result, these four triangles will be rendered with the same texture/material combination.

We use the same technique to add the left and right quads. Both will be assigned attribute IDs of 1 so they will belong to the same subset and be rendered with the same texture/material.

```
// Left Quad
Vertices[0] = CVertex( -10.0f,  10.0f, -10.0f, 0.0f, 0.0f );
Vertices[1] = CVertex( -10.0f,  10.0f,  10.0f, 1.0f, 0.0f );
Vertices[2] = CVertex( -10.0f, -10.0f,  10.0f, 1.0f, 1.0f );
Vertices[3] = CVertex( -10.0f, -10.0f, -10.0f, 0.0f, 1.0f );

// Build the left quad indices
Indices[0] = 8; Indices[1] = 9; Indices[2] = 11;
Indices[3] = 9; Indices[4] = 10; Indices[5] = 11;

// Add the vertices and indices to this mesh
CubeMesh.AddVertex( 4, &Vertices );
CubeMesh.AddFace( 2, Indices, 1 );

// Right Quad
Vertices[0] = CVertex(  10.0f,  10.0f,  10.0f, 0.0f, 0.0f );
Vertices[1] = CVertex(  10.0f,  10.0f, -10.0f, 1.0f, 0.0f );
Vertices[2] = CVertex(  10.0f, -10.0f, -10.0f, 1.0f, 1.0f );
Vertices[3] = CVertex(  10.0f, -10.0f,  10.0f,  0.0f, 1.0f );

// Build the right quad indices
Indices[0] = 12; Indices[1] = 13; Indices[2] = 15;
Indices[3] = 13; Indices[4] = 14; Indices[5] = 15;

// Add the vertices and indices to this mesh
CubeMesh.AddVertex( 4, &Vertices );
CubeMesh.AddFace( 2, Indices, 1 );
```

Finally we add the top and bottom quads as subset 2. It should be noted that while we have added the faces to the mesh in subset order, this is not a requirement. You will usually optimize the mesh once it is created so that faces are internally batched by subset anyway.

```
// Top Quad
Vertices[0] = CVertex( -10.0f,  10.0f, -10.0f, 0.0f, 0.0f );
Vertices[1] = CVertex(  10.0f,  10.0f, -10.0f, 1.0f, 0.0f );
Vertices[2] = CVertex(  10.0f,  10.0f,  10.0f, 1.0f, 1.0f );
Vertices[3] = CVertex( -10.0f,  10.0f,  10.0f,  0.0f, 1.0f );

// Build the indices
Indices[0] = 16; Indices[1] = 17; Indices[2] = 19;
Indices[3] = 17; Indices[4] = 18; Indices[5] = 19;

// Add the vertices and indices to this mesh
CubeMesh.AddVertex( 4, &Vertices );
CubeMesh.AddFace( 2, Indices, 2 );

// Bottom Quad
Vertices[0] = CVertex( -10.0f, -10.0f,  10.0f, 0.0f, 0.0f );
Vertices[1] = CVertex(  10.0f, -10.0f,  10.0f, 1.0f, 0.0f );
Vertices[2] = CVertex(  10.0f, -10.0f, -10.0f, 1.0f, 1.0f );
Vertices[3] = CVertex( -10.0f, -10.0f, -10.0f, 0.0f, 1.0f );
```

```
// Build the indices
Indices[0] = 20; Indices[1] = 21; Indices[2] = 23;
Indices[3] = 21; Indices[4] = 22; Indices[5] = 23;

// Add the vertices and indices to this mesh
CubeMesh.AddVertex( 4, &Vertices );
CubeMesh.AddFace( 2, Indices, 2 );
```

At this point the mesh has all vertices stored in its temporary vertex array, all indices in its temporary index array, and the attribute IDs for each face are stored in its temporary attribute array (describing three subsets).

If we were intending to use this mesh as a non-managed mesh then our work would be done (except for loading textures and making sure that they are set before rendering the correct subsets). However, in this example we will assume that this is a managed mesh with attribute IDs in the range of 0 to 2 (i.e., three subsets). Therefore, we need to add the attribute data to the mesh for each subset so that the mesh knows which textures and materials to set when rendering its subsets.

First we call the AddAttributeData function with a value of 3 so that the mesh allocates its MESH_ATTRIB_DATA array to hold 3 elements.

```
// Add the attribute data (We'll let the mesh manage itself)
CubeMesh.AddAttributeData( 3 );
```

Next we call CTriMesh::GetAttributeData which will return a pointer to the internal MESH_ATTRIB_DATA array so we can populate it with meaningful attribute data for each subset.

```
MESH_ATTRIB_DATA *pAttribData;
pAttribData = CubeMesh.GetAttributeData();
```

Now we can loop through each element and store the texture pointer and the material for the subset mapped to that attribute. In this example we are not storing normals in our vertices so will not be using the DirectX lighting pipeline. Therefore, we do not bother setting the material for each subset because it will not be used. We just create a default material and copy it into each attribute.

We also assume that pTexture is an application-owned array containing the three textures used by the subsets. These textures would have been created prior to this code being executed. What is worthy of note is that the texture and attribute callback functions are only used by the mesh when parsing X files. When the application manually creates meshes in this way, it is responsible for creating the required textures and storing their pointers in the mesh attribute array (in managed mode only).

```
D3DMATERIAL9 Material;
ZeroMemory( &Material, sizeof(D3DMATERIAL9));

// Set the attribute data for each subset
for ( ULONG i = 0; i < 3; ++i )
{
    pAttribData[i].Texture  = pTexture[I];
```

```
        pTexture[I]->AddRef();
        pAttribData[i].Material = Material;
    }
```

A good example of mesh creation happens when loading an IWF file. The IWF file contains all the texture filenames which would be initially created and stored by the scene. The IWF file also contains the face data and the material and texture mappings for each face. Using this information, the faces can be added to the mesh one triangle at a time and the attributes can be grouped and added as the subsets of the mesh.

All that is left to do at this point is instruct the CTriMesh object to build its internal ID3DXMesh object using the data we have added to the temporary arrays. Notice that when we call BuildMesh, we pass in the D3DXMESH_MANAGED member of the D3DXMESH enumerated type in this example. This indicates that we would like the mesh vertex and index buffers created in the managed resource pool so that they can support automatic recovery from a lost/reset device.

```
// Build the mesh
CubeMesh.BuildMesh( D3DXMESH_MANAGED, m_pD3DDevice );
```

CTriMesh::BuildMesh

The BuildMesh function should be called after the application has finished manually populating the mesh with data. It should not be called if we have loaded the data from an X file as the underlying mesh will have already been created. BuildMesh will generate the underlying ID3DXMesh object and fill its vertex and vertex buffers with the information currently stored in the temporary arrays. The code is shown next a few lines at a time. This listing has had some of the error checking removed to improve readability, but the error checking is performed in the actual source code.

The function takes three parameters. The first specifes zero or more members of the D3DXMESH enumerated type. This indicates which memory pool we wish the ID3DXMesh we are about to create to use for its vertex and index buffers. The second parameter is a pointer to the Direct3D device object which will own the mesh resources. The optional third parameter, which is set to TRUE by default, is a Boolean variable indicating whether we wish the temporary vertex, index and attribute arrays to be freed from memory after the ID3DXMesh has been successfully created.

Usually you would want to release these temporary storage bins as they are no longer required, but it can be useful to keep them around if the underlying mesh is to be created in the default pool. If the device should become lost, default pool meshes would need to be created again from scratch, requiring your application to manually add all the vertex and index data again. If you do not release the temporary storage bins, then a simple call to the CTriMesh::BuildMesh function is all that is needed to restore the mesh to its former status. The underlying ID3DXMesh will still be released and recreated, but the vertex and index data is still in the temporary bins and is automatically copied over by this function. This convenience obviously comes at the expense of increased memory requirement.

```
HRESULT CTriMesh::BuildMesh(ULONG Options, LPDIRECT3DDEVICE9 pDevice, bool ReleaseOriginals)
{
    HRESULT hRet;
    LPVOID  pVertices   = NULL;
    LPVOID  pIndices    = NULL;
    ULONG  *pAttributes = NULL;
```

If this CTriMesh object already has an ID3DXMesh assigned to it, we should release it. This allows us to call this function to rebuild meshes that have become invalid due to device loss / reset.

```
    // First release the original mesh if one exists
    if ( m_pMesh ) { m_pMesh->Release(); m_pMesh = NULL; }
```

Next we test the m_nIndexStride member variable to see if the user has set the index data format to 32-bit. By default D3DXCreateMeshFVF creates meshes with 16-bit indices, so we will need to modify the mesh creation options to include the D3DXMESH_32BIT flag in that case.

```
    // Force 32 bit mesh if required
    if ( m_nIndexStride == 4 ) Options |= D3DXMESH_32BIT;
```

Now we call D3DXCreateMeshFVF to create the ID3DXMesh. We pass in the number of faces and the number of vertices the mesh will require, followed by the creation options. We also pass the FVF flags that were registered with the mesh and a pointer to the device that will own the mesh. The final parameter is the CTriMesh::m_pMesh pointer that will point to a valid ID3DXMesh interface if the function is successful.

```
     // Create the blank empty mesh
    D3DXCreateMeshFVF(m_nFaceCount,m_nVertexCount,Options,m_nVertexFVF,pDevice,&m_pMesh);
```

At this point our D3DXMesh has been created, but it contains no data. The next step is to lock the mesh vertex, index, and attribute buffers and copy over all of the information stored in our temporary arrays.

```
    // Lock the vertex buffer and copy the data
    m_pMesh->LockVertexBuffer( 0, &pVertices );
    memcpy( pVertices, m_pVertex, m_nVertexCount * m_nVertexStride );
    m_pMesh->UnlockVertexBuffer();

    // Lock the index buffer and copy the data
    m_pMesh->LockIndexBuffer( 0, &pIndices );
    memcpy( pIndices, m_pIndex, (m_nFaceCount * 3) * m_nIndexStride );
    m_pMesh->UnlockIndexBuffer();

    // Lock the attribute buffer and copy the data
    m_pMesh->LockAttributeBuffer( 0, &pAttributes );
    memcpy( pAttributes, m_pAttribute, m_nFaceCount * sizeof(ULONG) );
    m_pMesh->UnlockAttributeBuffer();
```

Finally, if the ReleaseOriginals Boolean parameter was set to TRUE (the default setting) then the temporary storage bins are de-allocated and their pointers are set to NULL. We also set all other variables that describe the data in the temporary arrays to zero.

```
    // Release the original data if requested
    if ( ReleaseOriginals )
    {
        if ( m_pVertex    ) delete []m_pVertex;
        if ( m_pIndex     ) delete []m_pIndex;
        if ( m_pAttribute ) delete []m_pAttribute;

        m_nVertexCount    = 0;
        m_nFaceCount      = 0;
        m_pAttribute      = NULL;
        m_pIndex          = NULL;
        m_pVertex         = NULL;
        m_nVertexCapacity = 0;
        m_nFaceCapacity   = 0;
     }

    // We're done
    return S_OK;
}
```

At this point the mesh has been fully created and populated and can be rendered using the DrawSubset function or the Draw function (if this is a managed mesh).

CTriMesh::Draw

CTriMesh::Draw automates the rendering of a managed mesh and should not be used to render non-managed meshes. A managed mode mesh maintains internal texture and material resources for subset rendering. As this is not the case for non-managed meshes, this function only works in managed mode and will immediately return if called for a non-managed mesh.

```
void CTriMesh::Draw(  )
{
    LPDIRECT3DDEVICE9 pD3DDevice = NULL;

    // If the mesh has not been created yet bail
    if (!m_pMesh ) return;

    // This function is invalid if there is no managed data
    if ( !m_pAttribData ) return;

    // Retrieve the Direct3D device
    m_pMesh->GetDevice( &pD3DDevice );

    // Set the attribute data
    pD3DDevice->SetFVF( GetFVF() );

    // Render the subsets
    for ( ULONG i = 0; i < m_nAttribCount; ++i )
    {
        pD3DDevice->SetMaterial( &m_pAttribData[i].Material );
        pD3DDevice->SetTexture( 0, m_pAttribData[i].Texture );
```

```
        m_pMesh->DrawSubset( i );

    } // Next attribute

    // Release the device
    pD3DDevice->Release();
}
```

After checking for managed mode rendering, the function retrieves the device from the ID3DXMesh. We then loop through each subset of the mesh, set its texture and material, and call ID3DXMesh::DrawSubset with the subset attribute ID. Finally, we release the device interface because ID3DXMesh::GetDevice increments the device reference count before returning the pointer. CTriMesh::GetFVF is a simple wrapper that passes the request through to ID3DXMesh::GetFVF to get the FVF flags the mesh was created with.

CTriMesh::DrawSubset

DrawSubset provides an interface for rendering individual mesh subsets. It can be used in both managed and non-managed modes. It is in fact our only means for rendering a non-managed mesh. A higher level process will be required to set the texture, material, and other states for each subset prior to the render call (as seen in the CTriMesh::Draw function shown above). This allows the scene to batch render subsets from multiple meshes to achieve attribute order rendering across mesh boundaries. This function can also be called to render a subset of a managed mesh, in which case the texture and material of the subset will be set automatically.

```
void CTriMesh::DrawSubset( ULONG AttributeID )
{
    LPDIRECT3DDEVICE9 pD3DDevice = NULL;

    // Set the attribute data if managed mode mesh
    if ( m_pAttribData && AttributeID < m_nAttribCount )
    {
        // Retrieve the Direct3D device
        m_pMesh->GetDevice( &pD3DDevice );

        pD3DDevice->SetMaterial( &m_pAttribData[AttributeID].Material );
        pD3DDevice->SetTexture( 0, m_pAttribData[AttributeID].Texture );

        // Release the device
        pD3DDevice->Release();
    }

    //draw the subset
    m_pMesh->DrawSubset( AttributeID );
}
```

If the mesh attribute data array is defined, then this is a managed mesh and we set the subset texture and material before rendering. If it is non-managed, then we simply call ID3DXMesh::DrawSubset straight away.

CTriMesh::OptimizeInPlace

CTriMesh::OptimizeInPlace is basically a wrapper around the ID3DXMesh::OptimizeInPlace function.

The first parameter is a DWORD containing one or more D3DXMESHOPT flags describing the optimization we wish to perform. The second and third parameters can be set to NULL or can be passed the address of ID3DXBuffer interface pointers that will contain the face and vertex remap information respectively. These should not be allocated buffers since the function will create both buffers for you.

```
HRESULT CTriMesh::OptimizeInPlace( DWORD Flags, LPD3DXBUFFER *ppFaceRemap,
                                   LPD3DXBUFFER *ppVertexRemap)
{
    HRESULT      hRet;
    LPD3DXBUFFER pFaceRemapBuffer = NULL;
    ULONG       *pData = NULL;
```

If the mesh has not yet had its adjacency information generated then we do so at this point. The m_pAdjacency member variable is a pointer to an ID3DXBuffer interface. The GenerateAdjacency function will create the D3DXBuffer object and fill it with adjacency information.

```
    // Generate adjacency if none yet provided
    if (!m_pAdjacency)
    {
        GenerateAdjacency();
    }
```

ID3DXMesh::OptimizeInPlace can be somewhat confusing when it comes to generating remap information. To get the face remap information you pass in a pointer to a pre-allocated DWORD array. To get vertex remap information you just pass a pointer to an ID3DXBuffer and the function will generate and fill it with the relevant data. To avoid confusion, our function will return both face and vertex remapping information in ID3DXBuffer objects. Therefore, we must first create the face remap buffer ourselves, obtain a pointer to its data area, cast it to a DWORD, and pass it into ID3DXMesh::OptimimzeInPlace.

```
    // Allocate the output face remap if requested
    if ( ppFaceRemap )
    {
        D3DXCreateBuffer( GetNumFaces() * sizeof(ULONG), ppFaceRemap );
         pData = (ULONG*)(*ppFaceRemap)->GetBufferPointer();
    }
```

Finally, we call ID3DXMesh::OptimizeInPlace to optimize the mesh data.

```
    // Optimize the data
    m_pMesh->OptimizeInplace(Flags, (DWORD*)m_pAdjacency->GetBufferPointer(),
                             (DWORD*)m_pAdjacency->GetBufferPointer(), pData, ppVertexRemap );
    return S_OK;
}
```

CTriMesh::Optimize

This function is a bit more complex than its predecessor due to the fact that it has to clone the optimized data into a new CTriMesh object. However, unlike ID3DXMesh::Optimize which automatically creates the output mesh, CTriMesh::Optimize expects the application to pass in a pre-created CTriMesh object. This mesh will be the recipient of the optimized data. This affords us the extra flexibility of being able to use a statically allocated or stack allocated CTriMesh object as the output mesh. This might be useful if you wanted to create a temporary optimized mesh locally inside a function, where the output mesh would be allocated on the stack and automatically discarded when the function returns.

The first parameter is a combination of D3DXMESH flags describing how the underlying ID3DXMesh object in the output mesh should be created. This can be combined with one or more D3DXMESHOPT flags describing the optimization to perform. The second parameter is a pointer to a CTriMesh object that will receive the optimized ID3DXMesh object. This CTriMesh pointer should point to an already created CTriMesh object. If the output mesh already contains an underlying ID3DXMesh object, this mesh will be released in favor of the new one that is created by this function.

```
HRESULT CTriMesh::Optimize(ULONG Flags, CTriMesh *pMeshOut, LPD3DXBUFFER *ppFaceRemap,
                           LPD3DXBUFFER *ppVertexRemap , LPDIRECT3DDEVICE9 pD3DDevice  )
{
    HRESULT             hRet;
    LPD3DXMESH          pOptimizeMesh = NULL;
    LPD3DXBUFFER        pFaceRemapBuffer = NULL;
    LPD3DXBUFFER        pAdjacency = NULL;
    ULONG              *pData      = NULL;
```

If the mesh we are cloning does not yet have its adjacency information generated, then we need to generate it, because it is needed in the call to ID3DXMesh::Optimize.

```
    // Generate adjacency if not yet available
    if (!m_pAdjacency)
    {
        hRet = GenerateAdjacency();
    }
```

If the caller did not pass in a pointer to a device, then we will use the device of the current mesh being cloned. Typically you will not want to specify a different device unless you are using multiple devices (very rare). Keep in mind that while the CTriMesh object is not bound to any particular device, its underlying ID3DXMesh object is. The next section of code calls CTriMesh::GetDevice to get a pointer to the current mesh's device if a device pointer was not specified. If a device pointer was passed, then we increment its reference count until we finish using it.

```
    if ( !pD3DDevice )
    {
        // we'll use the same device as this mesh
        // This automatically calls 'AddRef' for the device
        m_pMesh->GetDevice( &pD3DDevice );
```

```
    }
    else
    {
        // Otherwise we'll add a reference here so that we can
        // release later for both cases without doing damage :)
        pD3DDevice->AddRef();
    }
```

ID3DXMesh::Optimize also returns face adjacency information for the optimized mesh, so we create a buffer to store this information. As with the OptimizeInPlace method, we create the face remap buffer if a face remap pointer was passed into the function.

```
    // Allocate new adjacency output buffer
    D3DXCreateBuffer( (3 * GetNumFaces()) * sizeof(ULONG), &pAdjacency );

    // Allocate the output face remap if requested
    if ( ppFaceRemap )
    {
        // Allocate new face remap output buffer
        D3DXCreateBuffer( GetNumFaces() * sizeof(ULONG), ppFaceRemap );
        pData = (ULONG*)(*ppFaceRemap)->GetBufferPointer();
   }
```

At the top of this function we declared a local ID3DXMesh pointer called pOptimizeMesh. This pointer will be fed into the ID3DXMesh::Optimize function and will point to the newly created optimized mesh on function return.

```
   // Attempt to optimize the mesh
   m_pMesh->Optimize( Flags,
                      (ULONG*)m_pAdjacency->GetBufferPointer(),
                      (ULONG*)pAdjacency->GetBufferPointer(),
                       pData, ppVertexRemap, &pOptimizeMesh );
```

At this point we now have an optimized ID3DXMesh, but it is not yet connected to the output CTriMesh object that was passed into this function. So we call the CTriMesh::Attach method for the output CTriMesh object which points the m_pMesh pointer to the optimized ID3DXMesh. Notice that we also pass the face adjacency buffer so that the new mesh has this data resident.

```
    // Attach this D3DX mesh to the output CTriMesh
    // This automatically adds a reference to the mesh passed in.
    pMeshOut->Attach( pOptimizeMesh, pAdjacency );
```

The optimized mesh and its adjacency buffer have now been assigned to the output CTriMesh, which increases the reference count on both. We no longer need to use these interfaces in this function so we release them. This does not destroy the buffer or the mesh because they are now being referenced by the output CTriMesh object.

```
    // We can now release our copy of the optimized mesh and the adjacency buffer
    pOptimizeMesh->Release();
    pAdjacency->Release();
```

If we are optimizing a managed mesh, then the source mesh will have an array of mesh attribute data elements describing the textures and materials used by each subset. If this is the case, we must also copy this data into the mesh attribute array of the output CTriMesh. First we call AddAttributeData to make room for the new attributes and then we copy the data over.

```
    // Copy over attributes if there is anything here
    if ( m_pAttribData )
    {
        // Add the correct number of attributes
         pMeshOut->AddAttributeData( m_nAttribCount ) ;

        // Copy over attribute data
        MESH_ATTRIB_DATA * pAttributes = pMeshOut->GetAttributeData();
        for ( ULONG i = 0; i < m_nAttribCount; ++i )
        {
            MESH_ATTRIB_DATA * pAttrib = &pAttributes[i];

            // Store details
            pAttrib->Material = m_pAttribData[i].Material;
            pAttrib->Texture  = m_pAttribData[i].Texture;
            pAttrib->Effect   = m_pAttribData[i].Effect;

            // Add references so that objects aren't released when either of these
            // meshes are released, or vice versa.
            if ( pAttrib->Texture ) pAttrib->Texture->AddRef();
            if ( pAttrib->Effect  ) pAttrib->Effect->AddRef();
        } // Next Attribute
    } // End if managed

    // Release our referenced D3D Device
    if (pD3DDevice) pD3DDevice->Release();

    // Success!!
    return S_OK;
}
```

Notice that when we copy over each texture pointer (and effect pointer) we make sure that we increase the reference count so that it correctly reflects how many external pointers to the interface are in existence.

CTriMesh::GenerateAdjacency

The CTriMesh class includes a member variable called m_pAdjacency which is a pointer to an ID3DXBuffer interface. This function creates this buffer and calls ID3DXMesh::GenerateAdjacency to calculate the adjacency information. ID3DXMesh::GenerateAdjacency expects a DWORD pointer to an array large enough to hold the adjacency information, so we simply allocate the ID3DXBuffer large enough to hold three DWORDS per face and retrieve the buffer data pointer and cast it before passing it into the function. CTriMesh::GenerateAdjacency accepts an optional epsilon parameter which will default to 0.001. This is used as a tolerance value when comparing vertices in neighboring faces to see if they are joined.

Note: This function should only be called after the underlying ID3DXMesh has been created.

```
HRESULT CTriMesh::GenerateAdjacency( float Epsilon )
{
    HRESULT hRet;

    // Validate Requirements
    if ( !m_pMesh ) return D3DERR_INVALIDCALL;

    // Clear out any old adjacency information
    if (m_pAdjacency) m_pAdjacency->Release();

    // Create the new adjacency buffer
    hRet = D3DXCreateBuffer( GetNumFaces() * (3 * sizeof(DWORD)), &m_pAdjacency );
    if ( FAILED(hRet) ) return hRet;

    // Generate the new adjacency information
    hRet = m_pMesh->GenerateAdjacency( Epsilon, (DWORD*)m_pAdjacency->GetBufferPointer() );
    if ( FAILED(hRet) ) return hRet;

    // Success !!
    return S_OK;
}
```

CTriMesh::Attach

The Attach function is used when a new ID3DXMesh is created and needs to be attached to a pre-existing CTriMesh object. Its parameters are an ID3DXMesh and its adjacency buffer. The adjacency buffer passed is simply stored for later use. If you do not pass the adjacency buffer it will be generated when it is needed. The function returns NULL if a valid mesh pointer is not passed.

```
HRESULT CTriMesh::Attach( LPD3DXBASEMESH pMesh, LPD3DXBUFFER pAdjacency /* = NULL */ )
{
    HRESULT hRet;

    // Validate Requirements
    if ( !pMesh ) return D3DERR_INVALIDCALL;

    // Clear our current data
    Release();
```

We start by calling CTriMesh::Release to release any prior mesh or adjacency data. Since the input mesh is the generic base class, we use a method of the IUnknown interface to determine whether or not the passed pointer is to the correct COM interface (ID3DXMesh in this case). We call the IUnkown::QueryInterface method and pass the interface type we are querying and the m_pMesh pointer. If the mesh is a valid ID3DXMesh COM interface, it will be copied into the m_pMesh pointer and its reference count incremented automatically by the QueryInterface call.

```
    // Store this mesh (ensuring that it really is of the expected type)
```

```
    // This will automatically add a reference of the type required
    hRet = pMesh->QueryInterface( IID_ID3DXMesh, (void**)&m_pMesh );
    if ( FAILED(hRet) ) return hRet;
```

Next, we copy FVF, vertex and index stride, and the adjacency buffer (if it was passed in). We remember to call AddRef to ensure proper reference counting on the buffer. Once done, we return success.

```
    // Calculate strides etc
    m_nVertexFVF    = m_pMesh->GetFVF();
    m_nVertexStride = m_pMesh->GetNumBytesPerVertex();
    m_nIndexStride  = (GetOptions() & D3DXMESH_32BIT) ? 4 : 2;

    // If adjacency information was passed, reference it
    // if none was passed, it will be generated later, if required.
    if ( pAdjacency )
    {
        m_pAdjacency = pAdjacency;
        m_pAdjacency->AddRef();
    }
    // Success!!
    return S_OK;
}
```

CTriMesh::CloneFVF

A useful feature of the ID3DXMesh interface is the ability to clone the mesh into a new mesh with a different vertex/index format. This is especially handy when we load data from an X file which may lack certain pieces of information we need or more components than we intend to support.

This function is almost identical to our Optmize function, without the actual optimization call. The function simply clones and attaches the mesh based on the creation options and FVF specified as input parameters. Adjacency data is either copied or generated and attributes are copied if the mesh is in managed mode. The final mesh is passed out using the third parameter.

```
HRESULT CTriMesh::CloneMeshFVF( ULONG Options, ULONG FVF, CTriMesh * pMeshOut,
                                LPDIRECT3DDEVICE9 pD3DDevice /* = NULL */ )
{
    HRESULT             hRet;
    LPD3DXMESH          pCloneMesh  = NULL;

    // Validate requirements
    if ( !m_pMesh || !pMeshOut ) return D3DERR_INVALIDCALL;

    // Generate adjacency if not yet available
    if (!m_pAdjacency)
    {
       GenerateAdjacency();
    }

    // If no new device was passed...
    if ( !pD3DDevice )
```

```
    {
        // we'll use the same device as this mesh
        // This automatically calls 'AddRef' for the device
        m_pMesh->GetDevice( &pD3DDevice );
    }
    else
    {
        // Otherwise we'll add a reference here so that we can
        // release later for both cases without doing damage :)
        pD3DDevice->AddRef();
    }

    // Attempt to clone the mesh
    m_pMesh->CloneMeshFVF( Options, FVF, pD3DDevice, &pCloneMesh );

    // Attach this D3DX mesh to the output mesh
    // This automatically adds a reference to the mesh passed in.
    pMeshOut->Attach( pCloneMesh );

    // We can now release our copy of the cloned mesh
    pCloneMesh->Release();

    // Copy over attributes if there is anything here
    if ( m_pAttribData )
    {
        // Add the correct number of attributes
        if ( pMeshOut->AddAttributeData( m_nAttribCount ) < 0 ) return E_OUTOFMEMORY;

        // Copy over attribute data
        MESH_ATTRIB_DATA * pAttributes = pMeshOut->GetAttributeData();
        for ( ULONG i = 0; i < m_nAttribCount; ++i )
        {
            MESH_ATTRIB_DATA * pAttrib = &pAttributes[i];
            // Store details
            pAttrib->Material = m_pAttribData[i].Material;
            pAttrib->Texture  = m_pAttribData[i].Texture;
            pAttrib->Effect   = m_pAttribData[i].Effect;

            // Add references so that objects aren't released when either of these
            // meshes are released, or vice versa.
            if ( pAttrib->Texture ) pAttrib->Texture->AddRef();
            if ( pAttrib->Effect  ) pAttrib->Effect->AddRef();

        } // Next Attribute

    } // End if managed
    // Release our referenced D3D Device
    if (pD3DDevice) pD3DDevice->Release();

    // Success!!
    return S_OK;
}
```

CTriMesh::WeldVertices

WeldVertices is a thin wrapper around the D3DXWeldVertices function.

```
HRESULT CTriMesh::WeldVertices( ULONG Flags,  const D3DXWELDEPSILONS * pEpsilon  )
{
    HRESULT          hRet;
    D3DXWELDEPSILONS WeldEpsilons;

    // Validate Requirements
    if ( !m_pMesh ) return D3DERR_INVALIDCALL;

    // Generate adjacency if none yet provided
    if (!m_pAdjacency)
    {
        GenerateAdjacency();
    } // End if no adjacency

    // Fill out an epsilon structure if none provided
    if ( !pEpsilon )
    {
        // Set all epsilons to 0.001;
        float * pFloats = (float*)&WeldEpsilons;
        for ( ULONG i = 0; i < sizeof(D3DXWELDEPSILONS) / sizeof(float); i++ )
            *pFloats++ = 1e-3f;

        // Store a pointer (this doesn't get passed back or anything,
        // we're just reusing the empty var)
        pEpsilon = &WeldEpsilons;

    } // End if

    // Weld the vertices
    D3DXWeldVertices( m_pMesh, Flags, pEpsilon, (DWORD*)m_pAdjacency->GetBufferPointer(),
                      (DWORD*)m_pAdjacency->GetBufferPointer(), NULL, NULL );
     // Success!!
    return S_OK;
}
```

This function takes two parameters. The first is a flag containing zero or more members of the D3DXMESH enumerated type. While these are usually used as mesh creation flags and this function does not create a new output mesh, the weld operation will regenerate the vertex and index buffers. This means that we can optionally use the weld function to change the resource pool allocation strategy while we are welding it.

The second parameter is a pointer to a D3DXWELDEPSILONS structure which allows us to specify floating point tolerances for each possible vertex component. Specifying NULL for the second parameter will force the function to use a default comparison tolerance of 0.001 for each vertex component.

The D3DXWeldVertices function needs to be passed the face adjacency information, so if our CTriMesh object has not yet generated it, we tell it to do so. Next we test to see if a valid pointer to a

D3DXWELDEPSILONS structure was passed. If not, then we temporarily create one and set all of its tolerance values to 0.001. Finally, we call D3DXWeldVertices to perform the weld on the ID3DXMesh for this CTriMesh object.

CTriMesh::GetNumFaces

There are a number of CTriMesh functions we will not discuss here. They are all GetXX style functions which are generally one or two lines long. However we will use this one method as an example of the rest.

```
ULONG CTriMesh::GetNumFaces( ) const
{
    // Validation!!
    if ( !m_pMesh )
        return m_nFaceCount;           // Number of faces in temp index buffer
    else
        return m_pMesh->GetNumFaces(); // Number of faces in actual ID3DXMesh
}
```

This is a good example of how all of the GetXX functions work. Since the user may be creating meshes manually, they might call this function before calling the Build function to create the ID3DXMesh object. In this case, the function should return the number of faces that have currently been added to the temporary index arrays (m_nFaceCount). If the ID3DXMesh has been created however, then we call the ID3DXMesh::GetNumFaces function to return the number of faces in the actual mesh object. Many of these GetXX functions are built to work in these two modes.

Introducing IWF External References

In Chapter Five we discussed loading IWF files using the IWF SDK. While most of that code will remain intact, in this project we will be introducing some new IWF chunks that are specific to GILES™.

GILES™ v1.5 and above includes a new data type called a *reference*. References allow the artist to place multiple objects in the scene which all share the same physical mesh data. This is very much like the concept of instances we discussed in Chapter One. We only need to store one copy of the vertices and indices in memory and then have multiple objects reference the data. Any changes to the data will affect all objects that are referencing it. References can point to internal objects such as those created in GILES™ or they can point to external files. In the latter case, the IWF will contain filenames for X files. The X file data is not included within the IWF file, only the name is stored. Thus when we find an external reference, we will load the file ourselves.

External reference objects are very useful because they allow us to use GILES™ to place and position objects in the scene while still keeping the mesh data separate from the scene database. This means that if we need to tweak the polygons in one of our X files, we can do so without having to resave the scene. This also means that we can use GILES™ to create the scene and position placeholder objects in the world even before the artist has finalized the assets. Once the model is complete, it can be dropped into the game folder and (as long as the name has not changed) our code will display the scene properly.

You will recall from earlier lessons how the IWF SDK provides us with a helper function to automate the loading of IWF files. After the file has been loaded, the various components of the scene are stored in lists. As a simple example, all faces are stored in an IWFSurface list, all entities are stored in IWFEntity lists, etc. GILES™ reference objects (internal and external) are implemented as an entity plugin. This means that they will be stored in the entity list created by the IWF SDK loader, not the mesh list, and will require our code to load the mesh data using the given filename or object name contained inside the entity.

Below you can see how the reference entity is laid out in memory inside the entity's data area. This is the structure we will use in our CScene class to access the data stored in a reference entity loaded by the IWF SDK.

```
typedef struct _ReferenceEntity
{
    ULONG       ReferenceType;          // What type of reference is this
    ULONG       Flags;                  // Reserved flags
    ULONG       Reserved1;              // Reserved values
    ULONG       Reserved2;              // Reserved values
    ULONG       Reserved3;              // Reserved values
    char        ReferenceName[1024];    // External file name or internal object name
};
```

Many of these members are reserved for future use and can be ignored. Our focus is on the ReferenceType (0 for internal references, 1 for external references) and the ReferenceName (filename for external refernces, object name for internal references). For internal references, the name will be the

name of another object stored inside the IWF file. In GILES™, we can give objects in the scene unique names so that they can be referenced in this way. To keep things simple, our first application will support only external references (references to X files). This allows us to demonstrate how to use CTriMesh::LoadMeshFromX to load mesh data for each object in the scene stored in an IWF file.

> **Note:** The IWF file distributed with this project (Space_Scene.iwf) is unlike others we have loaded in past lessons. This file contains no actual geometry data. It contains only a skybox and a list of external reference entities. The scene uses four meshes, each stored in its own X file. Three of the meshes are spacecraft models (Cruiser1.x, Cruiser2.x, sfb-04.x). These objects were positioned in the scene using external referencing within GILES, so that only the object world matrix is stored in the IWF file along with its filename. The fourth X file is called Asteroid.x and is referenced many times in the scene. When we load these objects, we will give each reference its own CObject structure and attach the appropriate CTriMesh to each. From that point forward, rendering proceeds as usual.

The CScene Class

Our scene class will have several responsibilities:

- File loading
- Resource management
  - Textures
  - Materials
  - (Attributes)
  - Meshes
- Rendering

For mesh data, the scene class must be prepared to:

- Load externally referenced X files contained in IWF files
- Manually fill meshes with IWF data
- Manually fill meshes with procedural data (i.e. skyboxes, cubes, etc.)

CGameApp::BuildObjects starts asset loading with a call to CScene::LoadSceneFromIWF. This is very similar to previous projects we have developed. As before, we will use the CFileIWF class that ships with the IWF SDK to handle file import automatically on our behalf. This object contains a number of STL vectors for storage of entities, meshes, texture names, materials, etc that were extracted from the file. We will implement a number of processing functions (ProcessMeshes, ProcessEntities, etc.) to extract the relevant data from these vectors and convert them into a format which our scene object accepts.

> **Note:** We will not be covering all of the code in the CScene class since much of it is unchanged from previous applications. There are some small alterations where we might now copy data into a CTriMesh object instead of into a CMesh structure, but that is about the extent of it. We will focus on the major areas that have undergone revision such as data processing and rendering.

An abbreviated version of the CScene class declaration follows. The full declaration can be found in the header file CScene.h.

```
class CScene
{
public:
    //-----------------------------------------------------------------------
    // Constructors & Destructors for This Class.
    //-----------------------------------------------------------------------
     CScene( );
    ~CScene( );

    //-----------------------------------------------------------------------
    // Public Functions for This Class
    //-----------------------------------------------------------------------
    bool                LoadSceneFromIWF( TCHAR * strFileName,
                                          ULONG LightLimit = 0,
                                          ULONG LightReservedCount = 0 );

    bool                LoadSceneFromX  ( TCHAR * strFileName );

    void                Render          ( CCamera & Camera );
    void                RenderSkyBox    ( CCamera & Camera );
```

LoadSceneFromIWF will be called from CGameApp at application startup. This function was available in previous lessons when we discussed light groups (not used in this demo). The LightLimit parameter in the LoadSceneFromIWF file will simply be used to indicate how many lights we wish to load from the IWF file. For example, if the current hardware only supports eight simultaneous lights, we would set this to 8 so that only the first eight lights in the IWF file would be used and the rest would be ignored. In this application, the third parameter is not used but you may remember that it was used in the light group demo to reserve a number of light slots for dynamic lights.

The CScene class also has a LoadSceneFromX function which provides loading of X files which may contain individual or multiple meshes. Unlike LoadSceneFromIWF which gives each mesh loaded its own world matrix, LoadSceneFromX creates a single CTriMesh for the entire scene. If the X file contains multiple meshes, they will be collapsed into a single mesh. We will learn in the next chapter how to load hierarchical X files containing multiple meshes. In that case each mesh will maintain its own world matrix and can be manipulated separately from other meshes stored in the same X file.

CScene also has two render functions: CScene::Render is called by CGameApp::FrameAdvance to draw all scene meshes. CScene::RenderSkyBox draws the skybox and is called prior to mesh rendering to present a nice backdrop for the scene.

The next two methods are static callback functions that the scene will register with the CTriMesh class to handle the loading of textures and materials. We need two callback functions to differentiate the behaviour of managed vs. non-managed mesh modes. A managed mesh will call the CollectTexture function to load textures and store their pointers in its attribute data array. Non-managed meshes call CollectAttributeID to search the scene database for a material/texture combo index which is used to re-map the mesh attribute buffer to reference the global resource list.

```
    //-----------------------------------------------------------------------
    // Static Public Functions for This Class
    //-----------------------------------------------------------------------
    static LPDIRECT3DTEXTURE9   CollectTexture ( LPVOID pContext, LPCTSTR FileName );
    static ULONG                CollectAttributeID (
                                        LPVOID pContext, LPCTSTR strTextureFile,
                                        const D3DMATERIAL9 * pMaterial,
                                        constD3DXEFFECTINSTANCE *pEffectInstance=NULL);
```

In our demo project, we will use a managed mesh for our skybox because it shares no resources with other objects in the scene and non-managed meshes for all scene geometry. This should give you a good sense of how these types can be used in the same application.

After LoadSceneFromIWF calls CFileIWF::Load, the IWF file data is stored in the CFileIWF object's internal vectors. As in previous demos, the scene will then extract the required data from those vectors using a series of ProcessXX functions.

```
    private:
    //-----------------------------------------------------------------------
    // Private Functions for This Class
    //-----------------------------------------------------------------------
    bool                ProcessMeshes     ( CFileIWF & pFile );
    bool                ProcessVertices   ( CTriMesh * pMesh, iwfSurface * pFilePoly );
    bool                ProcessIndices    ( CTriMesh * pMesh, iwfSurface * pFilePoly,
                                            ULONG AttribID = 0, bool BackFace = false);
    bool                ProcessMaterials  ( const CFileIWF& File );
    bool                ProcessTextures   ( const CFileIWF& File );
    bool                ProcessEntities   ( const CFileIWF& File );
    bool                ProcessReference  ( const ReferenceEntity& Reference,
                                            const D3DXMATRIX & mtxWorld );
    bool                ProcessSkyBox     ( const SkyBoxEntity& SkyBox );
    long                AddMesh           ( ULONG Count = 1 );
    long                AddObject         ( ULONG Count = 1 );
```

Note that there is an AddObject function and an AddMesh function which are used for adding CObject structures to the scene's CObject array and CTriMesh objects to the scene's CTriMesh array respectively.

The first new class member variable is a single statically allocated CTriMesh object that will be used to store a skybox. Our scene will contain one skybox (at most) and it will be manually created when necessary. GILES™ does not export geometry information for a skybox, only the six texture file names needed to create the effect. So when the scene class encounters a skybox entity in the IWF file, it will extract the texture file names, create the textures and then create the cube faces manually. The SkyBox mesh will be created in managed mode so that it will render in a self-contained manner.

```
    //-----------------------------------------------------------------------
    // Private Variables for This Class
    //-----------------------------------------------------------------------
    CTriMesh            m_SkyBoxMesh;               // Sky box mesh.
```

The scene class will also be responsible for resource allocation and management regardless of the mesh management mode selected. A callback mechanism is provided to allow scene loading functions access to texture resources when needed. In order to avoid duplicating texture resources, the scene will store the texture pointer along with its filename in the structure shown below.

```
typedef struct _TEXTURE_ITEM
{
       LPSTR               FileName;   // File used to create the texture
       LPDIRECT3DTEXTURE9  Texture;    // The texture pointer
} TEXTURE_ITEM;
```

The global resource pool for textures is stored in the CScene class as a single array:

```
    TEXTURE_ITEM       *m_pTextureList [MAX_TEXTURES];      // Array of texture pointers
```

In the case of a managed mesh, the scene will return a pointer to the texture back to the mesh loading function after it has added the texture to this array. The managed mesh can store the texture pointer in its attribute data array for later use. In the case of a non-managed mesh, the texture will still be added to this array by the callback function, but the pointer will not be returned to the mesh loader. Instead, the index of a texture/material combination will be returned and used to re-map the mesh attribute buffer.

A similar strategy to avoid duplication is used for material resources, but only for non-managed meshes. Managed meshes will store their own materials internally, although as an exercise, you should be able to quickly modify the class to reference the global material pool and reduce memory requirements. The scene material list will contain all materials used by non-managed meshes.

```
    D3DMATERIAL9        m_pMaterialList[MAX_MATERIALS];    // Array of material structures.
```

The scene class also uses a D3DLIGHT9 array to store the lights that were loaded from the IWF file. To simplify the code, this particular demo project does not use light groups, so only the first N lights are loaded from the file (where N is the total number of simultaneous lights supported by the device). You could certainly add light group support as an exercise however.

```
    D3DLIGHT9           m_pLightList   [MAX_LIGHTS];          // Array of light structures
```

The next three variables describe how many items are in the arrays just discussed.

```
    ULONG               m_nTextureCount;          // Number of textures stored
    ULONG               m_nMaterialCount;         // Number of materials stored
    ULONG               m_nLightCount;            // Number lights stored here
```

The space scene IWF file used in this project contains three space ships and a number of asteroids. The scene object will thus contain an array of CObject structures for each object in the scene that needs to be rendered. The CObject structure contains a world matrix and a pointer to a CTriMesh. Recall that multiple CObject's may reference the same CTriMesh. This is the approach used for our asteroids and is a technique referred to as mesh instancing. The scene also contains an array of CTriMesh objects for the

actual geometry data used by the scene objects. For example, the CTriMesh array will contains 4 meshes (3 space ship meshes and 1 asteroid mesh).

```
    CObject           **m_pObject;             // Array of objects storing meshes
    ULONG               m_nObjectCount;        // Number of objects currently stored
    CTriMesh          **m_pMesh;               // Array of loaded scene meshes
    ULONG               m_nMeshCount;          // Number of meshes currently stored
```

Non-managed meshes are not aware of the texture or material each of its subsets is using, since this information is managed at the scene level. The mesh object attribute buffer IDs will simply reference a texture and material combination stored in the CScene ATTRIBUTE_ITEM array shown next.

```
    ATTRIBUTE_ITEM      m_pAttribCombo[MAX_ATTRIBUTES]; // Table of attribute combinations
    ULONG               m_nAttribCount;                 // Number of attributes.
```

The ATTRIBUTE_ITEM structure represents a unique texture/material pair. This allows us to batch subsets across mesh boundaries when they share the same attribute combination (used by non-managed meshes only).

```
typedef struct _ATTRIBUTE_ITEM
{
    long TextureIndex;          // Index into the texture array
    long MaterialIndex;         // Index into the material array
} ATTRIBUTE_ITEM;
```

When a matching attribute item is found during the mesh loading callback function for non-managed meshes, an index into this global array is returned and stored in the mesh attribute buffer. If a match was not found, a new ATTRIBUTE_ITEM is created and inserted into the list and its index returned. The global texture and material arrays are used to avoid resource duplication as mentioned previously (note that the ATTRIBUTE_ITEM members are indices into the scene global texture and material arrays).

Finally, the scene stores a default material that will be used for any faces that do not have a material explicitly assigned in the file.

```
    D3DMATERIAL9        m_DefaultMaterial;   // A plain white material for null cases.
};
```

Now that we have examined the CScene member variables, let us look at the member functions. We will try to do this in the approximate order that they would be called so that we can better understand how the scene is built.

CScene::LoadSceneFromIWF

This function manages the loading of IWF files from disk. We pass in the filename of the IWF file we wish to load (with absolute or relative path) as well as the device light limit and a count for reserved light slots for dynamic lights. This project will not use light groups so we can ignore the third parameter.

The first thing the function does is instantiate a CFileIWF object provided us by the IWF SDK. We then strip off the filename portion of the input string and store the path portion in the m_strDataPath member variable. This path will be used later to load textures that are stored in the same folder.

```
bool CScene::LoadSceneFromIWF(TCHAR *strFileName, ULONG LightLimit, ULONG ReservedCount  )
{
    CFileIWF File;

    // Retrieve the data path
    if ( m_strDataPath ) free( m_strDataPath );
    m_strDataPath = _tcsdup( strFileName );

    // Strip off the filename
    TCHAR * LastSlash = _tcsrchr( m_strDataPath, _T('\\') );
    if (!LastSlash) LastSlash = _tcsrchr( m_strDataPath, _T('/') );
    if (LastSlash) LastSlash[1] = _T('\0'); else m_strDataPath[0] = _T('\0');
```

The next step is loading the IWF file from disk using the CFileIWF::Load function.

```
    // File loading may throw an exception
    try
    {
        // Attempt to load the file
        File.Load( strFileName );
```

At this point, all of the meshes, materials, texture names, and entities have been loaded and are stored in a series of STL vectors internal to the CFileIWF object. We now record the input maximum light count in a scene member variable.

```
        // Store values
        m_nLightLimit     = LightLimit;
```

The remainder of the function calls the ProcessXX member functions to extract the stored data into application defined data types. The first two calls (ProcessMaterials/ProcessTextures) extract the scene materials and textures and store them in their respective global arrays.

Interestingly, the space scene IWF file that accompanies this demo does not contain material or texture information because it does not store any actual mesh data. Instead, all meshes are stored in the IWF file as external reference entities (X file names). The materials and texture names used by this scene will be stored in the referenced X files, so technically they do not need to be loaded for the IWF. However, we make the calls anyway to allow for scenes that do store such information. They simply load textures and materials stored in the CFileIWF object and add them to the scene texture and material arrays.

```
        // Process the materials and textures first (order is important)
        if (!ProcessMaterials( File )) return false;
        if (!ProcessTextures( File )) return false;
```

As you might expect, the same logic holds true for geometry data. Since the IWF file in this demo does not store any meshes, the function will actually wind up doing nothing, but we implement it anyway to allow for cases where mesh data is exported.

```
        // Process the pure mesh data
        if (!ProcessMeshes( File )) return false;
```

Now we are ready to parse the entities stored in the CFileIWF::m_vpEntityList. This job falls to the CScene::ProcessEntities function. While we have looked at this function in previous demos, its only responsibility was extracting scene lights. This time however, we have two new entity types that we will need to write code for: references and skyboxes. In this demo, our reference entities will contain the filename for the X file(s) we wish to load to create the actual meshes in the scene. The skybox entity will store a list of the six required textures required.

```
        // Copy over the entities we want from the file
        if (!ProcessEntities( File )) return false;
```

Now that we have extracted all of the information that was stored in the IWF file, we can release the memory used by the CFileIWF STL vectors.

```
        // Allow file loader to release any active objects
        File.ClearObjects();
```

If the m_nLightCount member variable is still set to 0 at this point, then the IWF file contained no lighting information. To ensure that we are able to see our objects in this case, we setup four default directional lights and add them to the scene light array. This is not something that you must do but we do it here for convenience.

```
        // If no lights were loaded, lets default some half-way decent ones
        if ( m_nLightCount == 0 )
        {
            // Set up an arbitrary set of directional lights
            ZeroMemory( m_pLightList, 4 * sizeof(D3DLIGHT9));
            m_pLightList[0].Type = D3DLIGHT_DIRECTIONAL;
            m_pLightList[0].Diffuse = D3DXCOLOR( 1.0f, 0.92f, 0.82f, 0.0f );
            m_pLightList[0].Specular = D3DXCOLOR( 1.0f, 0.92f, 0.82f, 0.0f );
            m_pLightList[0].Direction = D3DXVECTOR3( 0.819f, -0.573f, 0.0f );

            m_pLightList[1].Type = D3DLIGHT_DIRECTIONAL;
            m_pLightList[1].Diffuse = D3DXCOLOR( 0.4f, 0.4f, 0.4f, 0.0f );
            m_pLightList[1].Specular = D3DXCOLOR( 0.6f, 0.6f, 0.6f, 0.0f );
            m_pLightList[1].Direction = D3DXVECTOR3( -0.819f, -0.573f, -0.0f );

            m_pLightList[2].Type = D3DLIGHT_DIRECTIONAL;
            m_pLightList[2].Diffuse = D3DXCOLOR( 0.8f, 0.8f, 0.8f, 0.0f );
            m_pLightList[2].Specular = D3DXCOLOR( 0.0f, 0.0f, 0.0f, 0.0f );
            m_pLightList[2].Direction = D3DXVECTOR3( 0.0f, 0.707107f, -0.707107f );

            m_pLightList[3].Type = D3DLIGHT_DIRECTIONAL;
            m_pLightList[3].Diffuse = D3DXCOLOR( 0.6f, 0.6f, 0.6f, 0.0f );
            m_pLightList[3].Specular = D3DXCOLOR( 0.0f, 0.0f, 0.0f, 0.0f );
```

```
            m_pLightList[3].Direction = D3DXVECTOR3( 0.0f, 0.707107f, 0.707107f );

            // We're now using 4 lights
            m_nLightCount = 4;

        } // End if no lights

    } // End Try Block

    // Catch any exceptions
    catch (...)
    {
        return false;

    } // End Catch Block

    // Success!
    return true;
}
```

CScene::ProcessMaterials

This function (called by the CScene::LoadSceneFromIWF) loops through each material in the CFileIWF::m_vpMaterialList vector and copies the values into the scene material list. The internal material counter is incremented for each material copied.

```
bool CScene::ProcessMaterials( const CFileIWF& File )
{
    ULONG i;

    // Loop through and build our materials
    for ( i = 0; i < File.m_vpMaterialList.size(); i++ )
    {
        // Retrieve pointer to file material
        iwfMaterial * pFileMaterial = File.m_vpMaterialList[i];

        // Retrieve pointer to our local material
        D3DMATERIAL9 * pMaterial = &m_pMaterialList[i];

        // Copy over the data we need from the file material
        pMaterial->Diffuse  = (D3DCOLORVALUE&)pFileMaterial->Diffuse;
        pMaterial->Ambient  = (D3DCOLORVALUE&)pFileMaterial->Ambient;
        pMaterial->Emissive = (D3DCOLORVALUE&)pFileMaterial->Emissive;
        pMaterial->Specular = (D3DCOLORVALUE&)pFileMaterial->Specular;
        pMaterial->Power    = pFileMaterial->Power;

        // Increase internal vars
        m_nMaterialCount++;
        if ( m_nMaterialCount >= MAX_MATERIALS ) break;

    } // Next Material

    // Success!
    return true;
}
```

CScene::ProcessTextures

This function (called by CScene::LoadScene from IWF) loops through the CFileIWF::m_vpTextureList and uses the stored filenames to load the texture resources. This function does not need to worry about duplicates because IWF files only store unique texture filenames. As each texture is loaded, its IDirect3DTexture9 interface pointer and filename is stored in the scene objects m_pTextureList array.

The first thing we do is zero out the scene TEXTURE_ITEM array.

```
bool CScene::ProcessTextures( const CFileIWF& File )
{
    ULONG          i;
    TCHAR          Buffer[MAX_PATH];
    TEXTURE_ITEM * pNewTexture = NULL;

    ZeroMemory( m_pTextureList, m_nTextureCount * sizeof(TEXTURE_ITEM*));
```

Now we will loop through each TEXTURE_REF in m_vpTextureList. The TEXTURE_REF structure is defined in libIWF.h and contains the texture filename and possibly even the actual texture pixel data. We are interested only in the filename (and its string length) for now.

```
for ( i = 0; i < File.m_vpTextureList.size(); i++ )
    {
        // Retrieve pointer to file texture
        TEXTURE_REF * pFileTexture = File.m_vpTextureList[i];

        // Skip if this is an internal texture (not supported by this demo)
        if ( pFileTexture->TextureSource != TEXTURE_EXTERNAL ) continue;
```

As we have found a potentially valid texture, we will create a new TEXTURE_ITEM to store the filename and texture we are about to create. We add the item to the CScene::m_pTextureList array.

```
        // No texture found, lets create our texture data and store it
        pNewTexture = new TEXTURE_ITEM;
        ZeroMemory( pNewTexture, sizeof(TEXTURE_ITEM) );
```

The TEXTURE_REF structure stores only the filename and not the full path. This allows us to store the texture in any folder desired. We extracted the path information during the LoadSceneFromIWF function, so we can add the path string to the texture file name to get the full path for the texture for loading. We use D3DXCreateTextureFromFileEx to load the texture.

```
        // Now build the full path
        _tcscpy( Buffer, m_strDataPath );
        _tcscat( Buffer, pFileTexture->Name );

        // Create the texture (use 3 mip levels max) (Ignore error value)
        D3DXCreateTextureFromFileEx( m_pD3DDevice, Buffer, D3DX_DEFAULT, D3DX_DEFAULT, 3, 0,
                                     m_fmtTexture,D3DPOOL_MANAGED,D3DX_DEFAULT,D3DX_DEFAULT,
                                     0, NULL, NULL, &pNewTexture->Texture );
```

We copy the texture filename into the TEXURE_ITEM, add the structure to our global array, and then increment our counter.

```
        // Duplicate the filename for future lookups
        pNewTexture->FileName = _tcsdup( pFileTexture->Name );

        // Store this item
        m_pTextureList[ m_nTextureCount++ ] = pNewTexture;
        if ( m_nTextureCount >= MAX_TEXTURES ) break;

    } // Next Texture

    // Success!
    return true;
}
```

CScene::ProcessMeshes

ProcessMeshes extracts geometry from CFileIWF::m_vpMeshList and creates CTriMesh objects for each mesh. The m_vpMeshList vector contains one iwfMesh structure for each mesh extracted from the file (see libIWF.h).

```
bool CScene::ProcessMeshes( CFileIWF & pFile )
{
    HRESULT     hRet;
    CTriMesh * pNewMesh = NULL;
    long        i, j, MaterialIndex, TextureIndex;
    ULONG       AttribID = 0;

    // Loop through each mesh in the file
    for ( i = 0; i < pFile.m_vpMeshList.size(); i++ )
    {
        iwfMesh * pMesh = pFile.m_vpMeshList[i];

        // Allocate a new CTriMesh
        pNewMesh = new CTriMesh;
        if ( !pNewMesh ) return false;
```

We are going to populate mesh data buffers manually, so we need to tell the mesh about our vertex components and our index format so that it can properly allocate its vertex/index buffers. In this project, VERTEX_FVF is defined in CObject.h as:

```
#define VERTEX_FVF      D3DFVF_XYZ | D3DFVF_NORMAL | D3DFVF_TEX1
```

```
        // Set the mesh's data format
        pNewMesh->SetDataFormat( VERTEX_FVF, sizeof(USHORT) );
```

Now that we have created the CTriMesh, we can loop through each surface in the iwfMesh and add the geometry data. Note that we skip surfaces marked with the SURFACE_INVISIBLE flag.

```
        for ( j = 0; j < pMesh->SurfaceCount; j++ )
```

```
        {
            iwfSurface * pSurface = pMesh->Surfaces[j];

            // Skip if this surface is flagged as invisible
            if ( pSurface->Style & SURFACE_INVISIBLE ) continue;
```

First we extract the texture and material indices used by the face setting the indices to –1 if some error has occurred (e.g., the texture index has a larger value than the total number of textures stored in the IWF file). This would mean the IWF file has been created incorrectly. We do not halt execution but instead assign an idex of –1 indicating that the scene's default (white) material will need to be assigned to these faces.

```
           // Determine the indices we are using.
           MaterialIndex = -1;
           TextureIndex  = -1;
          if ( (pSurface->Components & SCOMPONENT_MATERIALS) && pSurface->ChannelCount > 0 )
             MaterialIndex = pSurface->MaterialIndices[0];

          if ( (pSurface->Components & SCOMPONENT_TEXTURES ) && pSurface->ChannelCount > 0 )
             TextureIndex  = pSurface->TextureIndices[0];

          if ( MaterialIndex >= m_nMaterialCount ) MaterialIndex = -1;
          if ( MaterialIndex >= m_nTextureCount  ) TextureIndex  = -1;
```

With the material and texture indices stored in temporary local variables (MaterialIndex and TextureIndex), we use them to get a pointer to the material in the scene material array and the texture filename for the texture stored in the scene texture array (shown below).

```
        LPCTSTR        strTextureFile = NULL;
        D3DMATERIAL9 * pMaterial      = NULL;

        // Retrieve information to pass to support functions
        if ( MaterialIndex >= 0 ) pMaterial = &m_pMaterialList[MaterialIndex];
        if ( TextureIndex  >= 0 ) strTextureFile = m_pTextureList[TextureIndex]->FileName;
```

Bear in mind when looking at the above code that when this function has been called, the ProcessMaterials and ProcessTextures function have already been executed. Therefore, all textures and materials stored inside the IWF file are already in the scene texture and material lists at this point. This means the texture and material index stored in each IWFSurface indexes correctly into the scene's texture and material arrays. This is because they will have been added to the scene in the same order as the materials and textures listed inside the IWF file. The texture and material indices stored in each IWFSurface are therefore still valid when used to access the scene textures and materials.

Now that we have a pointer to the material and the texture filename used by this face, we pass this information into the CScene::CollectAttributeID function. The function will look for a matching material/texture combination in its ATTRIBUTE_ITEM array and if one is not found, create a new entry, loading and creating any textures and materials as necessary. This is the same function that is used as a callback function for non-managed mode meshes when loading X file data.

The function returns the index of the ATTRIBUTE_ITEM which describes the global attribute ID that will be assigned to this face when it is added to the CTriMesh. Notice that we also pass in the 'this' pointer because CollectAttributeID is a static function.

```
        // Collect an attribute ID
        AttribID = CollectAttributeID( this, strTextureFile, pMaterial );
```

Now that we have the attribute index for this material/texture combination, we can add the face indices to the CTriMesh index buffer. For each triangle added (because this may be an N-gon), we also copy the attribute ID into the CTriMesh attribute buffer so that all triangles that share the same material and texture will belong to the same subset. This is all handled by the ProcessIndices function. We pass in a pointer to our new CTriMesh, a pointer to the iwfSurface that contains the index data for the face we wish to add, and the face attribute ID that we have just generated.

```
        // Process the indices
        if (!ProcessIndices( pNewMesh, pSurface, AttribID ) ) break;
```

If the surface has the SURFACE_TWO_SIDED flag set, then the level designer wants this surface to be visible from both its front and back sides. As our application uses back face culling, we add the face to the mesh again, this time passing in TRUE as the final parameter. This call reverses the winding order of the face before it adds it to the index buffer the second time. We have essentially created two polygons that share the same position in 3D space but face in opposing directions.

```
        if ( pSurface->Style & SURFACE_TWO_SIDED )
        {
            // Two sided surfaces have back faces added manually
            if (!ProcessIndices( pNewMesh, pSurface, AttribID, true ) ) break;
        }
```

Now we call ProcessVertices to add the vertex data to the new mesh.

```
           // Process vertices
           if (!ProcessVertices( pNewMesh, pSurface ) ) break;

    } // Next Surface
```

After the CScene::ProcessVertices and CScene::ProcesIndices have been called, the CTriMesh will have had all the vertex, index and attribute data added to its temporary storage bins.

If one of the processing functions failed, then the loop variable 'j' will be smaller than the surface count of the iwfMesh. If this is the case, then we release the new CTriMesh and return failure as we have data corruption.

```
        // If we didn't reach the end, then we failed
        if ( j < pMesh->SurfaceCount ) { delete pNewMesh; return false; }
```

We next instruct the CTriMesh object to build its underlying ID3DXMesh with a call to the CTriMesh::BuildMesh function. We pass in the D3DXMESH_MANAGED creation flag indicating our desire for allocating index and vertex buffers in the managed resource pool.

```
        // We're done, attempt to build this mesh
        hRet = pNewMesh->BuildMesh( D3DXMESH_MANAGED, m_pD3DDevice );
        if ( FAILED(hRet) ) { delete pNewMesh; return false; }
```

Next we clean and optimize the CTriMesh. We start with the CTriMesh::Weld function, passing in a 0.0 floating point tolerance so that only exact duplicated vertices are merged. Then we call the CTriMesh::OptimizeInPlace function to perform compaction, attribute sorting, and vertex cache optimizations on the underlying D3DXMesh data.

```
        // Optimize the mesh of possible
        pNewMesh->WeldVertices( 0 );
        pNewMesh->OptimizeInPlace( D3DXMESHOPT_VERTEXCACHE );
```

We now call the CScene::AddMesh() function, which is a simple utility function to resize the scene CTriMesh array (m_pMesh). This call returns the index of the newly added element, which we use to store the CTriMesh pointer to the mesh we have just created.

```
        // Store this new mesh
        if ( AddMesh( ) < 0 ) { delete pNewMesh; return false; }
        m_pMesh[ m_nMeshCount - 1 ] = pNewMesh;
```

Although we have added the mesh to the scene, we still require a higher level object to allow for mesh instancing, so we allocate a new CObject structure, passing our new mesh into the constructor. Note that while the CObject maintains a world matrix, meshes stored in IWF files exported from GILES™ are all defined in world space. So the CObject world matrix should just be set to identity, and this is done implicitly by the constructor.

```
        // Now build an object for this mesh (standard identity)
        CObject * pNewObject = new CObject( pNewMesh );
        if ( !pNewObject ) return false;
```

Finally, we add this new CObject to the scene level CObject array (m_pObject). The AddObject() member function resizes the array and returns the index where we will copy the pointer .

```
        // Store this object
        if ( AddObject() < 0 ) { delete pNewObject; return false; }
        m_pObject[ m_nObjectCount - 1 ] = pNewObject;

    } // Next Mesh

    // Success!!
    return true;
}
```

CScene::ProcessVertices

ProcessVertices is called by ProcessMeshes (discussed above) for each surface in the mesh. Its job is to add the vertices stored in the iwfSurface to the newly created CTriMesh object. Note that they are not copied straight into the vertex buffer because the ID3DXMesh will not have been created yet. Instead they are copied into the CTriMesh::pVertices array. Only after all vertices have been added and the underlying ID3DXMesh has been created will we fill the vertex buffer with this data.

```
bool CScene::ProcessVertices( CTriMesh * pMesh, iwfSurface * pFilePoly )
{
    ULONG i, VertexStart = pMesh->GetNumVertices();
    CVertex * pVertices = NULL;

    // Allocate enough vertices
    if ( pMesh->AddVertex( pFilePoly->VertexCount ) < 0 ) return false;
    pVertices = (CVertex*)pMesh->GetVertices();
```

We start by retrieving the number of vertices currently stored in the mesh. This tells us where we want to start appending our new vertex data. Next we call the CTriMesh::AddVertex function passing in the number of vertices in the iwfSurface. This function resizes the mesh's temporary vertex array if necessary to make room for the new data. We then get a pointer to the mesh vertex array so that we can start copying the vertex data.

```
    // Loop through each vertex and copy required data.
    for ( i = 0; i < pFilePoly->VertexCount; i++ )
    {
        // Copy over vertex data
        pVertices[i + VertexStart].x      = pFilePoly->Vertices[i].x;
        pVertices[i + VertexStart].y      = pFilePoly->Vertices[i].y;
        pVertices[i + VertexStart].z      = pFilePoly->Vertices[i].z;
        pVertices[i + VertexStart].Normal = (D3DXVECTOR3&)pFilePoly->Vertices[i].Normal;

        // If we have any texture coordinates, set them
        if ( pFilePoly->TexChannelCount > 0 && pFilePoly->TexCoordSize[0] == 2 )
        {
            pVertices[i + VertexStart].tu = pFilePoly->Vertices[i].TexCoords[0][0];
            pVertices[i + VertexStart].tv = pFilePoly->Vertices[i].TexCoords[0][1];
        } // End if has tex coordinates
    } // Next Vertex

    // Success!
    return true;
}
```

CScene::ProcessIndices

ProcessIndices remains relatively unchanged from our prior projects so we will only show the code that deals with face indices in indexed triangle list format. This means we simply copy the indices from the passed iwfSurface into the mesh. Please refer to Chapter Five for code that converts the other formats.

```
bool CScene::ProcessIndices( CTriMesh * pMesh, iwfSurface * pFilePoly,
                             ULONG AttribID, bool BackFace )
{
    ULONG    i, Counter, VertexStart, FaceStart, IndexStart;
    USHORT * pIndices = NULL;

    // Validate parameters
    if (!pMesh || !pFilePoly) return false;
```

Before we add indices to the new CTriMesh object, we need to retrieve the mesh vertex count so that we can correctly offset the zero-based index values. Keep in mind that this function is called before the vertices are processed, so if we did not do this, regardless of how many vertices we added, each triangle would refernce the first three vertices. We also also fetch the number of triangles currently stored in the CTriMesh so that we can correctly calculate the offset in the mesh index array for appending the new indices.

```
    // Store current Mesh vertex and face count
    VertexStart = pMesh->GetNumVertices();
    FaceStart   = pMesh->GetNumFaces();
    IndexStart  = FaceStart * 3;
```

If the iwfSurface has a non-zero index count then the face includes indices. If not, then the function will need to generate indices for the appropriate polygon type (see Chapter Five). All we have to do for the current case we are looking at is copy the index data.

```
    // Generate indices
    if ( pFilePoly->IndexCount > 0 )
    {
        ULONG IndexType = pFilePoly->IndexFlags & INDICES_MASK_TYPE;

        // Interpret indices (we want them in tri-list format)
        switch ( IndexType )
        {
             case INDICES_TRILIST:

                // We can do a straight copy (converting from 32bit to 16bit)
                if ( pMesh->AddFace( pFilePoly->IndexCount / 3, NULL, AttribID ) < 0 )
                       return false;

                pIndices = (USHORT*)pMesh->GetFaces( );

                // Copy over the face data
                for ( i = 0; i < pFilePoly->IndexCount; ++i )
                       pIndices[i + IndexStart] = pFilePoly->Indices[i] + VertexStart;

             break;
```

After the indices have been added, we test the BackFace Boolean passed into the function. If TRUE, then we need to reverse the order of the indices just added and re-copy them. This approach is used when we encounter a two sided face in the IWF file.

```
  // We now have support for adding the same polygon again, but in
  // reverse order to add a renderable back face if disabling culling
  // is not a viable option.
  if ( BackFace == true )
  {
        // If we specified back faces, invert all the indices recently added
               pIndices  = (USHORT*)pMesh->GetFaces( );
        for ( i = IndexStart; i < pMesh->GetNumFaces() * 3; i+=3 )
        {
               USHORT iTemp  = pIndices[i];
               pIndices[i]   = pIndices[i+2];
               pIndices[i+2] = iTemp;

        } // Next Tri

  } // End if back face

    // Success!
    return true;
}
```

CScene::CollectAttributeID

This function is called from two possible places. CTriMesh::LoadMeshFromX calls it to process a material/texture combination extracted from an X file. CScene::ProcessMeshes calls it to process a material/texture combination used by an iwfSurface. The function is responsible for making sure that textures and materials are not duplicated and it returns the global attribute ID for subsets in non-managed meshes.

The first parameter is a void pointer to a context. Remember that this function was declared as a static member function so that it can double as a callback function for non-managed mode meshes when needed. We use the context parameter in the ProcessMeshes function to pass the ‘this’ pointer so that there can be access to non-static member variables. The next three parameters are what we will match against when searching for the appropriate combination of attributes.

```
ULONG CScene::CollectAttributeID( LPVOID pContext, LPCTSTR strTextureFile,
                                  const D3DMATERIAL9 * pMaterial,
                                  const D3DXEFFECTINSTANCE * pEffectInstance )
{
    TEXTURE_ITEM * pNewTexture = NULL;
    ULONG          i;
    long           TextureMatch = -1, MaterialMatch = -1;
    bool           TexMatched = false, MatMatched = false;

    // Validate parameters
    if ( !pContext ) return 0;

    // Retrieve the scene object
    CScene *pScene = (CScene*)pContext;
```

We cast the context pointer to a CScene pointer so that we have access to the texture and materials arrays for the correct scene object instance. We can now loop through the scene ATTRIBUTE_ITEM array to see if an element with the passed texture/material combination already exists. The process should be relatively easy to follow, so we will not explain it in great detail. We start by checking texture filenames and then the material pointers.

```
    // Loop through the attribute combination table to see if one already exists
    for ( i = 0; i < pScene->m_nAttribCount; ++i )
    {
        ATTRIBUTE_ITEM * pAtrItem = &pScene->m_pAttribCombo[i];
        long TextureIndex  = pAtrItem->TextureIndex;
        long MaterialIndex = pAtrItem->MaterialIndex;

        TEXTURE_ITEM   * pTexItem = NULL;
        D3DMATERIAL9   * pMatItem = NULL;

        // Retrieve pointers
        if ( TextureIndex  >= 0 ) pTexItem = pScene->m_pTextureList[ TextureIndex ];
        if ( MaterialIndex >= 0 ) pMatItem = &pScene->m_pMaterialList[ MaterialIndex ];

        // Neither are matched so far
        TexMatched = false;
        MatMatched = false;

        // If both sets are NULL, this is a match, otherwise perform the real match
        if ( pTexItem == NULL && strTextureFile == NULL )
            TexMatched = true;

        else if ( pTexItem != NULL && strTextureFile != NULL )
        if ( _tcsicmp( pTexItem->FileName, strTextureFile ) == 0 ) TexMatched = true;

        if ( pMatItem == NULL && pMaterial == NULL )
            MatMatched = true;
        else if ( pMatItem != NULL && pMaterial != NULL )

        if ( memcmp( pMaterial, pMatItem, sizeof(D3DMATERIAL9) ) == 0 ) MatMatched = true;

        // Store the matched indices in case we can use the later on
        if ( TexMatched ) TextureMatch = TextureIndex;
        if ( MatMatched ) MaterialMatch = MaterialIndex;
```

If we have both a texture match and a material match, then we return the index of this attribute item to the caller. The CTriMesh::LoadMeshFromX function uses this index to remap its attribute buffer from mesh local attribute IDs to scene attribute IDs.

```
        // If they both matched up at the same time, we have a winner
        if ( TexMatched == true && MatMatched == true ) return i;

    } // Next Attribute
```

If we cannot find a match on both parameters (texture and material), then we will need to add a new ATTRIBUTE_ITEM structure to the scene array reflecting these attribute properties. We want to look

for individual matches on texture or material first to avoid duplicating data, so we will traverse those arrays again and record the index of the matches if we find them.

```
    ATTRIBUTE_ITEM AttribItem;

    if ( MaterialMatch < 0 && pMaterial != NULL )
    {
        for ( i = 0; i < pScene->m_nMaterialCount; ++i )
        {
            // Is there a match ?
            if ( memcmp( pMaterial, &pScene->m_pMaterialList[i], sizeof(D3DMATERIAL9)) == 0 )
                 MaterialMatch = i;

            // If we found a match, bail
            if ( MaterialMatch >= 0 ) break;

        } // Next Attribute Combination

    } // End if no material match

    if ( TextureMatch < 0 && strTextureFile != NULL )
    {
        for ( i = 0; i < pScene->m_nTextureCount; ++i )
        {
            if (!pScene->m_pTextureList[i] || !pScene->m_pTextureList[i]->FileName) continue;

            // Is there a match ?
            if ( _tcsicmp( strTextureFile, pScene->m_pTextureList[i]->FileName ) == 0 )
                 TextureMatch = i;

            // If we found a match, bail
            if ( TextureMatch >= 0 ) break;

        } // Next texture

    } // End if no Texture match
```

If matches are found (for either type), we simply copy the index value from the local variable into the new ATTRIBUTE_ITEM. When a match is not found, we must load the data into our global lists and record those indices instead. Materials will simply be copied, textures will require loading.

```
    // Now build the material index, or add if necessary
    if ( MaterialMatch < 0 && pMaterial != NULL )
    {
        AttribItem.MaterialIndex = pScene->m_nMaterialCount;
        pScene->m_pMaterialList[ pScene->m_nMaterialCount++ ] = *pMaterial;
    } // End if no material match
    else
    {
        AttribItem.MaterialIndex = MaterialMatch;
    } // End if material match
```

If a matching texture was not found in the scene texture array then we need to create a new texture with a call to the CollectTexture function. This function (also used as the texture callback function for managed mode meshes in the CTriMesh::LoadMeshFromX function) will load the texture if it does not yet exist

and will add it to the end of the scene texture array. If a texture was found, we copy this index into the attribute item structure as shown below.

```
    // Now build the texture index, or add if necessary
    if ( TextureMatch < 0 && strTextureFile != NULL )
    {
        // We know it doesn't exist, but we can still use
        // collect texture to do the work for us.
        AttribItem.TextureIndex = pScene->m_nTextureCount;
        CollectTexture( pScene, strTextureFile );

    } // End if no texture match
    else
    {
        AttribItem.TextureIndex = TextureMatch;

    } // End if Texture match
```

Finally, we add the new item to the scene m_pAttribCombo array and return the index of this new attribute.

```
    // Store this new attribute combination item
    pScene->m_pAttribCombo[ pScene->m_nAttribCount++ ] = AttribItem;

    // Return the new attribute index
    return pScene->m_nAttribCount - 1;
}
```

CScene::CollectTexture

This function searches the scene texture array to determine whether a texture with the passed texture filename already exists. If so, a pointer to this texture item is returned. Otherwise, a new texture is created, inserted into the array, and its pointer is returned.

CollectTexture is called from a number of places in our code. If we wish to load mesh data from an X file into a managed mode CTriMesh, we can register this function as the texture callback so that texture filenames returned from D3DXLoadMeshFromX can be mapped to textures in our scene texture array. The CollectAttributeID function, which can serve as a callback for non-managed meshes, calls this function to load its textures as well. We have just seen how ProcessMeshes calls the CollectAttributeID function (which in turn calls CollectTexture) to add the textures in an IWF file to the scene texture list.

```
LPDIRECT3DTEXTURE9 CScene::CollectTexture( LPVOID pContext, LPCTSTR FileName )
{
    HRESULT        hRet;
    TEXTURE_ITEM * pNewTexture = NULL;

    // Validate parameters
    if ( !pContext || !FileName ) return NULL;

    // Retrieve the scene object
```

```
    CScene *pScene = (CScene*)pContext;
```

Once we have a pointer to the scene instance, we can loop through its texture array and compare each texture name with the texture name passed into the function. If a match is found then the texture already exists and we immediately return a pointer to the texture.

```
    // Loop through and see if this texture already exists.
    for ( ULONG i = 0; i < pScene->m_nTextureCount; ++i )
    {
        if ( _tcsicmp( pScene->m_pTextureList[i]->FileName, FileName ) == 0 )
            return pScene->m_pTextureList[i]->Texture;

    } // Next Texture
```

If we exit the loop, then we know that a texture with a matching filename does not yet exist. Therefore, we need to create and initialize a new TEXTURE_ITEM structure that will be added to the texture array. Note that the texture filename passed into the function will not contain any path information. So in order to load the image file into a texture, we build the complete filename string with the full path. We will store the texture filename without a path in the TEXTURE_ITEM structure for future searches.

```
    // No texture found, so lets create and store it.
    pNewTexture = new TEXTURE_ITEM;
    if (!pNewTexture) return NULL;
    ZeroMemory( pNewTexture, sizeof(TEXTURE_ITEM) );

    // Build filename string
    TCHAR Buffer[MAX_PATH];
    _tcscpy( Buffer, pScene->m_strDataPath );
    _tcscat( Buffer, FileName);

    // Create the texture (use 3 mip levels max)
    hRet = D3DXCreateTextureFromFileEx(pScene->m_pD3DDevice, Buffer, D3DX_DEFAULT,
                                       D3DX_DEFAULT, 3, 0, pScene->m_fmtTexture,
                                       D3DPOOL_MANAGED, D3DX_DEFAULT, D3DX_DEFAULT,
                                       0, NULL, NULL, &pNewTexture->Texture );

    if (FAILED(hRet)) { delete pNewTexture; return NULL; }

    // Duplicate the filename for future lookups
    pNewTexture->FileName = _tcsdup( FileName );
```

Finally we add the new TEXTURE_ITEM to the scene array, increment the texture count, and return the new texture pointer.

```
    // Store this item
    pScene->m_pTextureList[ pScene->m_nTextureCount++ ] = pNewTexture;

    // Return the texture pointer
    return pNewTexture->Texture;
}
```

CScene::ProcessEntities

Our current project will support three different entity types: lights, skyboxes, and references. This function is responsible for navigating the CFileIWF::m_vpEntityList vector and extracting these types as they are encountered.

The first part of the function tests for light entities. The light entity is one of the IWF standard entity types and it is defined in the IWF SDK as an entity with an ID of 16:

```
#define ENTITY_LIGHT                        0x0010
```

```
bool CScene::ProcessEntities( const CFileIWF& File )
{
    ULONG      i, j;
    D3DLIGHT9  Light;
    USHORT     StringLength;
    bool       SkyBoxBuilt = false;

    // Loop through and build our lights & references
    for ( i = 0; i < File.m_vpEntityList.size(); i++ )
    {
        // Retrieve pointer to file entity
        iwfEntity * pFileEntity = File.m_vpEntityList[i];

        // Skip if there is no data
        if ( pFileEntity->DataSize == 0 ) continue;
```

We will extract light information from the entity data area directly into a D3DLIGHT9 structure and add the new light to our scene light array. In this project we will only process the light if we have not yet added the maximum number of lights to the array, otherwise it will be ignored.

```
        // Decide what to do here (skip all lights if we've already reached our limit)
        if ( (m_nLightCount < m_nLightLimit && m_nLightCount < MAX_LIGHTS)
              && pFileEntity->EntityTypeMatches( ENTITY_LIGHT ) )
        {
            LIGHTENTITY * pFileLight = (LIGHTENTITY*)pFileEntity->DataArea;
```

GILES™ can export ambient lights, but they are not particularly relevant in the DirectX lighting pipeline, so if the current light is an ambient light we will skip it

```
            // Skip if this is not a valid light type (Not relevant to the API)
            if ( pFileLight->LightType == LIGHTTYPE_AMBIENT ) continue;
```

Extracting the lighting information is very simple due to the fact that the LIGHTENTITY structure used by CFileIWF is almost identical to the D3DLIGHT9 structure.

```
            // Extract the light values we need
            Light.Type      = (D3DLIGHTTYPE)(pFileLight->LightType + 1);
            Light.Diffuse   = D3DXCOLOR(pFileLight->DiffuseRed, pFileLight->DiffuseGreen,
                                        pFileLight->DiffuseBlue, pFileLight->DiffuseAlpha);
```

```
            Light.Ambient   = D3DXCOLOR (pFileLight->AmbientRed, pFileLight->AmbientGreen,
                                         pFileLight->AmbientBlue, pFileLight->AmbientAlpha);

            Light.Specular  = D3DXCOLOR (pFileLight->SpecularRed, pFileLight->SpecularGreen,
                                         pFileLight->SpecularBlue,pFileLight->SpecularAlpha);
```

Every entity stores a world matrix, so we extract the bottom row to get the light position in world space.

```
            Light.Position  = D3DXVECTOR3(pFileEntity->ObjectMatrix._41,
                                          pFileEntity->ObjectMatrix._42,
                                          pFileEntity->ObjectMatrix._43 );
```

We also extract the look vector which describes the direction the light is pointing in world space.

```
            Light.Direction  = D3DXVECTOR3(pFileEntity->ObjectMatrix._31,
                                           pFileEntity->ObjectMatrix._32,
                                           pFileEntity->ObjectMatrix._33 );
```

The remaining light data is extracted and we add the light to our light array, incrementing the counter.

```
            Light.Range            = pFileLight->Range;
            Light.Attenuation0     = pFileLight->Attenuation0;
            Light.Attenuation1     = pFileLight->Attenuation1;
            Light.Attenuation2     = pFileLight->Attenuation2;
            Light.Falloff          = pFileLight->FallOff;
            Light.Theta            = pFileLight->Theta;
            Light.Phi              = pFileLight->Phi;

            // Add this to our array
            m_pLightList[ m_nLightCount++ ] = Light;

        } // End if light
```

Testing for skyboxes and reference entities requires a slightly different approach because these types are not defined by the IWF standard -- they are custom entity types defined by GILES™. The IWF specification provides applications the ability to specify their own entity types with their own entity IDs and chunk IDs provided they do not conflict with IDs reserved by the IWF standard.

To address the possibility of third party entities sharing the same IDs with each other, the IWF specification records an author ID in addition to the entity chunk IDs. For example, the skybox and reference entities both have the author ID for GILES™ embedded in those chunks. GILES™ uses a 5 BYTE author ID embedded in its custom chunks. Each byte is the ASCII code for the letters of its name. We define this array in CScene.cpp and we can use it to test if an entity is a custom GILES™ entity.

```
const UCHAR AuthorID[5] = { 'G', 'I', 'L', 'E', 'S' };
```

The iwfEntity class contains a helper function called EntityAuthorMatches. We pass in an array length and an array of bytes which will be compared against the entity's author ID, returning true if they match.

If the entity is not a light entity or a GILES™ custom entity (skybox/reference) we will ignore it.

```
        else if ( pFileEntity->EntityAuthorMatches( 5, AuthorID ) )
        {
```

At this point we do not know if this will be a skybox entity of a reference entity, so we will create two local variables that can be used to hold the information for both.

```
            SkyBoxEntity SkyBox;
            ZeroMemory( &SkyBox, sizeof(SkyBoxEntity) );

            ReferenceEntity Reference;
            ZeroMemory( &Reference, sizeof(ReferenceEntity ));
```

The SkyBoxEntity and ReferenceEntity structures are both defined in CScene.h.

```
typedef struct _ReferenceEntity
{
    ULONG       ReferenceType;          // What type of reference is this
    ULONG       Flags;                  // Reserved flags
    ULONG       Reserved1;              // Reserved values
    ULONG       Reserved2;              // Reserved values
    ULONG       Reserved3;              // Reserved values
    char        ReferenceName[1024];    // External file name

} ReferenceEntity;
```

The entity ID for the GILES™ reference entity is 0x203 (CScene.h).

```
#define CUSTOM_ENTITY_REFERENCE 0x203
```

Most of the members of the reference entity are reserved for later use. We are interested only in the reference type (0 for internal reference, 1 for external reference) and the ReferenceName. In this project we will work with external references only. The name of the referenced X file will be stored in the ReferenceName member.

The skybox entity stores a reserved DWORD followed by six texture filenames. When our application encounters one of these entities, we create the scene skybox mesh (m_SkyBoxMesh) as an inward facing cube, and then load the six textures using these filenames and map them to the cube faces.

```
typedef struct _SkyBoxEntity
{
    ULONG       Flags;                  // Reserved flags
    char        Textures[6][256];       // 6 Sets of external texture names
} SkyBoxEntity;
```

The entity ID for the GILES™ skybox entity is 0x202 (CScene.h).

```
#define CUSTOM_ENTITY_SKYBOX    0x202
```

To determine which entity type we have found, we retrieve a pointer to the entity data area and check its ID.

```
            // Retrieve data area
            UCHAR * pEntityData = pFileEntity->DataArea;
```

If it is a GILES™ reference entity then we extract the data into the temporary ReferenceEntity structure and pass it to CScene::ProcessReference for additional processing. Notice that the ProcessReference function accepts the ReferenceEntity and the entity world matrix. This matrix stores the world space position and orientation of the object that will ultimately be added to the scene for this reference. Every IWF entity contains a matrix describing the position and orientation of the entity in the scene. The following code shows how to extract all the entity information and pass it along to the ProcessReference function.

```
            switch ( pFileEntity->EntityTypeID )
            {
                case CUSTOM_ENTITY_REFERENCE:

                    // Copy over the the reference data
                    memcpy( &Reference.ReferenceType, pEntityData, sizeof(ULONG) );
                    pEntityData += sizeof(ULONG);

                    memcpy( &Reference.Flags, pEntityData, sizeof(ULONG) );
                    pEntityData += sizeof(ULONG);

                    memcpy( &StringLength, pEntityData, sizeof(USHORT) );
                    pEntityData += sizeof(USHORT);

                    if ( StringLength > 0 )
                       memcpy( Reference.ReferenceName, pEntityData, StringLength );
                    pEntityData += StringLength;

                    memcpy( &Reference.Reserved1, pEntityData, sizeof(ULONG) );
                    pEntityData += sizeof(ULONG);

                    memcpy( &Reference.Reserved2, pEntityData, sizeof(ULONG) );
                    pEntityData += sizeof(ULONG);

                    memcpy( &Reference.Reserved3, pEntityData, sizeof(ULONG) );
                    pEntityData += sizeof(ULONG);

                    // Process this reference (returns false only on fatal error)
                    if(!ProcessReference(Reference,(D3DXMATRIX&)pFileEntity->ObjectMatrix))
                        return false;

                    break;
```

For skybox entities we use a similar approach. We copy the data into the temporary SkyBoxEntity structure and pass it to ProcessSkyBox for final processing. Note that we only process the sky box entity if a sky box does not currently exist. This was done for simplicity only, so feel free to change this behavior to maintain an array of skyboxes that can be modified as you wish. Usually, a given scene will have one sky box defined, but this is not always necessarily the case.

```
                case CUSTOM_ENTITY_SKYBOX:
```

```
                    // We only want one skybox per file please! :)
                    if ( SkyBoxBuilt == true ) break;
                    SkyBoxBuilt = true;

                    // Copy over the skybox data
                    memcpy( &SkyBox.Flags, pEntityData, sizeof(ULONG) );
                    pEntityData += sizeof(ULONG);

                    // Read each of the 6 face textures
                    for ( j = 0; j < 6; ++j )
                    {
                        memcpy( &StringLength, pEntityData, sizeof(USHORT) );
                        pEntityData += sizeof(USHORT);

                        if ( StringLength > 0 )
                          memcpy( SkyBox.Textures[j], pEntityData, StringLength );
                        pEntityData += StringLength;

                    } // Next Face Texture

                    // Process this skybox (returns false only on a fatal error)
                    if ( !ProcessSkyBox( SkyBox ) ) return false;

                    break;

            } // End Entity Type Switch

        } // End if custom entities

    } // Next Entity

    // Success!
    return true;
}
```

CScene::ProcessReference

As mentioned previously, the space scene for this project stores all scene objects except for the skybox as external reference entities. These entities contain a world matrix and the filename for an X file which the object will use as its mesh.

The first thing this function does is check the scene mesh array to see if the mesh has already been loaded. This is done because there may be many reference entities which reference the same X file and we would prefer to avoid duplication, to keep memory footprint as small as possible. If the mesh already exists, then we will simply create a new CObject, instance the CTriMesh pointer, and then use the reference matrix for the object's world matrix. If the mesh does not currently exist, then we will need to create a new CTriMesh object and load the mesh data from the X file using the CTriMesh::LoadMeshFromX function, passing in the file name stored in the reference. It is in this function that we will see, for the first time, the registration of callback functions with the CTriMesh object. As discussed, these functions will automatically add the texture and materials in the X file to the scene level texture and material arrays.

The first thing the code does is test the ReferenceType member of the entity. If it is not set to 1 then this is an internal reference and we will ignore this entity and return. If it is set to 0, then we have an external reference, so we will build the full path and filename for the referenced X file (the reference entity will not contain any path information, only the name of the file).

```
bool CScene::ProcessReference(const ReferenceEntity& Reference, const D3DXMATRIX & mtxWorld)
{
    HRESULT     hRet;
    CTriMesh * pReferenceMesh = NULL;

    if (Reference.ReferenceType != 1) return true;

    // Build filename string
    TCHAR Buffer[MAX_PATH];
    _tcscpy( Buffer, m_strDataPath );
    _tcscat( Buffer, Reference.ReferenceName );
```

We now search the scene mesh array for a mesh with the same name as the file name. If a match is found, we will store a pointer to this matching mesh for now.

```
    // Search to see if this X file has already been loaded
    for ( ULONG i = 0; i < m_nMeshCount; ++i )
    {
        if (!m_pMesh[i]) continue;
        if ( _tcsicmp( Buffer, m_pMesh[i]->GetMeshName() ) == 0 ) break;
        } // Next Mesh

    // If we didn't reach the end, this mesh already exists
    if ( i != m_nMeshCount )
    {
        // Store reference mesh.
        pReferenceMesh = m_pMesh[i];

    } // End if mesh already exists
```

If the mesh is not already loaded then we will need to create a new CTriMesh object and call its LoadMeshFromX function to load the X file data into the mesh. Before we do that though, we register the CScene::CollectAttributeID function, which automatically places the mesh into non-managed mode. When the mesh loads the X file data, each texture and material loaded from the X file will be passed to the CollectAttributeID function. We saw earlier how this function adds the texture and material to the scene texture and material arrays and returns the index for this texture/material combo back to the mesh. The mesh will then use this index to remap its attribute buffer.

```
    else
    {
        // Allocate a new mesh for this reference
        CTriMesh * pNewMesh = new CTriMesh;

        // Load in the externally referenced X File
        pNewMesh->RegisterCallback(CTriMesh::CALLBACK_ATTRIBUTEID, CollectAttributeID, this);
        pNewMesh->LoadMeshFromX( Buffer, D3DXMESH_MANAGED, m_pD3DDevice );
```

Once the mesh is loaded, we weld its vertices and perform an in-place vertex cache optimimzation. This performs the attribute sort as well.

```
        // Attempt to optimize the mesh
        pNewMesh->WeldVertices( 0 );
        pNewMesh->OptimizeInPlace( D3DXMESHOPT_VERTEXCACHE );
```

We call the CScene::AddMesh function to make room for the new mesh in the scene mesh array and add the new mesh pointer to the end of the list.

```
        // Store this new mesh
        if ( AddMesh( ) < 0 ) { delete pNewMesh; return false; }
        m_pMesh[ m_nMeshCount - 1 ] = pNewMesh;

        // Store as object reference mesh
        pReferenceMesh = pNewMesh;

    } // End if mesh doesn't exist.
```

To position the mesh in the scene, we create a new CObject and store the mesh pointer and the entity world matrix inside the newly allocated CObject structure. The object is added to our global list and the function is complete. The CScene::AddObject function is very much like the CScene::AddMesh function in that it resizes the scene's CObject array making room for a new entry at the end.

```
    // Now build an object for this mesh (standard identity)
    CObject * pNewObject = new CObject( pReferenceMesh );
    if ( !pNewObject ) return false;

    // Copy over the specified matrix
    pNewObject->m_mtxWorld = mtxWorld;

    // Store this object
    if ( AddObject() < 0 ) { delete pNewObject; return false; }
    m_pObject[ m_nObjectCount - 1 ] = pNewObject;

    // Success!!
    return true;
}
```

CScene::ProcessSkyBox

ProcessSkyBox (called by CScene::ProcessEntities) adds six cube faces (12 triangles) to the scene skybox mesh and loads the six textures whose names are stored in the skybox entity passed into the function. This function provides some useful insight into populating a CTriMesh manually. It also demonstrates creation of a managed-mode mesh.

When we wish to create a managed-mode mesh from X file data, we would normally register the CollectTexture callback with the mesh so that the mesh loading function can pass the texture filenames found in the X file to the function and get back texture pointers for its own internal storage. The

managed mesh stores the texture pointer along with the matching material for each of its subsets in its internal attribute data array. In this particular case (skybox) we will not be loading the data from an X file, so we will not need to register the callback. We will manually add the texture and material information for each mesh subset to the mesh's internal attribute array ourselves.

The first thing we need to do is call CTriMesh::SetDataFormat to tell the mesh about our desired vertex/index formats. Because we will be adding vertices and indices to the cube mesh one face at a time (i.e. two triangles at a time) each cube face will consist of 4 vertices and 6 indices. We will use two temporary arrays, an index array and a vertex array, to build the cube faces as we go along. The front face case is examined first.

```
bool CScene::ProcessSkyBox( const SkyBoxEntity & SkyBox )
{
    MESH_ATTRIB_DATA * pAttribData;
    USHORT             Indices[6];
    CVertex            Vertices[4];

    // Set the mesh data format
    m_SkyBoxMesh.SetDataFormat( VERTEX_FVF, sizeof(USHORT) );

    // Build Front quad (remember all quads point inward)
    Vertices[0] = CVertex(-10.0f, 10.0f, 10.0f, D3DXVECTOR3(0.0f, 0.0f, 0.0f), 0.0f, 0.0f);
    Vertices[1] = CVertex( 10.0f, 10.0f, 10.0f, D3DXVECTOR3(0.0f, 0.0f, 0.0f), 1.0f, 0.0f);
    Vertices[2] = CVertex( 10.0f,-10.0f, 10.0f, D3DXVECTOR3(0.0f, 0.0f, 0.0f), 1.0f, 1.0f);
    Vertices[3] = CVertex(-10.0f,-10.0f, 10.0f, D3DXVECTOR3(0.0f, 0.0f, 0.0f), 0.0f, 1.0f);

    // Build the skybox indices
    Indices[0] = 0; Indices[1] = 1; Indices[2] = 3;
    Indices[3] = 1; Indices[4] = 2; Indices[5] = 3;
```

To add the indices and vertices for the quads to the mesh we call the AddVertex and AddFace functions. Notice that we are adding 2 triangles for the face and that we pass in an attribute ID of 0. Since each quad will have a different texture mapped to it, each will belong to a different subset. We will incremement this attribute ID for each quad that we add, such that the front face has an attribute ID of 0, the back face has an attribute ID of 1, and so on. The resulting mesh of the cube will contain 12 triangles and six subsets. Each subset represents one cube face and contains two triangles.

```
    // Add the vertices and indices to this mesh
    m_SkyBoxMesh.AddVertex( 4, &Vertices );
    m_SkyBoxMesh.AddFace( 2, Indices, 0 );
```

We repeat the process for the remaining five faces of the cube. Keep in mind when examining the vertex data that these cube faces are inward facing, so the vertex winding order will reflect this fact. Note as well that the zero length normal may seem strange, but the skybox will be rendered with lighting disabled anyway so the normal information will not be used. This allows us to use the same vertex flags for the skybox as the rest of the objects in our scene. Thus, we avoid calling IDirect3DDevice9::SetFVF in the scene's main render function to change vertex formats every time we render the skybox. Alternatively, you can use a vertex format with position and UV coordinates only if you prefer.

```
    // Back Quad
    Vertices[0] = CVertex( 10.0f, 10.0f,-10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 0.0f, 0.0f );
    Vertices[1] = CVertex(-10.0f, 10.0f,-10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 1.0f, 0.0f );
    Vertices[2] = CVertex(-10.0f,-10.0f,-10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 1.0f, 1.0f );
    Vertices[3] = CVertex( 10.0f,-10.0f,-10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 0.0f, 1.0f );

    // Build the skybox indices
    Indices[0] = 4; Indices[1] = 5; Indices[2] = 7;
    Indices[3] = 5; Indices[4] = 6; Indices[5] = 7;

    // Add the vertices and indices to this mesh
    m_SkyBoxMesh.AddVertex( 4, &Vertices );
    m_SkyBoxMesh.AddFace( 2, Indices, 1 );

    // Left Quad
    Vertices[0] = CVertex(-10.0f, 10.0f,-10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 0.0f, 0.0f );
    Vertices[1] = CVertex(-10.0f, 10.0f, 10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 1.0f, 0.0f );
    Vertices[2] = CVertex(-10.0f,-10.0f, 10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 1.0f, 1.0f );
    Vertices[3] = CVertex(-10.0f,-10.0f,-10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 0.0f, 1.0f );

    // Build the skybox indices
    Indices[0] = 8; Indices[1] = 9; Indices[2] = 11;
    Indices[3] = 9; Indices[4] = 10; Indices[5] = 11;

    // Add the vertices and indices to this mesh
    m_SkyBoxMesh.AddVertex( 4, &Vertices );
    m_SkyBoxMesh.AddFace( 2, Indices, 2 );

    // Right Quad
    Vertices[0] = CVertex( 10.0f, 10.0f, 10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 0.0f, 0.0f );
    Vertices[1] = CVertex( 10.0f, 10.0f,-10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 1.0f, 0.0f );
    Vertices[2] = CVertex( 10.0f,-10.0f,-10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 1.0f, 1.0f );
    Vertices[3] = CVertex( 10.0f,-10.0f, 10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 0.0f, 1.0f );

    // Build the skybox indices
    Indices[0] = 12; Indices[1] = 13; Indices[2] = 15;
    Indices[3] = 13; Indices[4] = 14; Indices[5] = 15;

    // Add the vertices and indices to this mesh
    m_SkyBoxMesh.AddVertex( 4, &Vertices );
    m_SkyBoxMesh.AddFace( 2, Indices, 3 );

    // Top Quad
    Vertices[0] = CVertex(-10.0f, 10.0f,-10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 0.0f, 0.0f );
    Vertices[1] = CVertex( 10.0f, 10.0f -10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 1.0f, 0.0f );
    Vertices[2] = CVertex( 10.0f, 10.0f, 10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 1.0f, 1.0f );
    Vertices[3] = CVertex(-10.0f, 10.0f, 10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 0.0f, 1.0f );

    // Build the skybox indices
    Indices[0] = 16; Indices[1] = 17; Indices[2] = 19;
    Indices[3] = 17; Indices[4] = 18; Indices[5] = 19;

    // Add the vertices and indices to this mesh
    m_SkyBoxMesh.AddVertex( 4, &Vertices );
    m_SkyBoxMesh.AddFace( 2, Indices, 4 );
    // Bottom Quad
    Vertices[0] = CVertex(-10.0f,-10.0f, 10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 0.0f, 0.0f );
    Vertices[1] = CVertex( 10.0f,-10.0f, 10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 1.0f, 0.0f );
    Vertices[2] = CVertex( 10.0f,-10.0f,-10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 1.0f, 1.0f );
```

```
    Vertices[3] = CVertex(-10.0f,-10.0f,-10.0f, D3DXVECTOR3( 0.0f, 0.0f, 0.0f), 0.0f, 1.0f );

    // Build the skybox indices
    Indices[0] = 20; Indices[1] = 21; Indices[2] = 23;
    Indices[3] = 21; Indices[4] = 22; Indices[5] = 23;

    // Add the vertices and indices to this mesh
    m_SkyBoxMesh.AddVertex( 4, &Vertices );
    m_SkyBoxMesh.AddFace( 2, Indices, 5 );
```

At this point the skybox mesh contains the six quads (12 triangles) needed and has an attribute buffer with values ranging from 0 to 5. Thus we have six subsets, with two triangles per subset.

To make the mesh self-contained, we populate its internal attribute data array with the appropriate texture and material for each subset. We allocate space in the mesh MESH_ATTRIB_DATA array for 6 elements, one for each subset, by calling AddAttributeData. We follow this with a call to GetAttributeData to return a MESH_ATTRIB_DATA pointer to the first element in the array. We will then populate the array with the appropriate subset rendering resources. Note that the skybox will use the same default white material for each subset. CScene::CollectTexture is used to load and/or retrieve the texture pointer based on the filenames stored in the skybox entity. Thus, these skybox textures will exist in the scene's main texture array like all the others.

```
    // Add the attribute data (We'll let the skybox manage itself)
    m_SkyBoxMesh.AddAttributeData( 6 );
    pAttribData = m_SkyBoxMesh.GetAttributeData();

    D3DMATERIAL9 Material;
    ZeroMemory( &Material, sizeof(D3DMATERIAL9));
    Material.Diffuse = D3DXCOLOR( 1.0, 1.0, 1.0, 1.0f );
    Material.Ambient = D3DXCOLOR( 1.0, 1.0, 1.0, 1.0f );

    // Build and set the attribute data for the skybox
    for ( ULONG i = 0; i < 6; ++i )
    {
        pAttribData[i].Texture  = CollectTexture( this, SkyBox.Textures[i] );
        pAttribData[i].Material = Material;
        if ( pAttribData[i].Texture ) pAttribData[i].Texture->AddRef();
    } // Next Texture
```

We also remember to call AddRef for each texture interface since we are making a copy of the pointer.

At this point the mesh contains all subset attribute information as well as the vertex and index data (in its temporary system memory vertex and index arrays). The underlying skybox ID3DXMesh has not yet been created, so this is our final step before returning to the caller.

```
    // Build the mesh
    m_SkyBoxMesh.BuildMesh( D3DXMESH_MANAGED, m_pD3DDevice );

    return true;
}
```

We have now discussed all functions of significance with respect to loading the IWF file and populating the scene's mesh, object and resource arrays. As it stands, the scene has everything it needs to render. Let us now look at how the CScene::Render function (called by CGameApp::FrameAdvance) renders all of its meshes.

CScene::Render

The CScene::Render function is responsible for rendering all the meshes which comprise the scene. In this application, all meshes, with the exception of one, are being used in non-managed mode. So this function has to be responsible for setting the states before rendering the subsets of each mesh. The exception is the scene's skybox mesh which is utilizing managed mode. The CScene::RenderSkyBox function is called to set the skybox's position in the world and render it. We will study the RenderSkyBox function shortly.

Depending on the type of scene being rendered, it may be more or less efficient to batch render based on either attribute or transform. We dicussed the various pros and cons of each approach earlier. To allow our code to easily be adjusted to use both rendering strategies, a pre-compiler define is used to control how this function is compiled. Using this technique, we can actually instruct the compiler, as our code is processed, to include or exclude certain sections of the code from the final build.

If we define DRAW_ATTRIBUTE_ORDER with a value of 1, the code that batch renders the scene based on attributes will be compiled. This will render the entire scene based on subsets minimizing texture and material state changes. This would be a suitable strategy if many of your meshes exist in world space and do not need to be transformed.

If we define DRAW_ATTRIBUTE_ORDER with a value of 0, then an alternative version of the render code will be compiled. This time the code will batch render on a per object basis, minimizing transform state changes.

In this demonstration we set DRAW_ATTRIBUTE_ORDER to 0 by default so that it renders on a per object basis by default. Feel free to change this value to 1 so that you can benchmark the different rendering strategies with different scenes.

The code will be discussed a section at a time. This function is longer than would have been the case had a single rendering strategy been used, but it is still pretty straightforward. Which of the two versions of the rendering code actually gets compiled is controlled by the directive just mentioned.

```
void CScene::Render( CCamera & Camera )
{
    ULONG i, j;
    long  MaterialIndex, TextureIndex;

    if ( !m_pD3DDevice ) return;

    // Setup some states...
```

```
    m_pD3DDevice->SetRenderState( D3DRS_NORMALIZENORMALS, TRUE );

    // Render the skybox first !
    RenderSkyBox( Camera );
```

The first thing the code does is set the D3DRS_NORMALIZENORMALS render state to true. This render state forces the pipeline to ensure that vertex normals are unit length before being used for the lighting calculations in the DirectX pipeline. While the normals of a mesh would almost certainly be unit length to begin with, using a world matrix that scales vertices can cause the normals of the vertex to be scaled when the vertex is transformed by the pipeline. If such a scaling matrix is being used, the vertex normals will no longer be unit length, resulting in incorrect lighting calculations. This render state addresses that potential problem.

The first thing we render is the skybox mesh by issuing a call to CScene::RenderSkyBox. The skybox must be rendered first so that its faces are rendered behind all other scene objects (making the skybox scenery appear distant).

The next section of code activates the lights used by the scene. Placing this code here makes sure that if the user loads a new scene with more (or fewer) lights than are currently active, they will automatically be set the next time the scene is rendered. This also makes sure that if the device is reset, the lights are also automatically reset. This code is placed here for simplicity and would be moved outside the main render loop in a real world situation (light states should not be needlessly set every time a frame is rendered).

```
    // Enable lights
    for ( i = 0; i < m_nLightCount; ++i )
    {
        m_pD3DDevice->SetLight( i, &m_pLightList[i] );
        m_pD3DDevice->LightEnable( i, TRUE );
    }
```

Next we define DRAW_ATTRIBUTE_ORDER to 0 so that the scene is rendered per object instead of per subset. By changing this value to 1, you can recompile the code and force the alternative rendering strategy to be used instead. It should be noted that both rendering strategies are mutually exclusive. That is, only one of the possible two sections of rendering code can be compiled into the application at any given time.

```
// For this demo
#define DRAW_ATTRIBUTE_ORDER 0
```

If we have not set DRAW_ATTRIBUTE_ORDER to 0 then it means we wish to compile the code that batch renders the scene across mesh boundries. This is done by looping through every attribute in the scene global list and rendering any meshes that contain a subset with a matching global attribute ID. This minimimzes texture changes but increases the number of times we must set the world matrix. As we are looping through the scene attributes in the outer loop and objects in the inner loop, the world matrix for a particular mesh must be set many times, once for each subset.

The code loops through each of the scene attributes and extracts from the attribute array the texture index and the material index used by that attribute. It uses the material index to get a pointer to the correct material in the scene's material array and sets it as the current material on the device. If the current scene attribute does not contain a material, then we set a default material. We also use the retrieved texture index to bind the correct texture to texture stage 0. If the current scene attribute contains no texture, we set texture stage 0 to NULL.

```
#if ( DRAW_ATTRIBUTE_ORDER != 0 )

    // Loop through each scene owned attribute
    for ( j = 0; j < m_nAttribCount; j++ )
    {
        // Retrieve indices
        MaterialIndex = m_pAttribCombo[j].MaterialIndex;
        TextureIndex  = m_pAttribCombo[j].TextureIndex;

        // Set the states
        if ( MaterialIndex >= 0 )
            m_pD3DDevice->SetMaterial( &m_pMaterialList[ MaterialIndex ] );
        else
            m_pD3DDevice->SetMaterial( &m_DefaultMaterial );

        if ( TextureIndex >= 0 )
            m_pD3DDevice->SetTexture( 0, m_pTextureList[ TextureIndex ]->Texture );
        else
            m_pD3DDevice->SetTexture( 0, NULL );
```

Now that we have the texture and the material set for this attribute, we will loop through every object in the scene, get a pointer to its CTriMesh object, set its world matrix and FVF flags, and draw the current subset. Of course, the subset we are currently processing may not exist in the mesh and it will result in a no-op and quickly return from the function.

```
        // Process each object
        for ( i = 0; i < m_nObjectCount; ++i )
        {
            CD3DXMesh * pMesh = m_pObject[i]->m_pMesh;
            if ( !pMesh ) continue;

            // Setup the per-mesh / object details
            m_pD3DDevice->SetTransform( D3DTS_WORLD, &m_pObject[i]->m_mtxWorld );
            m_pD3DDevice->SetFVF( pMesh->GetFVF() );

            // Render all faces with this attribute ID
            pMesh->DrawSubset( j );

        } // Next Object

    } // Next Attribute
```

The above code repeats for every scene attribute until all subsets of all non-managed meshes have been rendered.

If DRAW_ATTRIBUTE_ORDER is set to 0, alterative rendering code will be compiled instead. This code will render on a per object basis (which proved to be much faster in our example application). This is because it minimizes potential FVF changes and the number of times we have to set the world matrix, thus reducing stalls in the pipeline.

This approach (really just a re-ordering of the code shown above), loops through each of the scene objects and sets its FVF flags and associated world matrix. The next step loops through each of the scenes attributes, setting the material and texture for that attribute. Finally, all meshes are instructed to render any subsets which have matching subset IDs.

```
#else

    // Process each object
    for ( i = 0; i < m_nObjectCount; ++i )
    {
        CD3DXMesh * pMesh = m_pObject[i]->m_pMesh;
        if ( !pMesh ) continue;

        // Setup the per-mesh / object details
        m_pD3DDevice->SetTransform( D3DTS_WORLD, &m_pObject[i]->m_mtxWorld );
        m_pD3DDevice->SetFVF( pMesh->GetFVF() );

        // Loop through each scene owned attribute
        for ( j = 0; j < m_nAttribCount; j++ )
        {
            // Retrieve indices
            MaterialIndex = m_pAttribCombo[j].MaterialIndex;
            TextureIndex  = m_pAttribCombo[j].TextureIndex;

            // Set the states
            if ( MaterialIndex >= 0 )
                m_pD3DDevice->SetMaterial( &m_pMaterialList[ MaterialIndex ] );
            else
                m_pD3DDevice->SetMaterial( &m_DefaultMaterial );

            if ( TextureIndex >= 0 )
                m_pD3DDevice->SetTexture( 0, m_pTextureList[ TextureIndex ]->Texture );
            else
                m_pD3DDevice->SetTexture( 0, NULL );

            // Render all faces with this attribute ID
            pMesh->DrawSubset( j );

        } // Next Object

    } // Next Attribute

#endif // !DRAW_ATTRIBUTE_ORDER != 0
```

Before exiting, we disable any currently active lights so that if we load another IWF scene which uses fewer lights than the current scene, the current scene's lights do not remain active and influence the new scene. Of course, this could be done outside the render loop, and certainly would be in a real world situation. We placed it here for simplicity in our simple application.

```
    // Disable lights again (to prevent problems later)
    for ( i = 0; i < m_nLightCount; ++i ) m_pD3DDevice->LightEnable( i, FALSE );

}
```

CScene::RenderSkyBox

The CScene::RenderSkyBox function builds a world matrix for the skybox that will translate it to the camera's current position. This ensures that the camera remains at the center of the box at all times. We simply place the camera position in the fourth row (the translation vector) of the world matrix and render the cube.

```
void CScene::RenderSkyBox( CCamera & Camera )
{
    // Bail if there is no sky box
    if ( m_SkyBoxMesh.GetNumFaces() == 0 ) return;

    D3DXMATRIX mtxWorld, mtxIdentity;
    D3DXMatrixIdentity( &mtxWorld );
    D3DXMatrixIdentity( &mtxIdentity );

    // Generate our sky box rendering origin and set as world matrix
    D3DXVECTOR3 CamPos = Camera.GetPosition();
    D3DXMatrixTranslation( &mtxWorld, CamPos.x, CamPos.y + 1.3f, CamPos.z );
    m_pD3DDevice->SetTransform( D3DTS_WORLD, &mtxWorld );
```

We disable lighting and depth buffering since neither is appropriate for this type of effect. Lighting would create visible seams and strange coloring. Depth buffering is both unnecessary and undesirable -- it is unnecessary because we do not want to perform thousands of per-pixel depth tests when we know that the depth buffer is currently clear, and it is undesirable because we do not want to write depth values that may potentially occlude other scene objects (the skybox is only a background and should never occlude anything).

```
    // Set up rendering states for the sky box
    m_pD3DDevice->SetRenderState( D3DRS_LIGHTING, FALSE );
    m_pD3DDevice->SetRenderState( D3DRS_ZENABLE, D3DZB_FALSE );
```

When rendering a skybox, we set the texture addressing modes for both the U and V axes to D3DTADDRESS_CLAMP. This prevents pixels on the edge of each quad from being bilinearly filtered with pixels on the opposite side of the texture, creating a visible seam.

```
    m_pD3DDevice->SetSamplerState( 0, D3DSAMP_ADDRESSU, D3DTADDRESS_CLAMP );
    m_pD3DDevice->SetSamplerState( 0, D3DSAMP_ADDRESSV, D3DTADDRESS_CLAMP );
```

Since the skybox is a managed mesh, it will handle setting all texture and render states. It contains the textures used by each of its faces in its internal attribute array which we populated ealier. We simply need to call the self-contained CTriMesh::Draw function.

```
    // Render the sky box
    m_SkyBoxMesh.Draw( );
```

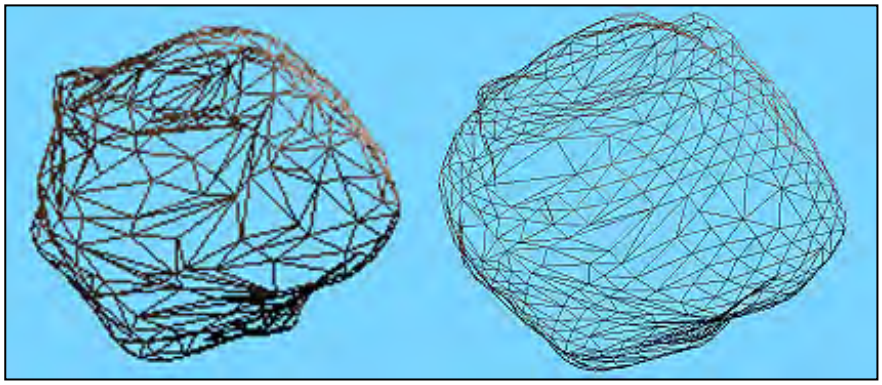
Finally, we reset all render and sampler states and the device world matrix before we return so that we do not influence how the rest of the scene is rendered.

```
    // Reset our states
    m_pD3DDevice->SetSamplerState( 0, D3DSAMP_ADDRESSU, D3DTADDRESS_WRAP );
    m_pD3DDevice->SetSamplerState( 0, D3DSAMP_ADDRESSV, D3DTADDRESS_WRAP );
    m_pD3DDevice->SetRenderState( D3DRS_LIGHTING, TRUE );
    m_pD3DDevice->SetRenderState( D3DRS_ZWRITEENABLE, TRUE );
    m_pD3DDevice->SetTransform( D3DTS_WORLD, &mtxIdentity );
}
```

Lab Project 8.2: Progressive Meshes

This lab project will add Progressive Mesh support to the code we studied in Lab Project 8.1.

To accomplish our objective, we will slightly modify our CTriMesh class so that it has the ability to be used as a static or progressive mesh. Most of the functionality for the mesh class (and indeed the entire application) will be similar to the code studied in the last project.



The CTriMesh (see CObject.h) object will now store two pointers: an ID3DXMesh pointer and an ID3DXPMesh pointer. If the m_pPMesh pointer is active then the progressive mesh will be used by all drawing and optimization functions. If not, the standard mesh will be used. This allows us to easily use the same mesh for both regular and progressive meshes and change from one to the other easily within a CTriMesh object.

```
class CTriMesh
{
  …

  LPD3DXMESH          m_pMesh;                        // Physical mesh object
  LPD3DXPMESH         m_pPMesh;                       // Physical PMesh object
```

We will add a few wrapper functions to set the current level of detail for the underlying progressive mesh. CTriMesh::SetNumVertices and CTriMesh::SetNumFaces simply pass on the request to the underlying ID3DXPMesh if it exists. They do nothing if the progressive mesh has not been generated.

```
  HRESULT           SetNumFaces       ( ULONG FaceCount );
  HRESULT           SetNumVertices    ( ULONG VertexCount );
```

We also include two more wrapper functions for trimming the base level of detail of the underlying progressve mesh. Once again, these functions do nothing if the progressive mesh has not been generated.

```
  HRESULT           TrimByFaces       ( ULONG NewFacesMin, ULONG NewFacesMax );
  HRESULT           TrimByVertices    ( ULONG NewVerticesMin, ULONG NewVerticesMax );
```

CTriMesh also provides a function to generate its progressive mesh using its underlying ID3DXMesh as the input for progressive mesh generation. This call essentially places the CTriMesh object into progressive mesh mode. The underlying ID3DXMesh interface must have been created before switching

to progressive mode. This is because the regular ID3DXMesh is used as the input mesh for D3DX progressive mesh generation.

```
 HRESULT          GeneratePMesh( CONST LPD3DXATTRIBUTEWEIGHTS pAttributeWeights,
                                 CONST FLOAT *pVertexWeights, ULONG MinValue,
                                 ULONG Options, bool ReleaseOriginal = true );
```

Cloning and optimizing are also supported for both standard and progressive meshes.

```
HRESULT          CloneMeshFVF ( ULONG Options, ULONG FVF, CTriMesh * pMeshOut,
                                  MESH_TYPE MeshType = MESH_DEFAULT,
                                  LPDIRECT3DDEVICE9 pD3DDevice = NULL );

HRESULT          Optimize     ( ULONG Flags, CTriMesh * pMeshOut,
                                  MESH_TYPE MeshType = MESH_DEFAULT,
                                  LPD3DXBUFFER * ppFaceRemap = NULL,
                                  LPD3DXBUFFER * ppVertexRemap = NULL,
                                  LPDIRECT3DDEVICE9 pD3DDevice = NULL );
```

Notice that we use a new parameter in both function calls. This is a member of the MESH_TYPE enumerated type. By default, this parameter is set to MESH_DEFAULT, which means that the output mesh will be the same type as the source mesh being cloned. We can also specify standard or progressive flags to convert between one mesh type and the other. This allows us, for example, to take a CTriMesh in progressive mesh mode and clone from another CTriMesh object in regular mesh mode and vice versa.

When cloning a CTriMesh in regular mesh mode out to a CTriMesh in progressive mesh mode, the underlying progressive mesh in the cloned object will use the regular mesh in the source object as its base (highest level of detail) geometry. When cloning a CTriMesh in progressive mesh mode to a CTriMesh in regular mesh mode, the underlying ID3DXMesh in the cloned object will contain the geometry taken from the progressive mesh of the source object at its *current* level of detail. This allows us to create a progressive CTriMesh object and simplify the data by altering its current detail setting, before cloning it back out to a new CTriMesh in regular mesh mode. The source mesh can then be released, leaving us with a simplified standard CTriMesh that can be rendered without the runtime overhead a progressive mesh would incur. If we need the ability to alter the geometric detail of a CTriMesh at runtime, we will want to use a CTriMesh in progressive mesh mode for rendering.

MESH_TYPE is now part of the CTriMesh namespace and is defined in CObject.h as:

```
enum MESH_TYPE     { MESH_DEFAULT = 0, MESH_STANDARD = 1, MESH_PROGRESSIVE = 2 };
```

Finally, CTriMesh now includes some utility wrapper functions for working with the progressive mesh and extracting its current settings. These functions should be self explanatory given our discussion of ID3DXPMesh in the textbook.

```
ULONG            GetMaxFaces       ( ) const;
ULONG            GetMaxVertices    ( ) const;
```

```
ULONG             GetMinFaces       ( ) const;
ULONG             GetMinVertices    ( ) const;
```

If the CTriMesh is not in progressive mesh mode, then all of these functions will return the number of vertices/faces in the regular ID3DXMesh. The existence of an underlying ID3DXPMesh interface takes precedence in such functions, in which case the functions return information about the progressive mesh.

Our application can get a pointer to the underlying ID3DXPMesh interface by calling the GetPMesh function. If the progressive mesh has not been generated, this call will return NULL.

```
LPD3DXPMESH       GetPMesh          ( ) const;
```

While the next two functions are not new to the CTriMesh class, they now behave differently when the mesh object is in progressive mode. In standard mode, these functions return the number of vertices and faces in the temporary arrays used to manually generate the ID3DXMesh when the CTriMesh::BuildMesh function is called. If the ID3DXMesh has already been built, then they return the number of vertices and faces in the underlying D3DXMesh object. But if the mesh object has its progressive mesh generated, then these functions will return the number of vertices and faces used to render the progressive mesh at its current level of detail.

```
ULONG             GetNumVertices    ( ) const;
ULONG             GetNumFaces       ( ) const;
```

The final new function we will add is called SnapshotToMesh. It clones the CTriMesh progressive mesh out to a standard mesh and stores the result in the CTriMesh ID3DXMesh pointer. This call does not destroy the current progressive mesh or change the mode of the CTriMesh object from progressive mesh to standard mesh mode unless the ReleaseProgressive Booelan parameter is set to true. This is handy because it allows us to create a CTriMesh object, generate a progressive mesh for it, lower its level of detail, and clone the current LOD progressive mesh to the underlying standard one. We can then release the progressive mesh, to place the same CTriMesh back into standard mode. We have simply used the progressive mesh in this case to perform a one-time simplification procedure on the mesh data.

```
HRESULT  SnapshotToMesh ( bool ReleaseProgressive = true );
```

If we specify false as the input parameter then the underlying progressive mesh will not be released and the CTriMesh remains in progressive mode. This is also useful since we can attach the simplified mesh to a new CTriMesh if desired. This allows for easy cloning of a progressive mode CTriMesh to a standard CTriMesh. In fact, we use this mechanism in CloneMeshFVF and Optimize to do exactly that.

Before we start examining the underlying code for these new and modified functions in more detail, let us briefly look at some usage scenarios for the updated CTriMesh.

Using CTriMesh to Create a Progressive Mesh

Creating a progressive CTriMesh is a two step process. Step one is exactly the same as our mesh creation code in the last project -- we simply build the mesh so that the underlying ID3DXMesh is created. Step two involves calling CTriMesh::GeneratePMesh to generate the ID3DXPMesh from the underlying ID3DXMesh. This places the CTriMesh in progressive mesh mode and will (by default) release the ID3DXMesh interface. The newly generated ID3DXPMesh will now be used for all rendering. The following example code shows how we might create a progressive CTriMesh using data loaded in from an X file stored on disk:

```
CTriMesh * pNewMesh = new CTriMesh;
pNewMesh->RegisterCallback( CTriMesh::CALLBACK_ATTRIBUTEID, CollectAttributeID, this );
pNewMesh->LoadMeshFromX( 'MyXFile.x', D3DXMESH_MANAGED, m_pD3DDevice );
pNewMesh->WeldVertices( 0 );
pNewMesh->OptimizeInPlace( D3DXMESHOPT_VERTEXCACHE );
```

At this point we have an optimized ID3DXMesh. So far, this has been exactly like the code in Lab Project 8.1. Now we call CTriMesh::GeneratePMesh to place the CTriMesh object into progressive mesh mode. We will pass in NULL in this example for the first two parameters so the default vertex component weighting is used (all vertices are assumed to have the same weight, and therefore will all be assigned the same priority for collapse). We also specify that the underlying progressive mesh should be generated such that it stores enough edge collapse structures to allow us to dynamically simplify down to a face count of 50. This target might not be possible, but the progressive mesh will calculate enough collapse structures to get as close to this number as possible without harming the topology of the mesh to an unacceptable degree.

```
pNewMesh->GeneratePMesh( NULL, NULL, 50, D3DXMESHSIMP_FACE );
```

At this point, the CTriMesh has released its ID3DXMesh interface and now has its m_pPMesh pointer pointing to a valid ID3DXPMesh interface. Finally, we optimize the progressive mesh for rendering.

```
pNewMesh->OptimizeInPlace( D3DXMESHOPT_VERTEXCACHE );
```

CTriMesh::GeneratePMesh

This function will use the standard mesh (CTriMesh::m_pMesh) as the base level of detail for a new progressive mesh. Therefore, the standard mesh should already be a valid ID3DXMesh when this function is called.

```
HRESULT CTriMesh::GeneratePMesh( CONST LPD3DXATTRIBUTEWEIGHTS pAttributeWeights,
                                 CONST FLOAT *pVertexWeights, ULONG MinValue,
                                 ULONG Options, bool ReleaseOriginal /* = true */ )
{
    HRESULT         hRet;
    LPD3DXMESH      pTempMesh      = NULL;
    LPD3DXBUFFER    pTempAdjacency = NULL;

    // Validate Parameters
```

```
    if (!m_pMesh) return D3DERR_INVALIDCALL;
```

The first thing the function does is ensure that m_pMesh is not NULL. If it is, then the function has been called prematurely and we return immediately. If the standard mesh has been created, then we release the current progressive mesh to make room for the new one we are about to create.

```
    // Release previous Progressive mesh if one already exists
    if ( m_pPMesh ) { m_pPMesh->Release(); m_pPMesh = NULL; }
```

To create a progressive mesh, we need adjacency information for the D3DXGeneratePMesh function call. If we have not created the adjacency array previously, we do so now.

```
    // Generate adjacency if not yet available
    if (!m_pAdjacency)
    {
        GenerateAdjacency();
    }
```

Next we need to validate the standard mesh to make sure it does not contain invalid data that would cause the generation of a progressive mesh to fail. We call D3DXValidMesh and pass in a pointer to the standard mesh along with its adjacency data.

```
    // Validate the base mesh
    hRet = D3DXValidMesh( m_pMesh, (DWORD*)m_pAdjacency->GetBufferPointer(), NULL );
```

If the D3DXValidMesh function fails, then the standard mesh contains invalid geometry. We will then attempt to repair the damage using the D3DXCleanMesh function. D3DXCleanMesh does not alter the actual geometry of the mesh being cleaned -- instead it clones the clean data out to a new ID3DXMesh. It also fills a new adjacency buffer, so we must allocate this buffer and pass its pointer into the function.

```
   if ( FAILED(hRet) )
   {
        // Allocate the temporary adjacency buffer
        hRet = D3DXCreateBuffer( m_pAdjacency->GetBufferSize(), &pTempAdjacency );
        if ( FAILED(hRet) ) {  return hRet; }

        // Clean the mesh data storing the new mesh interface pointer in pTempMesh.
        hRet = D3DXCleanMesh( m_pMesh, (DWORD*)m_pAdjacency->GetBufferPointer(), &pTempMesh,
                              (DWORD*)pTempAdjacency->GetBufferPointer(), NULL );

        if ( FAILED(hRet) ) { pTempAdjacency->Release(); return hRet; }
    }
```

The clean mesh is assigned to the local ID3DXMesh pointer pTempMesh. If the function fails, then there is nothing we can do; the data is simply incompatible with progressive mesh generation. If this is the case, we release the temporary adjacency buffer and return.

If the function is successful, pTempMesh will point to the cleaned ID3DXMesh interface pointer and pTempAdjacency will contain the updated face adjacency information.

If m_pMesh was valid to begin with, then we copy the mesh interface pointer and its adjacency buffer into the pTempMesh and pTempAdjacency pointers. This way, whether the mesh needed to be cleaned or not, pTempAdjacency and pTempMesh point to the adjacency buffer and the mesh we will use to create the progressive mesh.

```
    else
    {
        // Simply store common pointers
        pTempAdjacency = m_pAdjacency;
        pTempMesh      = m_pMesh;

        // Add references so that the originals are not released
        m_pAdjacency->AddRef();
        m_pMesh->AddRef();

    } // End if valid mesh
```

We generate the progressive mesh with a call to D3DXGeneratePMesh, passing in the source mesh and other required parameters. We store the new progressive mesh in the CTriMesh::m_pPMesh member pointer when complete and the CTriMesh object is now in progressive mesh mode.

```
  // Generate the progressive mesh
  hRet = D3DXGeneratePMesh(pTempMesh, (DWORD*)pTempAdjacency->GetBufferPointer(),
                           pAttributeWeights, pVertexWeights, MinValue, Options, &m_pPMesh );
```

We can now release pTempMesh and pTempAdjacency since we no longer need them.

```
    // Release all used objects
    pTempMesh->Release();
    pTempAdjacency->Release();
```

Finally, if the ReleaseOriginal Boolean paremeter is set to true (the default) then we release the standard mesh interface (m_pMesh) as well. From this point forward, any member functions we call will work with the underlying progressive mesh instead. Note that we only release the standard mesh if the progressive mesh was successfully generated.

```
    // Release the original mesh if requested, and PMesh generation was a success
    if ( ReleaseOriginal && SUCCEEDED(hRet) ) { m_pMesh->Release(); m_pMesh = NULL; }

    // Success??
    return hRet;
}
```

CTriMesh::CloneMeshFVF

The CloneMeshFVF function has had a fair bit of code added to it to cope with the dual-use nature of the modified CTriMesh class. The MESH_TYPE parameter allows the caller to specify whether the clone will be a progressive mesh (MESH_PROGRESSIVE), a standard mesh (MESH_STANDARD), or the same type as the source mesh (MESH_DEFAULT).

The results differ based on the source mesh type and the requested destination type. The semantics are detailed below:

Source Mesh: MESH_STANDARD
Destination Mesh: MESH_STANDARD -or- MESH_DEFAULT
In this case the output CTriMesh will be a standard ID3DXMesh. The vertices, faces, and attributes will be copied into the output mesh creating a duplicate CTriMesh. Vertex/index format may change depending on the Options and FVF flags passed into the function.

Source Mesh: MESH_STANDARD
Destination Mesh: MESH_PROGRESSIVE
In this case the output CTriMesh will be an ID3DXPMesh. The source mesh determines the base LOD for the progressive mesh. The source mesh remains in standard mode and the output mesh will be in progressive mesh mode. Vertex/index format may change depending on the Options and FVF flags passed into the function.

Source Mesh: MESH_PROGRESSIVE
Destination Mesh: MESH_PROGRESSIVE -or- MESH_DEFAULT
In this case the output CTriMesh will be an ID3DXPMesh. The source progressive mesh is copied in its entirety and the output mesh will have the same face and vertex count as the source. Vertex/index format may change depending on the Options and FVF flags passed into the function.

Source Mesh: MESH_PROGRESSIVE
Destination Mesh: MESH_STANDARD
In this case the output CTriMesh will be an ID3DXMesh. The clone will contain only geometry that is being used at the current level of detail for the source progressive mesh. This is essentially a snapshot of the source mesh at its current LOD. Vertex/index format may change depending on the Options and FVF flags passed into the function.

The first thing the clone function does is make sure that the mesh about to be cloned has a valid source mesh (standard or progressive). If the progressive mesh exists, then the mesh is assumed to be in progressive mesh mode and the standard mesh will be ignored. The progressive mesh will therefore be used as the source mesh in the cloning operation. We also generate face adjacency for the source mesh if it has not been previously generated because it is needed for the cloning operation. Note that the final parameter to this function is a pointer to an IDirect3DDevice9 interface describing the device we would like the output mesh to belong to. Usually we will want this to be the same as the source mesh that is

about to be cloned. If so, we can set this parameter to NULL and the device retrieved from the current mesh will be used.

```
HRESULT CTriMesh::CloneMeshFVF(ULONG Options, ULONG FVF, CTriMesh * pMeshOut,
                               MESH_TYPE MeshType , LPDIRECT3DDEVICE9 pD3DDevice)
{
    HRESULT         hRet;
    LPD3DXBASEMESH  pCloneMesh  = NULL;

    // Validate requirements
    if ( (!m_pMesh && !m_pPMesh) || !pMeshOut ) return D3DERR_INVALIDCALL;

    // Generate adjacency if not yet available
    if (!m_pAdjacency)
    {
        hRet = GenerateAdjacency();
        if ( FAILED(hRet) ) return hRet;

    } // End if no adjacency

    // If no new device was passed...
    if ( !pD3DDevice )
    {
        // we'll use the same device as this mesh
        // This automatically calls 'AddRef' for the device
        pD3DDevice = GetDevice();
    }
    else
    {
        // Otherwise we'll add a reference here so that we can
        // release later for both cases without doing damage :)
        pD3DDevice->AddRef();
    }
```

The next step is to determine the requested destination mesh type and process the request as described above.

If MESH_DEFAULT was passed in then we create a cloned CTriMesh of the same type as the current mesh object being cloned. Progressive meshes take priority, so if the m_pPMesh pointer is not NULL then the mesh is currently in progressive mesh mode and we will need to clone a new progressive mesh using the D3DXClonePMeshFVF function. If the m_pPMesh pointer is NULL then we assume the mesh is in standard mode and clone the standard mesh using D3DXCloneMeshFVF. Note that we store the cloned interface as an ID3DXBaseMesh. This allows us to use the same pointer type for both types.

```
    switch ( MeshType )
    {
        case MESH_DEFAULT:  // Continue to use the same type as 'this'
            if ( m_pPMesh )
            {
                // Attempt to clone the mesh
                hRet = m_pPMesh->ClonePMeshFVF( Options, FVF, pD3DDevice, \
                                                (LPD3DXPMESH*)&pCloneMesh );
                if ( FAILED(hRet) ) { pD3DDevice->Release(); return hRet; }
```

```
            } // End if Progressive
            else
            {
                // Attempt to clone the mesh
                hRet = m_pMesh->CloneMeshFVF( Options, FVF, pD3DDevice, \
                                              (LPD3DXMESH*)&pCloneMesh );
                if ( FAILED(hRet) ) { pD3DDevice->Release(); return hRet; }

            } // End if standard
            break;
```

Processing the request for a standard output mesh is just as easy. Again, we start by checking our progressive mesh first and then fall back to the standard mesh if necessary. Both cases use the CloneMeshFVF to accomplish the objective.

```
        case MESH_STANDARD: // Convert to, or continue to use standard mesh type
            if ( m_pPMesh )
            {
                // Attempt to clone the mesh
                hRet = m_pPMesh->CloneMeshFVF( Options, FVF, pD3DDevice, \
                                               (LPD3DXMESH*)&pCloneMesh );
                if ( FAILED(hRet) ) { pD3DDevice->Release(); return hRet; }
           }
            else
            {
                // attempt to clone the mesh
                hRet = m_pMesh->CloneMeshFVF( Options, FVF, pD3DDevice, \
                                              (LPD3DXMESH*)&pCloneMesh );
                if ( FAILED(hRet) ) { pD3DDevice->Release(); return hRet; }
            }
            break;
```

The final case handles cloning to a progressive mesh. If the progressive mesh exists in the source object, then this becomes a straight cloning operation. If not, then we must convert the standard mesh into progressive form, directly storing the result in the output mesh object.

```
        case MESH_PROGRESSIVE: // Convert to, or continue to use progressive mesh type
            if ( m_pPMesh )
            {
                // Attempt to clone the mesh
                hRet = m_pPMesh->ClonePMeshFVF( Options, FVF, pD3DDevice, \
                                                (LPD3DXPMESH*)&pCloneMesh );
                if ( FAILED(hRet) ) { pD3DDevice->Release(); return hRet; }
            }
            else
            {
                // Attempt to clone the mesh
                hRet = D3DXGeneratePMesh( m_pMesh, (DWORD*)m_pAdjacency->GetBufferPointer(),
                                NULL, NULL, 1, D3DXMESHSIMP_FACE, (LPD3DXPMESH*)&pCloneMesh );
                if ( FAILED(hRet) ) { pD3DDevice->Release(); return hRet; }
           }
        break;

    } // End type switch
```

We can now attach the new D3DXMesh to the output CTriMesh object that was passed into the function and release the base mesh interface pointer because we no longer need it.

```
    // Attach this D3DX mesh to the output mesh
    // This automatically adds a reference to the mesh passed in.
    pMeshOut->Attach( pCloneMesh );

    // We can now release our copy of the cloned mesh
    pCloneMesh->Release();
```

Our final task is to test whether the source CTriMesh has any data in its attribute data array. If it does then we are cloning from a managed CTriMesh and we should copy over the attribute data to the output mesh so that it will have the required textures and materials for each of its subsets.

```
    // Copy over attributes if there is anything here
    if ( m_pAttribData )
    {
        // Add the correct number of attributes
        if ( pMeshOut->AddAttributeData( m_nAttribCount ) < 0 ) return E_OUTOFMEMORY;

        // Copy over attribute data
        MESH_ATTRIB_DATA * pAttributes = pMeshOut->GetAttributeData();
        for ( ULONG i = 0; i < m_nAttribCount; ++i )
        {
            MESH_ATTRIB_DATA * pAttrib = &pAttributes[i];
            // Store details
            pAttrib->Material = m_pAttribData[i].Material;
            pAttrib->Texture  = m_pAttribData[i].Texture;
            pAttrib->Effect   = m_pAttribData[i].Effect;

            // Add references so that objects aren't released when either of these
            // meshes are released, or vice versa.
            if ( pAttrib->Texture ) pAttrib->Texture->AddRef();
            if ( pAttrib->Effect  ) pAttrib->Effect->AddRef();

        } // Next Attribute

    } // End if managed

    // Release our referenced D3D Device
    if (pD3DDevice) pD3DDevice->Release();

    // Success!!
    return S_OK;
}
```

It should be noted that the CTriMesh::Attach function has been altered so that it accepts an ID3DXBaseMesh pointer. It will determine whether it is a standard or progressive mesh using IUnknown::QueryInterface and assign the pointer to the underlying ID3DXMesh or ID3DXPMesh member pointer of the CTriMesh object appropriately.

CTriMesh::Optimize

The optimize function has had some small changes to accommodate our dual-use CTriMesh concept. Recall that this function works like a combination clone/optimize-in-place operation. The output mesh type is once again specified using the MESH_TYPE input parameter. The caller must pass in a pointer to an already instantiated CTriMesh object that will receive the new cloned and optimized D3DX mesh.

The first part of this function is the same as CTriMesh::CloneMeshFVF. It exits if the standard or progressive meshes are not yet created, it generates adjacency information if it does not yet exist, and it retrieves the device from the source mesh if the caller passes NULL for the device parameter.

```
HRESULT CTriMesh::Optimize( ULONG Flags, CTriMesh * pMeshOut, MESH_TYPE MeshType ,
                            LPD3DXBUFFER * ppFaceRemap , LPD3DXBUFFER * ppVertexRemap ,
                            LPDIRECT3DDEVICE9 pD3DDevice )
{
    HRESULT             hRet;
    LPD3DXMESH          pOptimizeMesh = NULL;
    LPD3DXBUFFER        pFaceRemapBuffer = NULL;
    LPD3DXBUFFER        pAdjacency = NULL;
    ULONG              *pData      = NULL;

    // Validate requirements
    if ( (!m_pMesh && !m_pPMesh) || !pMeshOut ) return D3DERR_INVALIDCALL;

    // Generate adjacency if not yet available
    if (!m_pAdjacency)
    {
        hRet = GenerateAdjacency();
        if ( FAILED(hRet) ) return hRet;

    } // End if no adjacency

    // If no new device was passed...
    if ( !pD3DDevice )
    {
        // we'll use the same device as this mesh
        // This automatically calls 'AddRef' for the device
        pD3DDevice = GetDevice( );

    }
    else
    {
        // Otherwise we'll add a reference here so that we can
        // release later for both cases without doing damage :)
        pD3DDevice->AddRef();

    } // End if new device
```

Next we allocate an ID3DXBuffer which we can pass into the Optimize function and it will be filled with the face adjacency information for the new optimized mesh. Also, if the ppFaceRemap parameter is not NULL, then the caller would like to know how the faces were re-mapped from their original positions. In that case, we need to allocate an ID3DXBuffer object to contain this information.

```
    hRet = D3DXCreateBuffer( (3 * GetNumFaces()) * sizeof(ULONG), &pAdjacency );
    if ( FAILED(hRet) ) { pD3DDevice->Release(); return hRet; }

    // Allocate the output face remap if requested
    if ( ppFaceRemap )
    {
        // Allocate new face remap output buffer
        hRet = D3DXCreateBuffer( GetNumFaces() * sizeof(ULONG), ppFaceRemap );
        if ( FAILED(hRet) ) { pD3DDevice->Release(); pAdjacency->Release(); return hRet; }
        pData = (ULONG*)(*ppFaceRemap)->GetBufferPointer();
    } // End if allocate face remap data
```

We now optimize the CTriMesh into a new object. Priority is once again given to the progressive mesh and we fall back to the standard mesh if the progressive mesh has not been created. The mesh that is output from the Optimize call will match the type of the mesh that called the function.

```
    if ( m_pPMesh )
    {
        // Attempt to optimize the progressive mesh
       m_pPMesh->Optimize( Flags, (ULONG*)pAdjacency->GetBufferPointer(), pData,
                           ppVertexRemap, &pOptimizeMesh );
    }
    else
    {
        // Attempt to optimize the standard mesh
     m_pMesh->Optimize( Flags, (ULONG*)m_pAdjacency->GetBufferPointer(),
                       (ULONG*)pAdjacency->GetBufferPointer(),  pData, ppVertexRemap,
                        &pOptimizeMesh );
    }
```

We attach the new mesh to the output CTriMesh object passed into the function.

```
    // Attach this D3DX mesh to the output mesh
    // This automatically adds a reference to the mesh passed in.
    pMeshOut->Attach( pOptimizeMesh, pAdjacency );
```

Our next task is to convert the new mesh (if necessary) into the format requested by the caller.

```
    switch ( MeshType )
    {
        case MESH_DEFAULT:  // Continue to use the same type as 'this'

            // Already a standard mesh, does it need converting ?
            if ( m_pPMesh ) pMeshOut->GeneratePMesh(NULL, NULL, 0, D3DXMESHSIMP_FACE, true);
            break;

        case MESH_PROGRESSIVE: // Convert to, or continue to use progressive mesh type

            // Already a standard mesh, convert it
            pMeshOut->GeneratePMesh( NULL, NULL, 0, D3DXMESHSIMP_FACE, true );
            break;

    } // End type switch
```

Now that the new mesh is attached to the output mesh, we can release the temporary pOptimizeMesh interface and the temporary adjacency buffer. Our final task is to copy the attribute array (if it exists) to accommodate managed meshes.

```
    // We can now release our copy of the optimized mesh and the adjacency buffer
    pOptimizeMesh->Release();
    pAdjacency->Release();

    // Copy over attributes if there is anything here
    if ( m_pAttribData )
    {
        // Add the correct number of attributes
        if ( pMeshOut->AddAttributeData( m_nAttribCount ) < 0 ) return E_OUTOFMEMORY;

        // Copy over attribute data
        MESH_ATTRIB_DATA * pAttributes = pMeshOut->GetAttributeData();
        for ( ULONG i = 0; i < m_nAttribCount; ++i )
        {
            MESH_ATTRIB_DATA * pAttrib = &pAttributes[i];
            // Store details
            pAttrib->Material = m_pAttribData[i].Material;
            pAttrib->Texture  = m_pAttribData[i].Texture;
            pAttrib->Effect   = m_pAttribData[i].Effect;

            // Add references so that objects aren't released when either of these
            // meshes are released, or vice versa.
            if ( pAttrib->Texture ) pAttrib->Texture->AddRef();
            if ( pAttrib->Effect  ) pAttrib->Effect->AddRef();

        } // Next Attribute

    } // End if managed

    // Release our referenced D3D Device
    if (pD3DDevice) pD3DDevice->Release();

    // Success!!
    return S_OK;
}
```

CTriMesh::OptimizeInPlace

OptimizeInPlace has also been slightly modified to accommodate our new progressive mesh functionality, although to a lesser degree than the Optimize call. The only different between this version of the function and the version from Lab Project 8.1 is that it tests to see if the object is in progressive mesh or standard mesh mode. In standard mesh mode, this function simply wraps a call to the ID3DXMesh::OptimizeInPlace function for its internal ID3DXMesh object. Since this function does not exist in the ID3DXPMesh interface, we use the less flexible D3DX optimization function called OptimizeBaseLOD to optimize the underlying progressive mesh if the CTriMesh object is in progressive mesh mode.

```
HRESULT CTriMesh::OptimizeInPlace( DWORD Flags, LPD3DXBUFFER * ppFaceRemap ,
                                   LPD3DXBUFFER * ppVertexRemap  )
{
    HRESULT      hRet;
    LPD3DXBUFFER pFaceRemapBuffer = NULL;
    ULONG       *pData = NULL;

    // Validate Requirements
    if ( (!m_pMesh && !m_pPMesh) ) return D3DERR_INVALIDCALL;

    // Generate adjacency if none yet provided
    if (!m_pAdjacency)
    {
        hRet = GenerateAdjacency();
        if ( FAILED(hRet) ) return hRet;
    }

    // Allocate the output face remap if requested
    if ( ppFaceRemap )
    {
        // Allocate new face remap output buffer
        hRet = D3DXCreateBuffer( GetNumFaces() * sizeof(ULONG), ppFaceRemap );
        if ( FAILED(hRet) ) { return hRet; }
        pData = (ULONG*)(*ppFaceRemap)->GetBufferPointer();
    }

    // Optimize the data
    if ( m_pPMesh )
        hRet = m_pPMesh->OptimizeBaseLOD( Flags, pData );
    else
        hRet = m_pMesh->OptimizeInplace( Flags, (DWORD*)m_pAdjacency->GetBufferPointer(),
                                        (DWORD*)m_pAdjacency->GetBufferPointer(),
                                         pData, ppVertexRemap );
        if ( FAILED( hRet ) ) return hRet;

    // Success!!
    return S_OK;
}
```

CTriMesh::SetNumFaces/SetNumVertices

These functions simply wrap the ID3DXPMesh calls of the same names and allow us to dynamically alter the current LOD of the underlying progressive mesh. The function does nothing if the CTriMesh object has not had its underlying ID3DXPMesh generated.

```
HRESULT CTriMesh::SetNumFaces( ULONG FaceCount )
{
    HRESULT hRet = D3DERR_INVALIDCALL;

    // Set number of faces (this is a no-op if there is no pmesh)
    if ( m_pPMesh ) hRet = m_pPMesh->SetNumFaces( FaceCount );

    // Success??
    return hRet;
}
```

```
HRESULT CTriMesh::SetNumVertices( ULONG VertexCount )
{
    HRESULT hRet = D3DERR_INVALIDCALL;

    // Set number of vertices (this is a no-op if there is no pmesh)
    if ( m_pPMesh ) hRet = m_pPMesh->SetNumVertices( VertexCount );

    // Success??
    return hRet;
}
```

CTriMesh::TrimByFaces

TrimByFaces is a dual-mode function that works differently depending on whether the CTriMesh is in progressive or standard mesh mode. In progressive mode, this call simply wraps the call to ID3DXPMesh::TrimByFaces. This will set new upper and lower boundaries for the progressive mesh. The caller specifies the new maximum number of faces, which must be less than or equal to the current maximum number of faces, and the new minimum number of faces which must be greater than or equal to the current minimum number of faces. This function allows us to trim the dynamic range of the progressive mesh freeing collapse structures from memory allowing the mesh to consume less memory.

If this function is called and the CTriMesh is in standard mode (no progressive mesh exists) then the function is interpreted as a request to simplify the underlying ID3DXMesh standard mesh down to a new level of detail. When this is the case, we call D3DXSimplifyMesh to reduce the input mesh (the current standard mesh) to the requested LOD. Since the output of this call is a new mesh, the old standard mesh is released and the new simplied ID3DXMesh is assigned as the new standard mesh for the CTriMesh.

```
HRESULT CTriMesh::TrimByFaces( ULONG NewFacesMin, ULONG NewFacesMax )
{
    HRESULT hRet = D3DERR_INVALIDCALL;

    // Trim by faces
    if ( m_pPMesh )
    {
        // Drop through to P mesh trimming
        hRet = m_pPMesh->TrimByFaces( NewFacesMin, NewFacesMax, NULL, NULL );
    }
    else if ( m_pMesh )
    {
        LPD3DXMESH pMeshOut = NULL;

        // Generate adjacency if not yet available
        if (!m_pAdjacency)
        {
             GenerateAdjacency();
        }

        // Since there is no PMesh, we can only comply by simplifying
        D3DXSimplifyMesh(m_pMesh, (DWORD*)m_pAdjacency->GetBufferPointer(), NULL, NULL,
                         NewFacesMax, D3DXMESHSIMP_FACE, &pMeshOut);
```

```
        // Release old mesh and store the new mesh
        m_pMesh->Release();
        m_pMesh = pMeshOut;

        // Adjacency will be out of date, update it
       GenerateAdjacency();
   }

    // Success??
    return hRet;
}
```

> **Note:** There is also a CTriMesh::TrimByVertices function which is exactly the same code as above but trims LOD based on vertices instead of faces. Check the source code for this project for a listing of this function.

CTriMesh::GetNumFaces

All of the GetXX functions of the CTriMesh class have been slightly modified to accommodate our dual-use mesh class. We will examine the GetNumFaces call in this example, but you should be aware that all of these functions behave in exactly the same way.

In progressive mesh mode, GetNumFaces returns the number of faces being used by the progressive mesh at its current LOD. In standard mesh mode, there are two possible cases. The first is when the ID3DXMesh has been created. In this case GetNumFaces will return the number of faces in the underlying ID3DXMesh. The second case handles the mesh as it is undergoing manual construction, before it has been converted into a D3DX mesh type. In this case we return the number of faces in the temporary index array.

```
ULONG CTriMesh::GetNumFaces( ) const
{
    // Validation!!
    if ( m_pPMesh )       return m_pPMesh->GetNumFaces();
    else if ( m_pMesh )   return m_pMesh->GetNumFaces();
    else                  return m_nFaceCount;
}
```

CTriMesh::DrawSubset

The DrawSubset function has hardly changed at all. ID3DXMesh and ID3DXPMesh both support the DrawSubset function, so this function only needs to determine whether the progressive mesh has been generated or if we should render using the standard mesh. We use an ID3DXBaseMesh pointer to render the subset to handle both cases.

```
void CTriMesh::DrawSubset( ULONG AttributeID )
{
    LPDIRECT3DDEVICE9 pD3DDevice = NULL;
```

```
    LPD3DXBASEMESH    pMesh      = m_pMesh;

    // Retrieve mesh pointer
    if ( !pMesh ) pMesh = m_pPMesh;
    if ( !pMesh ) return;

    // Set the attribute data if it exisits (which means it is a managed mesh)
    if ( m_pAttribData && AttributeID < m_nAttribCount )
    {
        pD3DDevice = GetDevice( );
        pD3DDevice->SetMaterial( &m_pAttribData[AttributeID].Material );
        pD3DDevice->SetTexture( 0, m_pAttribData[AttributeID].Texture );
        pD3DDevice->Release();
    }

    // simply render the subset(s)
    pMesh->DrawSubset( AttributeID );
 }
```

Additional Code Changes

The rest of the changes to our scene viewer can be found in the CScene class. Most changes are relatively minor and you will find most of the code from Lab Project 8.1 intact.

The first change is the addition of one line of code to the ProcessMeshes and ProcessReference functions. Once these functions have created the CTriMesh and generated the underlying ID3DXMesh, we call the new function CTriMesh::GeneratePMesh to generate the underlying progressive mesh (placing it into progressive mesh mode) before adding it to the scene mesh array. The following snippet from ProcessReference illustrates the idea:

```
…
CTriMesh * pNewMesh = new CTriMesh;

// Load in the externally referenced X File
pNewMesh->RegisterCallback( CTriMesh::CALLBACK_ATTRIBUTEID, CollectAttributeID, this );
pNewMesh->LoadMeshFromX( Buffer, D3DXMESH_MANAGED, m_pD3DDevice );

// Attempt to optimize the standard mesh ready fro progressive mesh generation
pNewMesh->WeldVertices( 0 );
pNewMesh->OptimizeInPlace( D3DXMESHOPT_VERTEXCACHE );

// Convert this mesh to a progressive mesh
pNewMesh->GeneratePMesh( NULL, NULL, 50, D3DXMESHSIMP_FACE );

// Optimize the progressive form of the mesh
pNewMesh->OptimizeInPlace( D3DXMESHOPT_VERTEXCACHE );

// Store this new mesh
if ( AddMesh( ) < 0 ) { delete pNewMesh; return false; }
m_pMesh[ m_nMeshCount - 1 ] = pNewMesh;
…
```

In this demo, all of the meshes in our scene mesh array will be progressive meshes with an arbitrarily set minimum LOD of 50 faces. Note that the skybox will not be a progressive mesh.

CScene::CalculateLODRatio

We have added a few new functions to our CScene class to set the current LOD for our meshes prior to rendering. The LOD selected will be based on the distance from the mesh to the camera. As meshes get further away from the camera, they will use fewer faces and vice versa. This is easiest to see if you switch the application to wireframe render mode.

CalculateLODRatio manages this process. The function returns a value between 0.0 and 1.0 based on camera distance. This value will be used to select a new LOD for the number of mesh faces in the CScene::Render function. The [0.0, 1.0] range serves as a percentage between the minimum and maximum number of faces for the mesh.

```
float CScene::CalculateLODRatio( const CCamera & Camera, const D3DXMATRIX & mtxObject ) const
{
    // Retrieve object position.
    D3DXVECTOR3 vecObject = D3DXVECTOR3( mtxObject._41, mtxObject._42, mtxObject._43 );

    // Calculate rough distance to object
    float Distance = D3DXVec3Length( &(vecObject - Camera.GetPosition()) );

    // Calculate the LOD Ratio, from 0.0 to 1.0 within the first 60% of the frustum.
    float Ratio = 1.0f - (Distance / (Camera.GetFarClip() * 0.6f));
    if ( Ratio < 0.0f ) Ratio = 0.0f;

    // We have our value
    return Ratio;
}
```

We pass in the camera and the world matrix for the object we are about to render. The world space position is extracted from the fourth row of the matrix and the distance to the camera is calculated using the D3DXVec3Length function. We then divide the distance by the distance to the camera far plane and multiply by 0.6. This means that any mesh that is over 60% of the distance from the camera, between the near and far planes, will always have a ratio of 0.0. In this case the mesh will be set to its lowest level of detail.

CScene::Render

The CScene::Render function has not been modified much since Lab Project 8.1 so we will examine only the changes that were made. Three new lines were added to the call (highlighted in the following listing) to manage the LOD transition for each mesh.

For each mesh, we calculate its LOD ratio by passing its object world matrix to CalculateLODRatio. The return value is used to calculate the desired face count for the progressive mesh. The ratio interpolates between the minimum and maximum number of faces for the mesh. We then set the mesh LOD with a call to the CTriMesh::SetNumFaces.

```
    for ( i = 0; i < m_nObjectCount; ++i)
    {
        CTriMesh * pMesh = m_pObject[i]->m_pMesh;

        // Calculate LOD ratio
        float Ratio = CalculateLODRatio( Camera, m_pObject[i]->m_mtxWorld );

        // Calculate the number of faces (simple linear interpolation)
        ULONG FaceCount = pMesh->GetMinFaces() +
                          (ULONG)((float)(pMesh->GetMaxFaces()–pMesh->GetMinFaces()) * Ratio);

        // Set the LOD's number of faces
        pMesh->SetNumFaces( FaceCount );

        // Setup the per-mesh / object details
        m_pD3DDevice->SetTransform( D3DTS_WORLD, &m_pObject[i]->m_mtxWorld );
        m_pD3DDevice->SetFVF( pMesh->GetFVF() );

        // Loop through each scene owned attribute
        for ( j = 0; j < m_nAttribCount; j++ )
        {
            // Retrieve indices
            MaterialIndex = m_pAttribCombo[j].MaterialIndex;
            TextureIndex  = m_pAttribCombo[j].TextureIndex;

            // Set the states
            if ( MaterialIndex >= 0 )
                m_pD3DDevice->SetMaterial( &m_pMaterialList[ MaterialIndex ] );
            else
                m_pD3DDevice->SetMaterial( &m_DefaultMaterial );

            if ( TextureIndex >= 0 )
                m_pD3DDevice->SetTexture( 0, m_pTextureList[ TextureIndex ]->Texture );
            else
                m_pD3DDevice->SetTexture( 0, NULL );

            // Render all faces with this attribute ID
            pMesh->DrawSubset( j );

        } // Next Attribute

        // Increase tri-rendering count
        m_nTrisRendered += pMesh->GetNumFaces();

    } // Next Object
```

Notice that while the progressive mesh provided by D3DX is a view *independent* progressive mesh, we calculate the LOD based on view dependant information. This is a common strategy, but not the only way to do it. You might instead enable a menu option for reducing/increasing LOD. Perhaps certain meshes are considered more important than others and the lower priority meshes can be simplified. The

bottom line is that how you choose to modify LOD is up to you. Here we have implemented a distance based approach simply to show how the CTriMesh in progressive mesh mode can be used by an application.

We now have a CTriMesh class that is much more than a simple wrapper. Indeed, it is more like a complete mesh toolkit handling resource management, standard and progressive meshing techniques, optimization and cloning from standard to progressive meshes and vice versa and finally, automated or scene handled rendering strategies are exposed to the application. This functionality will serve us well in future applications as we move forward in the course.

Chapter Nine

Frame Hierarchies

Introduction

In Chapter Eight, while examining the process of loading and rendering mesh data stored in X files, we learned that the D3DXLoadMeshFromX function provided a useful and yet restrictive service: regardless of how many meshes were contained in the X file, a single mesh was always output. Multiple meshes, were they to exist in the file, were simply transformed and collapsed into a single output mesh. While this outcome may be acceptable under certain conditions, a more flexible X file loading system that allows us to optionally maintain the individual mesh entities would certainly be ideal. This is because there are circumstances that frequently occur in game development where the preservation of the distinct meshes is preferred. We will examine a number of these cases as we move forward in this chapter.

For example, consider the case where an X file is used to store the representation of an automobile. It is not uncommon for an automobile model to be constructed using several meshes (ex. chassis, doors, trunk, hood, and tires), each requiring independent animation. The game designer may want the wheels to rotate as the car accelerates or the doors to swing open and closed when the player enters or exits the vehicle. It would be difficult indeed to apply such localized animations to the various sections of the automobile if a single mesh representation was used. Earlier lessons have taught us that when we apply a transform to a mesh, it is applied to all of its vertices. Therefore, if we wish to represent a model that has independently moving parts, it should be represented as a collection of unique meshes that, taken together, represent the overall model. With a multiple mesh representation, each mesh is rendered separately. This affords us the freedom to alter the transformation matrix for a given mesh before it is rendered, applying animation to position, orientation, or even both simultaneously.

The X file loading techniques we have discussed thus far would not be able to be used in circumstances where such a representation is stored in the X file. Using the D3DXLoadMeshFromX function, we would effectively abandon the multi-mesh layout of the file, getting back a single mesh that is the sum of all specified submeshes. While the process of collapsing submeshes into a single mesh is handled intelligently by D3DX (the original submeshes are correctly positioned within the overall model representation) we will have lost the ability to animate/transform those original sub-meshes separately from the rest of the model.

When constructing or loading a multi-mesh representation, we do not simply want the various sub-meshes stored such that they are transformed and rendered in total isolation from one another. Rather, it would be expected that the underlying spatial relationship between each of these individual meshes will still be preserved, even when these submeshes experience their own unique transformations. If the vehicle moves, then all of its submeshes must move together, to maintain model integrity. We would not want to move the automobile chassis mesh only to find that the wheels have not moved along with it. However, we do want the freedom to rotate the wheels without rotating the chassis.

Designing such an automobile representation in any of the popular 3D modeling packages is quite common, and we are generally going to want to use a multi-mesh representation in our application as well. One important question is, when this automobile is exported to the X file format, how are these meshes arranged in the file such that they can be imported and assembled into a multi-mesh vehicle model that behaves as expected? The quick answer is that each mesh in the file will have a

transformation matrix assigned to it that describes how it is positioned relative to something else in the scene. This 'something else' might be another mesh used in the model, or some other point in space (perhaps even the scene origin itself). The result is a spatial hierarchy of meshes, arranged in a tree-like fashion. There is a root node, and then a series of child nodes positioned relative to the root. These children may have child nodes positioned relative to themselves, and so on.

Using our automobile example, the chassis mesh might be stored in the root node of the tree and the four wheel meshes might be stored as child nodes of the root. In each child node, a wheel submesh would also be accompanied by a 4x4 transformation matrix which describes the position and orientation of the wheel mesh. This description is *not* an absolute (i.e. world space) transformation as we might expect, but is in fact a transformation *relative* to the parent node; in this case, the chassis. In this simple example, the transformation matrix for each wheel mesh would describe the position and orientation of the wheel relative to the location and orientation of the chassis mesh (the parent node). Therefore, regardless of how we animate the chassis (by applying transformations to the matrix in the root node), the world matrix used to render each submesh can always be calculated such that object integrity is maintained.

In this example, the root node matrix is used to set the world space transformation for the chassis mesh. This is essentially the world matrix for the entire automobile representation. It is this matrix that would be used to transform the chassis mesh into world space prior to rendering it. The world space matrices used to render each submesh are *not* directly contained in the representation (or in the X file for that matter) and must be calculated each time the root node matrix is updated by the application. We accomplish this by combining a parent node matrix (the chassis/root matrix in this example) with the child transformation matrix (a wheel matrix) prior to rendering. As each child wheel matrix describes the position of the wheel relative to the chassis, and the root node matrix describes the world space position of the chassis itself, multiplying these two matrices produces the world space transformation matrix for the wheel. By generating the world matrices for each submesh at runtime, just prior to rendering, we are assured that whenever we apply a transformation to the root node matrix, the world matrix generated for each child mesh will correctly transform the child along with the parent. This ensures that the spatial relationship between the children (the wheel meshes) and the parent (the chassis mesh) is maintained and that changes to the root node matrix are propagated through the entire tree. The result is that we can move the entire model, with all of its submeshes, by applying transformations to the root node matrix and then calculating the new world space matrix for each child mesh that results from these changes to the root. Note as well that we also have the ability to apply transformations to the relative matrix of a child object. In this manner, local rotations could be applied to our wheel meshes without being applied to the chassis.

Graphics programmers commonly refer to the data arrangement that describes these relative relationships as a *spatial hierarchy* or a *frame hierarchy*. Understanding how to load, animate, and render a multi-mesh frame hierarchy is vital if we are to progress past the simple mesh representations we have covered thus far. To understand the relative arrangement of a frame hierarchy, we must first examine the concept of *frame of reference*. This will be the subject of the next section.

9.1 Frame Hierarchies

Physicists and mathematicians use the concept of a *frame of reference* (a.k.a. *reference frame*) to describe an arbitrary point in space with an arbitrary orientation. We use frames of reference all the time in our everyday lives to achieve all manner of tasks and as such, we are often not aware that we are using them at all. Without a frame of reference it would be impossible to evaluate a grid coordinate on a map, give somebody directions to your house, or even specify a position in 2D or 3D space.

A simple example of why we need to use a frame of reference is apparent when we consider giving somebody travel directions. Imagine that Person A lives in San Francisco and that Person B resides in Miami. If A asks B the general direction he should travel to reach Mexico City, B might incorrectly assume that they both live in Miami and offer information describing Mexico City as being positioned due west. If A also assumes that B is living in San Francisco and is offering his directions based from that location, A would head off in a westerly direction and find himself in the middle of the Pacific Ocean. Of course, Person A could have stayed dry if B had revealed that his directions were using Miami as a frame of reference. The correct directions should have been given as "From Miami, head west". In this case, Person A could have traveled to Miami first and then followed the directions provided, or he could have extrapolated his own directions from the Miami-based directions. This would have informed him that he needed to head due south and then east.

Another common example of frame of reference is one which demonstrates how the perceived velocity of a moving object is changed when classified using different frames of reference. This example will also have some relevance to 3D animation, as we will learn later. To demonstrate, imagine Person A (who we shall refer to as Speedy Steve) riding a motorcycle up the street in a northerly direction at a speed of 150 kph. Just as he passes by Person B (who we shall call Dastardly Dennis), Dennis walks out into the center of the street and positions himself directly behind Speedy Steve. He then pulls back on his super-slingshot as hard as he can, and releases a stone in the direction Speedy Steve is traveling. The stone leaves the slingshot and travels at a constant 155 kph. Dennis is a rather nasty fellow whose intention is to strike Speedy Steve in the back of the head so hard that he is knocked from his motorcycle. However, what Dennis had cruelly planned does not come to fruition. Instead, the stone gently taps Speedy Steve on the back of the helmet, so softly that he hardly notices it. He carries on northbound and vanishes out of sight. Dennis is left scratching his head and wondering why his dastardly plan failed.

The reason Dennis' plot did not work becomes clear when we examine the nature of the relative velocities. Although the stone that Dennis fired was traveling at a frightening 155 kph in Dennis' frame of reference, Speedy Steve is also traveling at 150 kph himself in the same direction. So from Steve's perspective, the stone is only gaining on him at a relative velocity of (155 – 150) 5 kph. That it, using Speedy Steve as a frame of reference, the velocity of the stone is only 5 kph. Therefore it strikes him with very little force. Of course, if Speedy Steve was stationary like Dennis, then the stone would have hit him at 155 km per hour and probably done some serious damage. For maximum dastardly effect, Dennis should have preempted Steve's arrival and been laying in wait. If he would have released the stone at the same speed from in front of Steve, and in a southerly direction, it would have hit Steve head-on with devastating force. Using Steve as a frame of reference in this example, what would be the velocity of the stone at the point of impact? The answer is (155 + 150) 305 kph. This is because both

Steve and the stone are traveling in exact opposite directions and therefore their combined velocity is used to calculate their impact velocity. As Steve hurtles towards the stone, it in turn is hurtling towards him. So from Steve's point of view, that stone is getting closer at a very high rate of speed indeed. The main point is that the position, orientation and velocity of something can actually be very different when observed using different frames of reference.

As it turns out, we have consistently used frames of reference throughout this course series when dealing with mesh data and transformations, although their application is so obvious it might be overlooked. The 3D vector <10, 10, 10> would mean nothing to us, and could not even be evaluated, if we did not know that these numbers describe a position in space relative to the origin of some coordinate system. Indeed, a coordinate system provides a means for describing locations within a frame of reference. When plotting points in any coordinate system (world space, view space, projection space, screen space, etc.) we are using a frame of reference with the origin of the coordinate system serving as the origin of the frame. We know that this is usually classified as position (0, 0, 0).

Throughout Graphics Programming Module I we discussed mathematical 'spaces' and coordinate systems in some detail. So we see now that in effect, we have been discussing frames of reference all along. Each of the 'spaces' we discussed (model space, world space, view space, etc.) had an origin and orientation which described a frame of reference. All positions in that space are defined relative to this origin and axis orientation. In model space, all vertex positions are defined relative to the fixed position (0,0,0) and the coordinate axes are the standard orthogonal XYZ axes. In world space, those same vertices are then defined relative to another fixed point in space (also assigned the coordinates (0,0,0)) with its own orthogonal set of XYZ axes. This point is considered the origin of our world space system and is therefore the frame of reference for all vectors plotted in world space. View space is yet another frame of reference that exists at the camera position (in which (0,0,0) is also used as the frame of reference origin for all points described within that space). It too has its own set of XYZ orthogonal axes which, with respect to the world's standard axes, describe the orientation of the camera.

It should now be clear then that transformations provide us with a means for modifying values within a frame of reference. If we consider the three transformations we have studied in most detail (scaling, translation, and rotation) we understand that they can be used to modify the position of a point in order to generate a new position within the same coordinate space (frame of reference). Transformations also provide us the ability to transform (or perhaps more appropriately, "reclassify") values from one frame of reference to another. We have seen how the world space transformation transitions vectors relative to the model space frame of reference into vectors relative to the world space frame of reference. Many people actually find this a more intuitive way of visualizing transformations from one space to another. We are simply taking a point in one frame of reference and reclassifying it in another.

So then a frame of reference is essentially a *local space*: it has an origin from which emerges a set of axes that define how the space is oriented and thus how things in that local space are measured with respect to that origin. Through the use of transformations we can create a situation in which we redefine points in one frame of reference to be classified with respect to another frame of reference. That is how our models maintain a presence in our game world. Each model usually has its own frame of reference (model space, in which its vertices are initially defined), but through our transformation pipeline, we can also describe how those same vertices are situated in the world frame of reference, the camera frame of reference, and so on.

The reason why an understanding of frames of reference is so important can be demonstrated when we examine our automobile example. We will use a simple example of five separate meshes (four wheels and a car body) for our automobile. These meshes will be arranged in the X file in a hierarchical format such that the positions of the four wheels are defined relative to the position of the car body. In other words, the car body is stored at the root of the automobile hierarchy and the four wheels will be children of this node.

In Fig 9.1 we see the automobile hierarchy. In the diagram, we see a **frame** structure which will represent a node in the tree. A single frame contains a 4x4 transformation matrix defining a location and orientation as just described and stores pointers to *N* child frames. Each frame (short for 'frame of reference') can also store one or more pointers to data items -- car part meshes in this case. In this example, each frame contains only a single child mesh, but this need not always be the case.

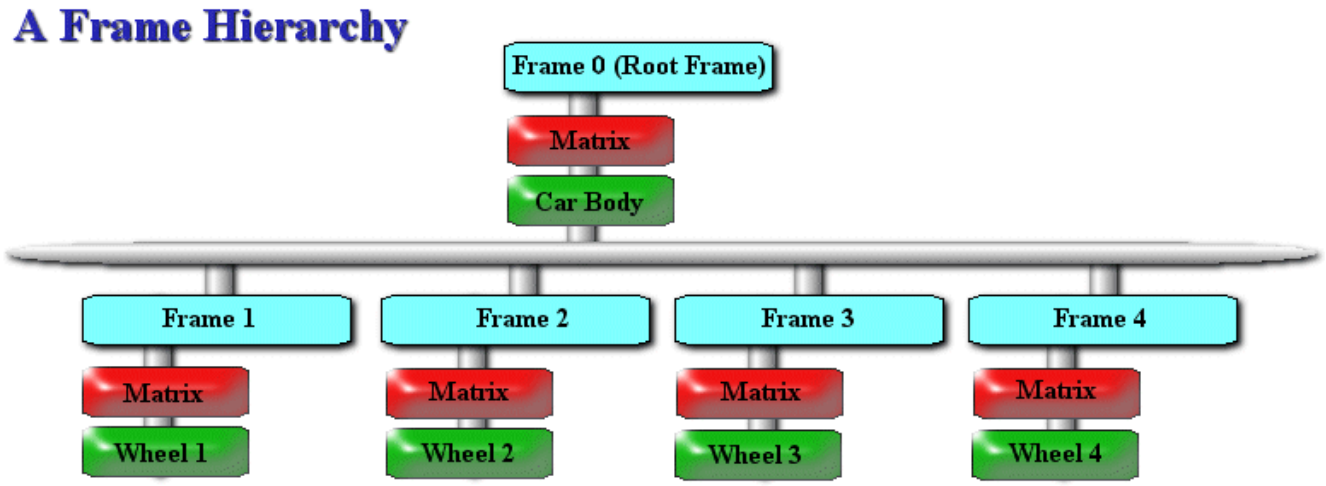


Figure 9.1

Each 4x4 frame matrix consists of two components. It has a translation component in its bottom row which describes the origin of the frame of reference. This origin is defined *relative to* its parent (i.e. it tells us the location of the origin of the child frame within the parent's frame of reference). The rest of the matrix describes the parent-relative orientation of the frame itself (i.e. how much rotation off the parent axes the child axes happen to be). The combination of parent-child relationships defined by the transformations stored in each node matrix creates a spatial hierarchy.
While the root node has no direct parent in the hierarchy, we can still think of its matrix as a relative matrix. In this particular case, the root node 'parent' is the world system origin, and the root frame matrix stores a position/orientation relative to that system. As such, the root frame transformation matrix will serve as a world matrix for the entire hierarchy, enabling us to position and orient the entire set of hierarchy data in our world (assuming the root node does not get attached to some other parent of course – for example, an automobile carrier that is transporting cars to the showroom). This is possible because the children of the root frame are defined in its local space (i.e. reference frame), so by moving the root frame in the world, we are moving its frame of reference and thus any items that are defined within it.

So in our simple case, applying a translation to the root frame would position that frame somewhere in the game world. Certainly we would expect that the children must also experience the same transformation so that they follow their parent to the new location (the spatial dispositions of the child

objects in the hierarchy must be preserved in the process of moving their parent). Keep in mind that while the root node world transformation must be propagated down to each child so that they move as well, the relative relationships between parents and children must remain intact since they exist within that given reference frame. Thus the world transformation and the parent-relative transformations at each node must be combined in some fashion. We will examine the appropriate matrix combination strategy shortly.

The root frame in this particular example stores a single mesh (the car body) and its transformation matrix describes the world orientation and position of the frame. Thus to transform the car body mesh vertices into world space, we would just multiply the vertices by the frame 0 matrix directly. In that sense, we can think of the mesh stored in the root frame as having a local space defined by that root frame (i.e. the mesh vertices are defined as if the root frame origin were the model space origin for the mesh itself). We will see shortly that in fact, this holds true for all of our frames and that we are essentially building a tree of local space coordinate systems all nested within each other.

We will want to store each wheel in a separate frame so that rotation can be applied to the individual wheels when the car accelerates. This would be a local rotation for the wheel, likely around its local X or Z axis depending on how the wheel model was oriented in the modeling program. Thus matrix multiplication order is very important here since the frame matrix stores a translation that already positions the wheel away from the center of the car body. Of course, we would not want that translation to happen first, since that would just rotate the wheel around the parent. Thus the local wheel rotation would have to happen before the wheel was translated into its world space position. In other words, we want to start with the wheel at the origin, rotate it around its local X or Z axis so that it spins, and then push that wheel out into its final position relative to its parent. So the local rotation matrix would have to come first in the multiplication order, followed by the parent-relative frame matrix, and not the other way around.

For simplicity, let us forget about the mesh vertices and work only with mesh center points. In a sense we can even think of each mesh as a single vertex in a model called ‘scene’. Let us further assume that we would like the car to be moved to world location (100,100,100) and we define a 4x4 translation matrix **W** to accommodate this.

If we assume that our car body is centered at the origin of the model and thus requires no additional transformations relative to the center of the model, its parent-relative (i.e. frame) transformation matrix would be an identity matrix (which we can call **F0** for Frame 0). As mentioned above, this will actually be our root frame matrix in the case of the car body since this mesh stored in the root frame.

Let us call the final world space transformation matrix for the car body **B**. This will be the matrix that we use to transform the car body mesh into world space.

B = **F0** * **W**
B = W (since F0 is an identity matrix)

As you can see, all we have done above is multiply the matrix in the root frame with translation matrix **W**. This results in matrix **B**, which is a matrix describing a world space translation of (100,100,100) to move the car body vertices into world space.

Now let us examine one of our wheel frames and say that in this example, each wheel is offset 10 units from the center of the car body. Thus each wheel frame will have a 4x4 translation matrix defining its relationship to its parent. This is the frame matrix for the wheel and we will call it **F1** (for the first wheel).

The question is, how do we find the final *world space* transformation for the wheel (we will call it **T1**)? F1 does not describe the position of the wheel using the world space frame of reference, but that is exactly what we need in order to transform its vertices into world space prior to rendering. Therefore, the wheel frame matrix must be multiplied with something else to generate the final world space transformation matrix for the wheel.

T1 = **F1** * ?

We know that matrix **F1** contains a transformation relative to its parent **F0**, so these will have to be multiplied together so that both meshes are in the same space and share a common frame of reference. However, as we have potentially repositioned **F0** in the world by multiplying it with translation matrix **W**, the final world space position of the wheel must take this into account also so that the wheel and the car body frames are translated by the same amount.

T1 = **F1** * (**F0 * W)**
T1 = F1 * B

As you can see, **F1** describes its position relative to **F0**, so multiplying these matrices together will move the wheel from its own local space into the local space of the entire automobile representation. We can imagine at this point that the wheel has been correctly positioned relative to the car body but that the car itself is still at the origin of world space. Finally, **W** contains the transform matrix that positions the entire model in the world (we used this to position the car body mesh) so this too must be applied to the wheel mesh. Therefore, the car body world matrix is **B=F0*W** and the world matrix of the wheel is **F1*B**.

So if we wanted to rotate the wheel around its own local Z axis, it should be apparent to you where that 4x4 rotation matrix ($\mathbf{Z_{rot}}$) would need to go in the chain:

T1 = $\mathbf{Z_{rot}}$ * **F1** * **F0 * W**

Now in this particular case, the parent of the wheel is the root node of the hierarchy. Thus the equation simplifies to:

T1 = $\mathbf{Z_{rot}}$ * **F1** * **B**

Hopefully you see the pattern here. If you wanted to attach something to the wheel (a hubcap for example), you would add a new frame for it and define it relative to its parent (the wheel) and continue on down the chain.

It is important to keep in mind that any transformation at a node affects all of its children when we combine the matrices in this way to generate world matrices for each frame (and the meshes they may

contain). In that sense, it can be helpful to think of frames as a system of joints. Any part of the scene that needs to be moved or rotated independently will be assigned its own joint. The connections between those joints are essentially offsets of some distance from the parent, represented by the translation row in the frame matrix. How those joints are oriented would be represented in the upper 3x3 portion of the matrix (an orthogonal rotation matrix). Thus at any given node in the tree, its world transformation matrix is defined as the concatenation of any local transforms we wish to apply to that frames matrix, the parent-relative transformation matrix stored in the frame itself, and the parent's current **world** space transformation matrix (which is itself a by-product of the same logic). Therefore, in order to calculate the world space transformation matrix of a given frame in the hierarchy, we must have first calculated the world space transformation matrix for its parent frame, as it is used in the concatenation.

In our automobile example we saw that each wheel has its own frame of reference (Fig 9.1). We now also know that a frame matrix stores a mathematical relationship describing some translational offset from a parent frame and a local orientation for that node which is relative to the parent node's orientation. Practically speaking, we can consider the mesh vertices that are stored at a given frame as children of that frame as well. That is, they utilize the same matrix concatenation scheme to describe how far away they need to be from the frame root node. The only real difference is that the vertices will have their final matrix concatenation done in the pipeline during rendering (just as we saw in Graphics Programming Module I) while child frames have to calculate their new matrix information manually as we descend the hierarchy. In reality though, both are experiencing the same thing -- offsetting and orienting with respect to their parent, which itself was offset with respect to its parent and so on up the chain. Also remember that while the root frame's matrix will often serve as the world matrix for any immediate child meshes of the root frame (again, the parent of the root frame is often going to be the world origin itself) we now know that this is not the case for meshes stored at subsequent child frames -- their world matrices must be generated by stepping down the tree to those frames, concatenating any direct or indirect parent matrices as we go.

Before wrapping up, let us step through our automobile example one more time, using some real values to try to clarify the important points.

If we reconsider Figure 9.1, we can imagine the root frame (we will assume the root frame has no specified parent in the scene and thus defaults to having the world origin as its parent frame) might have a matrix that stores a translation vector of (100,100,100). This then describes the center of the entire automobile as being at location (100,100,100) in world space. We will assume for now that the matrix contains no rotational information and that the car body has been designed such that its front faces down the world Z axis when no rotations are being applied. Now, let us assume that the wheels themselves are placed at offsets of 10 units along both the automobile's X and Z axes, such that the front driver's side wheel for example (wheel 1) is positioned (assuming a steering wheel on the left hand side) at offsets <–10,0,10> from the automobile center point, the front passenger wheel (wheel 2) is positioned at offset <10,0,10> from the automobile center point, the driver side rear wheel (wheel 3) is positioned at offset <–10,0,-10> and finally the passenger side rear wheel is located at offset <10,0,-10> from the automobile center point. Remember that the world space center point of the automobile is the root frame position described by its matrix.

Prior to our previous discussion, we might well have assumed that the information would be stored in the X file such that the matrices of each wheel frame would describe the absolute world space position

of that wheel. That is, it would have been easy to assume that the five matrices in this example had their translation vectors (the 4th row of each matrix) represented as:

Matrix Translation Vectors (This is not correct)

Root Matrix	= **100 , 100 , 100**	(The World Matrix of the Hierarchy)	
Wheel 1 Matrix	= **90 , 100 , 110**	(World Matrix offset by	–10, 0, 10)
Wheel 2 Matrix	= **110 , 100 , 110**	(World Matrix offset by	10, 0, 10)
Wheel 3 Matrix	= **90 , 100 , 90**	(World Matrix offset by	-10, 0, -10)
Wheel 4 Matrix	= **110 , 100 , 90**	(World Matrix offset by	10, 0, -10)

If the wheel frames contained absolute matrices such as these, which described the complete world space transformation for any child objects of the frame (the wheels in this example), then rendering the hierarchy would be very straightforward:

1. set root frame matrix as device World Matrix
2. render any child meshes of the root frame (the car body)
3. for each child frame of the root frame
4. set child frame matrix as device World Matrix (a wheel matrix)
5. render the wheel mesh for that child

While this is certainly easy enough to code (and in fact, we have done this throughout the last course module and in the last chapter), this is no longer the hierarchy we envisioned. In this case, all frames share the same parent since they are all defined relative to the same point in space (the world origin). What was a hierarchy has now devolved into a set of standard world space meshes. The relationship between the car body and the wheels exists in name only, for the children are not affected by changes to their assigned parent. In terms of their behavior, the world is their parent since that is what they are defined relative to.

However, if we were to examine the translation vector of each of the five matrices in a proper automobile X file, we would correctly find that the wheel matrices would actually describe transformations relative to their parent (the root frame in this case). Again, we would notice that the root frame has no parent frame so can be thought of as being a transformation relative to the origin of world space and serves as the base world matrix for the entire hierarchy:

Matrix Translation Vectors (Correctly stored relative matrices for child frames)

Root Matrix	= **100 , 100 , 100**	(The World Matrix of the Hierarchy)
Wheel 1 Matrix	= **-10 , 0 , 10**	(RootMatrix * Wheel1Matrix = 90 , 100 , 110)
Wheel 2 Matrix	= **10 , 0 , 10**	(RootMatrix * Wheel2Matrix = 110 , 100 , 110)
Wheel 3 Matrix	= **-10 , 0 , -10**	(RootMatrix * Wheel3Matrix = 90 , 100 , 90)
Wheel 4 Matrix	= **10 , 0 , -10**	(RootMatrix * Wheel4Matrix = 110 , 100 , 90)

Using the render approach described previously would obviously not work any longer. If we were to simply set wheel matrix 1 as the world matrix before rendering wheel 1 then the wheel would be rendered at world space position (–10,0,10) while the car body sits at position (100,100,100). Also, when we wish to move the automobile about in the world, ideally we only want to translate or rotate the

root frame and let the children experience these updates appropriately. As discussed previously, for this to work we must move through the hierarchy one level at a time, concatenating matrices as we go. So we would start at the root level, set the root frame's matrix and render any immediate child meshes -- in this case the car body. At this point the car body would be rendered at world space position (100,100,100). Next we would iterate through each child frame of the root. For each child frame we create a temporary matrix by multiplying its frame (i.e. parent-relative) matrix by the root frame matrix. In the case of wheel 1 for example, the translation vector of this combined matrix in the above example would now be (90,100,110). This clearly describes a world space position, but it also shows us that this wheel remains correctly offset (-10,0,10) from the current root frame position. We then set this temporary combined matrix as the device world matrix and render that wheel. We repeat this process for each additional wheel.

Since a given hierarchy could be many levels deep, we see right away that this concatenation/rendering approach would be nicely served by a simple recursive function call. When the matrix of any frame in the hierarchy is altered, these changes will automatically be propagated down through all child frames as we traverse the hierarchy and combine the matrices at each frame prior to rendering their immediate child meshes.

If we were to change the root frame matrix in our above example to some new position, then the next time we render the hierarchy and step through the levels of the hierarchy combining matrices, the world space positions of all the wheels would be updated too -- even though we do not physically alter the matrices of these child frames. This last point is important to remember. If our application were to alter the root frame matrix so that it now had a translation vector of <50,0,50>, then the next time the automobile is rendered using the concatenation technique just described we know certain things will be true. For starters, the car body would be rendered with its center point at (50,0,50). This is obvious because for the root frame meshes we simply set the root frame matrix as the world matrix. When we render the wheel 1 mesh, we create a temporary world matrix by combining the root frame matrix with the wheel 1 frame matrix (which still has a translation vector of <–10,0,10> and has not changed) and use this to render the wheel 1 mesh as before. This time, the combined matrix would have a translation vector which places the wheel at position (40,0,60) in the world, still an offset of (-10,0,10) from the root matrix position (50,0,50). So while the wheel matrices have not changed, the temporary matrices we generate to render the frame's meshes have changed. The result is that the wheels will automatically move along with the car body as expected and maintain their proper spatial positioning at all times.

Matrix Translation Vectors (Root Matrix now contains position 50,0,50)

Root Matrix	=	**50, 0, 50**	(The World Matrix of the Hierarchy)
Wheel 1 Matrix	=	**-10, 0, 10**	(RootMatrix * Wheel1Matrix = 40 , 0 , 60)
Wheel 2 Matrix	=	**10, 0, 10**	(RootMatrix * Wheel2Matrix = 60 , 0 , 60)
Wheel 3 Matrix	=	**-10, 0, -10**	(RootMatrix * Wheel3Matrix = 40 , 0 , 40)
Wheel 4 Matrix	=	**10, 0, -10**	(RootMatrix * Wheel4Matrix = 60 , 0 , 40)

The same logic holds true for any rotations or scaling we may apply to any matrix in the hierarchy. If we were to rotate the root frame 45 degrees clockwise about its local Y axis (by creating a Y axis rotation matrix and multiplying it with the root matrix), then when we traverse the hierarchy combining matrices as we go from level 1 to level 2, the temporary matrix created for each wheel will also rotate the wheel by the same amount. The offset of <–10,0,10> for wheel 1 for example is still preserved of course. The

result is that as the car body rotates, the wheels rotate too -- not about their own center points but about the center point of the car body. This is because the frame of reference they are defined in is experiencing its own local rotation, thus dragging its children along with it. This allows the children to remain in their correct position at all times.

Seeing some example code on how to traverse and render a hierarchy should cement all of this into place. This is not our final code of course because we have not yet discussed how to load the hierarchy from an X file or what support structures we may need, but we can imagine that each frame in the hierarchy could be represented using a structure a little like the following:

```
struct CFrame
{
      LPSTR             pFrameName;
      D3DXMATRIX        Matrix;
      CSomeMeshClass *  pMesh;
      CFrame *          pChildFrame;
      CFrame *          pSiblingFrame;
};
```

Keep in mind how the frames are connected together and that each frame contains a pointer to a mesh which is assigned to that frame. Everything stored in this frame, be they vertices or other frames are all children of the frame. That is, they are live in its local space and are defined relative to its origin and are affected by its orientation. In our example, if this was the root frame, then this mesh pointer would point to the model for the car body.

The pChildFrame pointer points to a linked list of child frames, but it is important to note that the linked list is not organized in the way you might expect. Rather, you should think of the pSiblingFrame member as being the pNext member of a traditional linked list and then visualize each tier in the hierarchy as a separate linked list. So the linked list of one level will be attached to its parent level using the pChildFrame pointer of the parent frame. Using our hierarchy as an example, the root frame would have its pSiblingFrame pointer set to NULL because the root frame is not actually part of any linked list of frames at that level in the hierarchy (there is only one frame at the root level – Level 0). The root frame's pChildFrame pointer would point to Frame1 (the first wheel), linking the root level to Level 1. Frame 1 would have its pChildFrame point set to NULL (as will frames 2, 3, and 4) because it has no additional child frames. However, Frame1 will connect to Frame2 via its pSiblingFrame pointer. Frame2 will have its pSiblingFrame pointer pointing to Frame3. Finally, Frame3 will have its pSiblingFrame pointer pointing to Frame4. Frame4 will have a NULL pSiblingFrame pointer since it is the end of the list at that level in the hierarchy.

In summary, the pChildFrame pointer for a given frame structure points to the first child frame in a linked list of child frames and represents another level in the tree. Each child frame in the linked list would be attached by their pSiblingFrame pointer. From this we can understand that all frames linked by their pSiblingFrame pointers belong to the same level in the hierarchy and share the same parent. Their transformation matrices will define their positions and orientations relative to the same frame of reference, which would be the world space position described by the parent frame. In our automobile example, the hierarchy has two levels: the first level contains only the root frame, the second level contains the four wheel frames. The wheels are all considered siblings because they share the same parent.

In order to render this hierarchy, we could use a recursive function like the following:

```
void DrawHierarchy(CFrame *pFrame, D3DXMATRIX *pParentMatrix,
                   IDirect3DDevice9 *pDevice )
{
    D3DXMATRIX  mtxCombined;

    if ( pParentMatrix != NULL)
      D3DXMatrixMultiply( &mtxCombined, &pFrame->Matrix, pParentMatrix);
    else
      mtxCombined = pFrame->Matrix;

    pDevice->SetTransform ( D3DTS_WORLD , &mtxCombined );
    pFrame->pMesh->Render( );

    // Move on to sibling frame
    if(pFrame->pSiblingFrame)
        DrawHierarchy(pFrame->pSiblingFrame, pParentMatrix, pDevice);

    // Move on to first child frame
    if(pFrame->pChildFrame)
        DrawHierarchy(pFrame->pChildFrame, &mtxCombined, pDevice);
}
```

There are a few key points to note about this code. First, we only need to call this recursive function once from our application, passing in the hierarchy root frame as the first parameter and NULL as the second parameter (because the root frame has no parent). Actually, this latter point is only true if we do not wish the root frame to move in our world in some way. If we wanted to translate the root frame, and thus the entire hierarchy, to some new location in the world, we can pass in a translation matrix as the second parameter. This represents a translation relative to the world frame of reference, which is the root frame's parent under normal circumstances.

Of course, we could simply modify the root frame matrix directly to generate the same result, but it is preferable not to do this. If we change the contents of the root frame matrix (which is virtually always an identity matrix), we make it more difficult to attach this hierarchy to a node in another hierarchy should we want to do so at a later time. For example, consider a machine gun hierarchy that contains moving parts. If we wanted to attach the root frame of the machine gun (assume the handle/grip is the root frame location in the gun model hierarchy) to a character's hand frame, then all we would have to do is make the machine gun root frame a child of the hand frame. If we kept the gun root frame matrix an identity matrix, then as the character moves his hand and passes those transforms down the tree, the matrix multiplication step would just give the machine gun root frame the same position/orientation as the character's hand (since the multiplication by identity just results in the same matrix). Thus attaching and detaching hierarchies to/from other hierarchies to build more complex hierarchy trees becomes a simple matter of pointer reassignment in a linked list.

However, to keep things simple, in the root node case for this example, pParentMatrix will be NULL. Therefore, the matrix of the root frame would not be combined and would instead be used directly as the world matrix for rendering the car body.

You should also note that it is possible for a single frame to contain more than one mesh, so we might imagine that the pMesh pointer actually points to a linked list of meshes attached to this frame. Thus calling the pMesh->Render function would actually step through all sibling meshes in the list and render them. Generally, artists will not design a model where several meshes belong to a single frame because we would have no individual control over these meshes since they would all share the same frame matrix. Applying an animation to the frame matrix would animate all the meshes that are stored in that frame, which is not something we usually want to do. In such an instance, it would probably make more sense for the artist to combine the multiple meshes into a single mesh and assign it to the frame as a single mesh. Either way, for now we can forget about the semantics of multiple meshes per frame because our example deals with only one mesh per frame.

As the code shows, after the child meshes of the current frame have been rendered, it is time to process any sibling frames this level in the hierarchy might have. As it happens, the root frame is the only frame in this level of the hierarchy and does not have any sibling frames. The frame's pSiblingFrame pointer would be set to NULL in this instance and so we move on.

Child frame processing is next. The root frame's pChildFrame pointer will point to Frame1 (in our example). So we call DrawHierarchy again (recursively) passing in as the first parameter the child frame (Frame1) and the root frame matrix as the second parameter (the parent matrix). Keep in mind that at this point the car body mesh has been rendered and the root frame has been totally processed.

As we enter DrawHierarchy for the second time, we are now dealing with Frame1 as the current frame and the root frame matrix is the parent matrix passed in as parameter two. We multiply the frame matrix with the parent matrix so that we now have a temporary combined matrix that contains the complete world space transformation for any meshes in this frame. This combined matrix is sent to the device as the current world matrix and the mesh attached to this frame is drawn (the Wheel 1 mesh in our example).

Next we test to see if this frame has a sibling frame, and indeed it has: Frame1's pSiblingFrame pointer will be pointing to Frame2. So we call the DrawHierarchy function again, passing in Frame2 as the first parameter and the parent matrix passed into this function as the second parameter.

This is a very important point to remember when processing siblings -- we do not pass in the combined matrix that we have just calculated because it is only relevant to the current frame and its children. We can see for example, that while Frame2 should be combined with the root frame matrix (its parent), it should not be combined with Frame1's matrix. So for each sibling that we process, we pass in and use the same parent matrix that was passed into that level of the hierarchy by the level above it. The root frame passed its matrix down to level 2 when it processed its child pointer; now this same matrix (the root frame matrix) is passed along to every sibling at that level and combined with their frame matrices to create their world space transforms.

The story obviously changes when processing child frames. When we call DrawHierarchy for a child frame, we are actually stepping down to the next level of the hierarchy for that particular frame. Therefore, any frames in the lower levels of that branch of the tree must have their matrices combined with the combination of matrices that went before them. If our Wheel 1 frame had a single child frame introducing a new level (a 3rd level) into the hierarchy, this new frame would be traversed down into

when we call DrawHierarchy for the child pointer of Frame1. In that case, we would pass the combined matrix (Frame1 * Parent), and not the initial parent matrix that is used to process siblings. The parent matrix passed into this child of Frame 1, would be (Frame1 Matrix * Root Matrix) which describes the world space position of its parent (Frame 1). It is this world space position that is the frame of reference for the matrix that would be stored in Frame 1's child. In summary, the process is as follows:

1. **For each frame**
2. **Combine frame matrix with parent matrix (if exists)**
3. **Render current frame's mesh(es) using combined matrix**
4. **Process all sibling frames (frames on the same level of the hierarchy). Pass them the same parent frame that the current frame was passed, so that they too can combine their matrices with the parent matrix.**
5. **Process the child frame of this frame. Pass in the new combined matrix that was used to render the mesh(es) at this frame. This effectively steps us down into the next level of the hierarchy for children of the current frame where the world space position generated for the current frame, becomes the frame of reference that any child frames have been defined relative too.**

Hopefully the concept of a spatial hierarchy now makes more sense to you. It is vital that you understand how these relationships work because we will encounter them again and again in graphics programming projects. Not only will we be dealing with spatial hierarchies here in this chapter, but we will see them again in the next two chapters and indeed throughout this entire series of courses. Make sure that you are comfortable with how a hierarchy works in theory as well as how to traverse and render one. In summary, we can think of a spatial hierarchy as a nested set of local space coordinate systems, where each local system is defined relative to the parent system it is attached to one level up in the tree. Also, do not forget that changes to a frame's matrix will automatically influence all of the world matrices generated for its children, since they are defined in its local space.

9.2 Frame Animation

To apply animation to a given frame, the most common approach is to assign it a unique **animation controller**. The animation controller's job is to ensure that the frame matrix to which it is attached is properly updated for the frame (i.e. it *controls* how the frame animation proceeds). Note that animations are generally going to be locally applied to a given frame (which in turns affects any children of course). In this section we will compose some simple code to help examine this process. To be clear, this will all be for illustration only -- we will not use any of this code in our applications. We will examine animation in much more detail in the next chapter, but for now, let us just get a high level understanding of the process since it illustrates the need for frame hierarchies and lets us see how they work.

Let us imagine that we wanted to rotate the four wheels of our example car by some fixed amount over time. We can do this by periodically applying transformations to the matrices of the wheel frames. In our example, each wheel frame requires local rotation updates at regular intervals and thus four animation controllers will be needed; one to manage each frame matrix. For the sake of this discussion, let us call this animation controller type a CAnimation. We will see later how this fits in with the D3DX

framework we will be using and thus we are going to get used to this naming convention early on. Our animation controller class (CAnimation) in this case could be very simple since it need only rotate the wheels about their center points.

```
class CAnimation
{
public:
    CFrame *pAttachedFrame;
    void Rotate ( float Degrees ) ;
};
```

Our CAnimation object is tasked with applying rotations to a single frame matrix. It contains a pointer to a frame in the hierarchy (i.e, the frame which it should animate) and a method that will build a rotation matrix to concatenate with the frame matrix whenever it is called. Calling this function multiple times will allow us to accumulate rotations for the frame by a specified number of degrees.

After the frame hierarchy is loaded at application startup and stored in memory as a tree of D3DXFRAME structures (we will see how to do this later in the chapter), we can call a function that searches through the hierarchy for the wheel frames and creates a CAnimation instance for each one. Again, our CAnimation object is a controller, attached to a single frame and used to manipulate its matrix to animate the frame (and thus its children). In a moment we will see how a global function might be constructed to traverse the frame hierarchy searching for the wheel frames and create new CAnimation objects which will be attached to each of them. For each animation, we will set its pAttachedFrame pointer to point at the wheel frame it is intended to animate.

> **Note:** When we use the D3DX library later to load a frame hierarchy from an X file, we will see that each frame will include a string storing its name. This is typically assigned to the frame by the artist or modeler who created the X file. This allows us to locate a frame in the hierarchy by searching for its name. In our hierarchy we can imagine that frames 1, 2, 3 and 4 would have the names 'Wheel 1', 'Wheel 2' , 'Wheel 3' and 'Wheel 4'. In the example code that follows we use the _tcsstr function to search for all frames that have the words 'Wheel' in their frame name.

As our four CAnimation objects will, in effect, combine to create a set of animation data for the automobile we will also write a simple container class that will handle the task of maintaining the list of animations. We will appropriately call this container a CAnimationSet. In our example, we will need to add four CAnimation objects to our CAnimationSet because we wish to animate the four wheels of our automobile (thus we wish four animations to be played).

```
class CAnimationSet
{
 public:
   CAnimation   **m_ppAnimations;
   DWORD          m_nNumberOfAnimations;

   void AddAnimation ( CAnimation pAnimation );
};
```

Once the X file data is loaded into the hierarchy we will call our CreateAnimations function (see below) to search for the four wheel frames and create, attach, and store our CAnimation objects. CreateAnimations would be recursive of course and need only be called once by our application. The

application will pass in a pointer to the root frame of the hierarchy to start the process, along with a pointer to an empty CAnimationSet object. Each CAnimation created by this function will be added to the CAnimationSet object.

```
void CreateAnimations ( CFrame *pFrame , CAnimationSet *pAnimationSet )
{
    CAnimation *pAnimation = NULL;
    if ( !pFrame )  return;
    if ( _tcsstr ( pFrame->pFrameName , "Wheel" )
    {
       pAnimation = new CAnimation;
       pAnimation->pAttachedFrame = pFrame;
       pAnimationSet->AddAnimation ( pAnimation );
    }

    if ( pFrame->pSiblingFrame ) CreateAnimations (pFrame->pSiblingFrame);
    if ( pFrame->pChildFrame   ) CreateAnimations (pFrame->pChildFrame);
}
```

When the above function returns, the application's CAnimationSet object will have an array of four pointers to CAnimation objects (one for each wheel frame) and its m_nNumberOfAnimations member will be set to 4. Notice that the CreateAnimations function adds a newly created animation to the animation set using the CAnimationSet::AddAnimation member function. We will not show any code for this function but we can imagine that it might be a simple housekeeping function that resizes the m_ppAnimations array and adds the passed CAnimation pointer to the end of it.

Once our main game loop is running, we will need to animate and render the hierarchy. The animation update might take place in a separate application-level animation function (ex. AnimateObjects) or it could take place as we traverse the hierarchy for rendering. If we were going to use the latter approach, then each frame would have to know about its assigned controller so that it could run its update on the spot, prior to concatenating with its parent matrix. If we are going to do the animation updates before the hierarchy traversal, then this is not necessary. For example we could write a function that loops through all of the animations in the animation set and calls their Rotate functions like so:

```
void AnimateObjects ( float AngleInDegrees )
{
      for ( DWORD i = 0 ; i < pAnimationSet->m_nNumberOfAnimations; i++ )
      {
            CAnimation *pAnimation = pAnimationSet->m_ppAnimations[i];
            pAnimation->Rotate( AngleInDegrees );
      }
}
```

This function would ensure that all of the frame matrices were updated by their attached animation controllers prior to the hierarchy traversal. The CAnimation::Rotate method would be responsible for applying a local rotation for the frame to which it is attached. Again, this will ultimately wind up rotating all child frames and child meshes as well, once we do our hierarchy traversal.

In our example it is assumed that each wheel mesh has been defined in its own model space such that its center is at the origin and it is facing down the positive Z axis. We can think of the model space X axis

as being the axle on which the wheel rotates. Thus, we wish the animation object to rotate its attached wheel around the wheel frame's local X axis. In this case, we might imagine our CAnimation::Rotate method to look something like this.

```
void CAnimation::Rotate ( float Degrees )
{
   D3DXMATRIX  mtxRotX;
   D3DXMatrixRotationX( &mtxRotX , D3DXToRadian (Degrees) );
   D3DXMatrixMultiply(&pAttachedFrame->Matrix, &mtxRotX, &pAttachedFrame->Matrix);
}
```

As you can see, the function will first build an X axis rotation matrix. This will then be multiplied with the relative matrix of the attached frame, the result of which will replace this frame matrix. The order of the matrix multiplication is significant. We wish to rotate the wheel about its own X axis and then combine it with the current matrix of the frame so that the rotated wheel is then translated out to its position relative to the parent frame *after* being rotated. Therefore, we do (RotMatrix * FrameMatrix) so that the final matrix first rotates any children around their local X axis and then positions them relative to the parent frame of reference.

In our current example, each time the Rotate function is called, the matrices belonging to the wheel frames will store cumulative rotations. That is, the rotation is permanent and the frame matrix contents are directly modified (not done in a temporary matrix) by the attached CAnimation object. This may or may not be desirable depending on the circumstances, but it illustrates the point and works fine.

Rendering the newly animated hierarchy is no different than the code we saw previously. All our CAnimation objects have done is modified the relative matrix stored in the frame for which each is attached. We still start at the root and work our way down through the levels, combining the matrices of each frame with their parent. When we reach the frame for wheel 1, the parent matrix will be combined with the newly rotated frame matrix to create the frame world matrix and the wheel will be rendered. It will still be in its correct position relative to the car (wherever we may have moved the root frame to in the world) but will have been successfully rotated about its own center point.

Again you are reminded that these localized rotations affect all children for a frame – meshes and other child frames alike. For example, imagine that our car representation has another frame containing the mesh of a wheel hubcap attached to wheel 1 as a child (Fig 9.2).

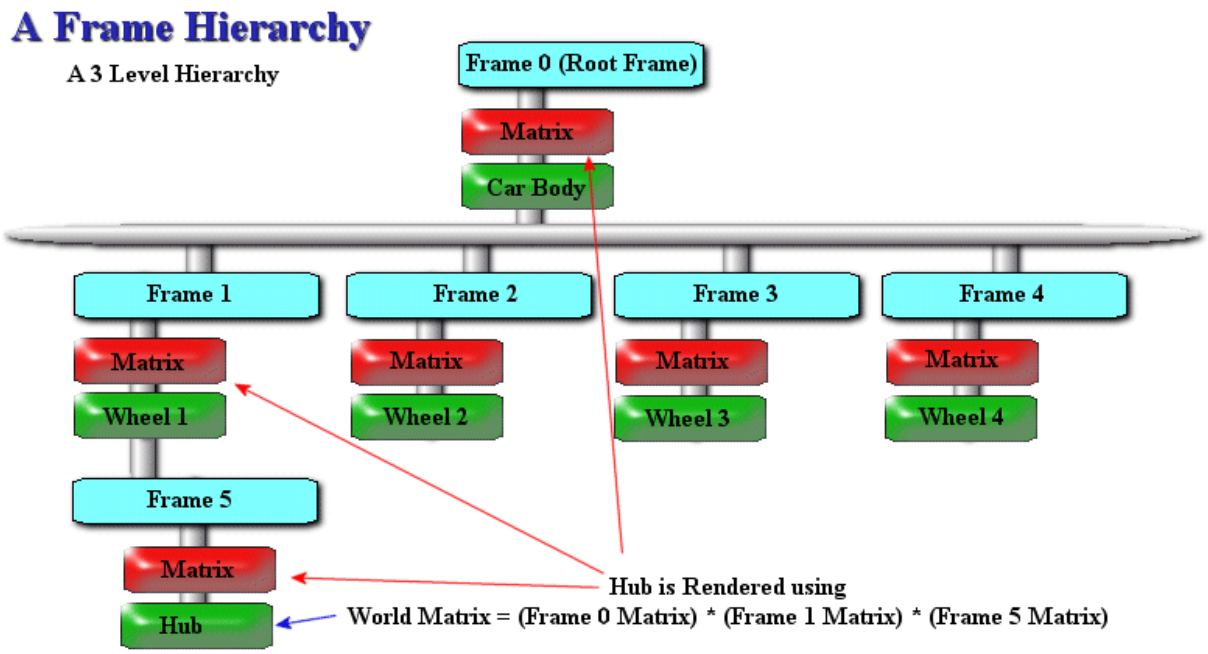

Figure 9.2

When we arrive at Frame 5 in our tree, the DrawHierarchy function will have been passed a parent matrix from the previous recursion (when processing Frame 1). That matrix will actually be the root frame matrix combined with the Frame 1 matrix. If the animation attached to Frame 1 rotated its assigned frame matrix, then this rotation will be propagated down to the hubcap frame as well and the hubcap will rotate along with its parent. This is as it should be of course since the hubcap is defined in the (now modified) local space of its parent.

As we will see later in this course, it is precisely this characteristic of a hierarchy that makes them perfect candidates for modeling articulated structures like game characters. It is easy to see the hierarchical relationship between the parts of the human body. The upper arm (origin = shoulder) would have the forearm (origin = elbow) as a child frame. The forearm would have the hand (origin = wrist) as its child frame and the hand would have five finger frame children (which might themselves be jointed and linked in a similar manner). If we wanted the model to raise its arm in the air by rotating about the shoulder, we could simply have a CAnimation object attached to the upper arm frame generate a local rotation matrix and use it to transform the frame (by multiplying it with the upper arm frame matrix). As a result, all of the children will move as expected since the rotation is propagated down through the hierarchy during our tree traversal.

So in summary, we now understand what a hierarchy is and we should be to see how an artist might design a scene or an object, not as a single mesh, but as a number of different meshes which are all spatially positioned and oriented relative to one another. These meshes are stored in frames, where each frame will have a transformation matrix that will not represent an absolute world transformation but a relative transformation describing the relationship of its own local system with its parent frame. The exception to the rule is the root frame which initially has no parent. The root frame matrix can instead be thought of as storing the core model space coordinate system (i.e. the base reference frame) from which

the rest of the hierarchy proceeds. This means that it can serve as a world space transformation for the entire hierarchy if it takes on values other than identity.

We also know that when we render the hierarchy we must process each frame, combining its matrix with the current combined matrix containing the concatenation of all the higher level frames in the hierarchy linked via its parent. We examined how to render the siblings and child frame objects for each frame using the parent matrix and the combined frame matrix respectively. Finally, we learned that because the matrices for our frames are not absolute, we can very easily animate individual frames in the hierarchy in their own local space and watch those animations propagate down through the subsequent levels of the tree. We used the concept of animation objects (CAnimation) to handle the animation (matrix updating) of the frame to which it is attached.

Finally, we discussed that a set of frame animations could be intuitively packaged together to represent an animation set. While the discussion of CAnimation and CAnimationSet classes may have seemed trivial since the animation data could be contained in any arbitrary structures, getting used to the idea of how these objects work with the frame hierarchy will greatly help us in understanding the loading of multi-mesh X files. It will also help us understand the animation system that D3DX provides to assist with the animation of frame hierarchies.

Unfortunately, when we load an X file using D3DXLoadMeshFromX or its sibling functions, any hierarchy information stored in the file is discarded. Instead, the function traverses the hierarchy in the file, applying the relative transformations so that all of the vertices in all of the meshes in the file are now in their model space positions. At this point, the mesh information has now been correctly transformed and collapsed into a single mesh object which is returned to the caller. So in the case of our automobile hierarchy, D3DXLoadMeshFromX would correctly offset each of the wheels from the car body mesh, but then collapse it all into a single mesh object, discarding the entire hierarchy. While the single mesh will look correct when not in motion, because the wheels are not separate meshes, we have lost the ability to animate them independently from the rest of the car.

Not to worry though, we do have some solutions at our disposal that allow for preservation of the hierarchy. As this chapter progresses, we will begin to examine some of our options. To get things started, the best place to begin is by looking more closely at the way our data is going to be stored. So in the next few sections we will examine X files in some detail.

9.3 X File Templates

Before DirectX 9.0, hierarchical scenes stored in X files had to be loaded and parsed manually using a set of packaged COM objects. These COM objects still exist today and they can continue to be used to parse X files, but as of DirectX 9.0, the D3DX library contains a function called D3DXLoadMeshHierarchyFromX that automates the entire process. The complete hierarchy is loaded (all child frames, meshes, textures, materials, and so on) in such a way that it still affords our application complete control over how the hierarchy data is allocated in memory. This level of insulation is certainly welcome and it will save us a good deal of coding and debugging, but it is still helpful to be at least somewhat familiar with how the data is stored in the X file and how it can be extracted. That is the purpose of this section.

The X file format is essentially a collection of templates. A **template** is a data type definition, very similar to a C structure, describing how the data for an object of a given type is stored in the file. Just as a C structure describes how variables of that type will have their member variables arranged in memory, an X file template describes how data objects with the same name (and GUID) will have their data laid out in the file. Once we know how to inform DirectX about the components of a template, the X file loading functions will recognize objects of that type in the file, know exactly how much memory is required, and understand how to load the data. The X file format is actually similar to the IWF format in many ways. We can think of a data object in the X file as the equivalent of the IWF chunk. Just as there are many different chunk types in the IWF format for representing different types of information, there are different data objects in an X file represented as templates. IWF chunks can also have child chunks, just as X file templates can have child templates for data objects.

For example, the X file Frame template can have many different types of child templates: the TransformationMatrix data type (which is the matrix for a frame in the hierarchy) and the Mesh data type (of which there can be many) are common examples. The Frame can also have other Frames as children, which we now know is the means by which a hierarchy is constructed.

As in the IWF format, you can also create custom data templates that are understood by your own application, but are not a part of the X file standard. For example, you could have a PersonalDetails template which contains a name, address, and telephone number, turning the X file into a standard address book (not that we would likely do such a thing). When the D3DXLoadMeshHierarchyFromX function encounters a custom data object, it will pass the custom data to your application using something similar to a callback function. This gives the application a chance to process that data.

Fortunately, we will not have to create our own templates to load a hierarchical X file. When using the D3DX library supplied X file loading functions, the standard templates are registered automatically. We will be studying some of the standard templates in this lesson to get a feel for how a hierarchy is laid out in the X file, but for details on all standard templates (Table 9.1), look at the SDK documentation in the section *DirectXGraphics / Reference / X File Reference / X File Format Reference / X File Templates*.

Table 9.1: X File Standard Templates

• Animation • AnimationKey • AnimationOptions • AnimationSet • AnimTicksPerSecond • Boolean • Boolean2d • ColorRGB • ColorRGBA • Coords2d • DeclData • EffectDWord • EffectFloats • EffectInstance • EffectParamDWord • EffectParamFloats • EffectString • FaceAdjacency • FloatKeys • Frame • FrameTransformMatrix • FVFData • IndexedColor	• Material • Matrix4x4 • Mesh • MeshFace • MeshFaceWraps • MeshMaterialList • MeshNormals • MeshTextureCoords • MeshVertexColors • Patch • PatchMesh • PatchMesh9 • PMAttributeRange • PMInfo • PMVSplitRecord • SkinWeights • TextureFilename • TimedFloatKeys • Vector • VertexDuplicationIndices • VertexElement • XSkinMeshHeader

Note: We will not need to register these standard templates with DirectX. In fact, even if we use custom objects in our X file which are not part of the standard, we do not have to register those either. We can simply store the template definitions at the head of the X file itself (just underneath the standard X file header) and the Direct X loading functions will automatically register them for us before it parses the file. More on this momentarily...

9.3.1 X File Components

At the top of every X file is a small line of text which looks something like this:

Xof 0303txt 0032

This value is written to the file by the modeling application and serves as a signature to identify the file to the loading application as a valid X file. The ‘Xof’ portion identifies it as an X file. The ‘0303’ text tells us that this X file was built using the X file version 3.3 templates. Following the version number is ‘txt’, which tells us that this file is a text file. X files can also be stored in binary format, and if this is the case then we would see ‘bin’ instead. Finally, the file signature line ends with ‘0032’ which tells us the file uses 32-bit floating point values instead of 64-bit floats.

We never have to read or parse this line manually as it is handled by the D3DX loading functions and the appropriate action will be taken. The following example shows the signature of a binary X file created using the version 3.2 templates with 64-bit floating point precision:

Xof 0302bin 0064

Following the signature there may be a list of template definitions that describe the data format for objects found in the file. This will typically be the case only if the X file uses custom data objects, but it is possible that some X files may include template definitions that are part of the standard.

X files contain three types of data objects: **top level**, **child**, and **child data reference**. A data object is a packet of information stored in the format of a registered template. Let us have a look at a very simple X file to see what a data object is and how it is stored. This example will use a common top level data object: a Mesh. The Mesh will contain a child data object for defining a Material. First we will look at the DirectX standard templates for both a Mesh and a Material.

```
template Mesh
{
        <3D82AB44-62DA-11cf-AB39-0020AF71E433>
        DWORD   nVertices;
        array   Vector vertices[nVertices];
        DWORD   nFaces;
        array   MeshFace faces[nFaces];
        [ ... ]                         // An open template
}
```

The template above is of type ‘Mesh’ and this is the name we would use to define instances of this object in the X file. The first member of any template is its GUID. Every template must include a GUID so that it can be uniquely identified. This prevents name mangling when a custom template shares the same name as another custom template or one of the standard templates. Keep this requirement in mind if you develop your own custom templates.

You can generate a GUID using the ‘Guidgen.exe’ tool that ships with the Microsoft visual C/C++ compiler. You can find it in the ‘\Common\Tools’ directory of your MSVC installation. Fig 9.3 shows the tool in action.

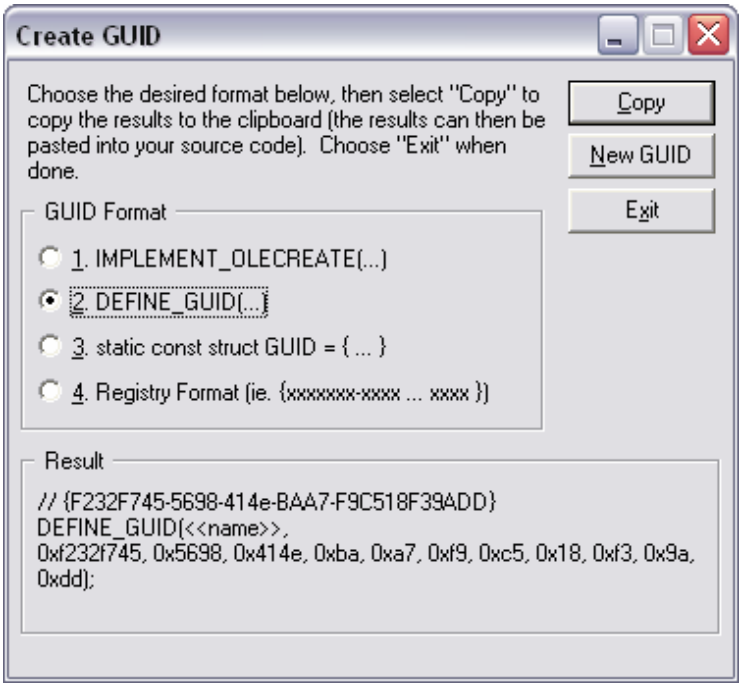

Figure 9.3

Guidgen uses a combination of parameters (hardware serial numbers, current date/time, etc.) to generate an ID that is guaranteed to be unique throughout the world. If for some reason you do not like the GUID it generates, you can simply hit the 'New GUID' button to build another one. In Fig 9.3 the second radio button selected helps format the GUID in the result window so that you can cut and paste it into an application. If we were to generate a GUID for a custom template called Contact, we would include it in the definition like so:

```
template Contact
{
     < F232F745-5698-414e-BAA7-F9C518F39AD >
     STRING Name;
     STRING Address1;
     STRING Address2;
     STRING PhoneNumber;
     DWORD Age;
}
```

Here we have simply copied over the top line of the Guidgen result pane and removed the two forward slashes and replaced the curly braces with chevrons.

When we use the D3DXLoadMeshHierarchyFromX function to load an X file, all standard templates will be recognized by their GUIDs and loaded on our behalf. In the case of a custom data object, something more akin to a callback function will be used instead. The application defined callback function (which will be triggered by D3DX when a custom template is encountered) will check the GUID that is passed and determine whether or not it matches a custom template the application would like to support. The application can skip this data if it does not match.

The DEFINE_GUID macro stores GUID information in a structure with a name that you can assign so that you can do fast GUID comparison tests. For our Contact template example above:

```
// {F232F745-5698-414e-BAA7-F9C518F39ADD}
DEFINE_GUID(ID_Contact, 0xf232f745, 0x5698, 0x414e, 0xba, 0xa7, 0xf9, 0xc5, 0x18,
0xf3, 0x9a, 0xdd);
```

This might look like a complex way to assign a name to a GUID at first, but if you examine the Guidgen result window, you will see that the code is the same. We have simply substituted ID_Contact in the <<name>> section.

With this alias defined, our application callback mechanism can do a quick test to determine whether to process a data object passed from a D3DX loading function:

```
if( *pDATAGUID == ID_Contact ){ // Process the objects data here }
```

Again, for standard templates, these steps are unnecessary. All standard templates such as the Mesh template we are discussing will be identified automatically by D3DXLoadMeshHierarchyFromX and loaded on our behalf.

Let us take another look at the standard Mesh template and continue our discussion of its members.

```
template Mesh
{
        <3D82AB44-62DA-11cf-AB39-0020AF71E433>
        DWORD   nVertices;
        array Vector   vertices[nVertices];
        DWORD   nFaces;
        array MeshFace faces[nFaces];
        [ ... ]                         // An open template
}
```

The basic building blocks for a template are the data types that it stores. For example, we see that the first data member after the GUID in this template is a DWORD which describes how many vertices are in the mesh. Table 9.2 presents a list of all of the basic data types you can use in a template.

Table 9.2: Template Data Types

Type	Size
WORD	16 bit integer
DWORD	32 bit integer
FLOAT	32 bit floating point value
DOUBLE	64 bit floating point value
CHAR	8 bit char
UCHAR	8 bit unsigned char
BYTE	8 bit unsigned char
STRING	NULL terminated string

We can also specify arrays of the supported types or even other templates using the **array** keyword. A good example is the array of Vector objects in the mesh which contains one Vector for each mesh vertex. The Vector template is another standard template:

```
template Vector
{
   < 3D82AB5E-62DA-11cf-AB39-0020AF71E433 >
    float x;
    float y;
    float z;
}
```

The preceding nVertices DWORD (in the Mesh template) describes the number of items in the vector array that follows. This is the pattern that will be followed when arrays are used in a template. In this example it describes the number of vertices the Mesh object contains followed by an array of that many Vector data objects.

Following the Mesh vertex array is another DWORD that describes how many faces are in the Mesh. That value is followed by an array of MeshFace objects (another standard template).

```
template MeshFace
{
   < 3D82AB5F-62DA-11cf-AB39-0020AF71E433 >
    DWORD nFaceVertexIndices;
    array DWORD faceVertexIndices[nFaceVertexIndices];
}
```

This object type describes a single face in a mesh. The first member is a DWORD describing how many vertices the face uses (3 for a triangle, 4 for a quad, etc.) and it is followed by an array of that many DWORDs. Each DWORD in the array is the **index** of a vertex in the Vector array just discussed.

All of these components describe the Mesh object in its most basic form and every Mesh object must have the previously discussed components (a vertex and face list). At the bottom of the Mesh template we have a set of square brackets with ellipsis in between. This indicates that the Mesh template is an *open template* format that can include any type and any number of additional data objects.

9.3.2 Open, Closed, and Restricted Templates

Some templates will include child objects, and others will not. Templates that cannot include children are considered **closed**. This is the default template type. Conversely, templates that allow for any child type and number are called **open** templates. The Mesh template is an example of an open template. The third type of template can have child objects, but only of specific types specified by the template. These are called **restricted** templates and they must specifically list the templates that are legal child objects. A restricted template can have any number of the data objects specified by the template as embedded child data objects.

When a template is closed it cannot have any children. If children are somehow included in a closed template, they will be ignored by the loading code. The following example will demonstrate what this means. We start with two example templates:

```
template Matrix4x4 {
  <DED0E885-ED92-4224-A090-E81FC8AB2B83>
  array FLOAT Matrix[4][4];
}

template TestTemplate {
  <A96F6E5D-04C4-49C8-8113-B5485E04A866>
  DWORD Flags;
}
```

At the moment, these are closed templates. But we can certainly imagine a situation where an object like the following could be useful:

```
TestTemplate ChildTest {
  0;                    // Flags
  Matrix4x4 MyMatrix    // Matrix
  {
      1.0; 0.0; 0.0; 0.0;
      0.0; 1.0; 0.0; 0.0;
      0.0; 0.0; 1.0; 0.0;
      0.0; 0.0; 0.0; 1.0;;
  }
}
```

Given the previous template definitions, this is not legal. Technically we can do it, but the D3DX loading functions would completely ignore the matrix data because the TestTemplate definition described a closed data object which cannot have child objects (the Matrix4x4 object above) embedded. However, if we were to use ellipsis in the template definition to open the template, our usage above becomes completely legal:

```
template TestTemplate {
  <A96F6E5D-04C4-49C8-8113-B5485E04A866>
  DWORD Flags;
  [ ... ]
}
```

You may have noticed the additional semi-colon at the end of the child matrix data object in the above example. This was not a typo -- it signifies the end of a child object within a parent data object. Therefore, we have a semi-colon separating each member of the matrix plus an additional semi-colon denoting the end of the matrix data object within the outer data object. There is some helpful discussion of the usage of commas and semi-colons in the SDK documentation.

The use of the ellipsis is much like their use in C/C++: they indicate that some variable set of data can be included. To restrict the legal child types for a template (therefore creating a restricted template type), we simply include the list of types within the square brackets:

```
template TestTemplate {
  <A96F6E5D-04C4-49C8-8113-B5485E04A866>
  DWORD Flags;
  [ Matrix4x4, Vector3 ]
}
```

The comma separated list for a restricted template can include type names with optional GUIDs:

```
[ Matrix4x4 <DED0E885-ED92-4224-A090-E81FC8AB2B83>, Vector3 ]
```

Using a GUID is not required, but it can be a good idea to avoid ambiguity if new templates are introduced that cause a name clash. It also provides the ability to overload templates with the same name and restrict children to a specific type.

Describing the X file format layout is not easy and often is best accomplished with a simple example of an actual X file.

X File Sample 1: Basic Mesh

Here we see the contents of an actual X file that contains a single top level data object (a Mesh). Notice how the data is laid out in the exact format described by the Mesh template discussed earlier.

```
Xof 0303txt 0032

mesh{
  6;              // Number of vertices
 -5.0;-5.0;0.0;,  // Vertex list ( Vector array )
 -5.0;5.0;0.0;,
  5.0;5.0;0.0;,
  5.0;-5.0;0.0;,
 -5.0;5.0;-5.0;,
 -5.0;5.0;5.0;;

  2;              // Number of faces
  3;0,1,2;,       // MeshFace Array
  3;3,4,5;;
}
```

This example contains no color information or vertex normals, but it does define a basic mesh and provide the core requirements discussed previously.

Since the Mesh template is open, we can embed any child data objects we wish, although only a certain subset of child data objects will be understood by the D3DX loading functions. So let us take a look at another standard X file template that defines a material just like the D3DMATERIAL9 structure we looked at in Chapter Five of Module I.

```
template Material
{
  < 3D82AB4D-62DA-11cf-AB39-0020AF71E433 >
    ColorRGBA  faceColor;
    float      power;
    ColorRGB   specularColor;
    ColorRGB   emissiveColor;
}
```

Notice that the standard Material template does not include an Ambient member. We actually mentioned this in passing in Chapter Eight, and now we see this to be true at the low level. The D3DXLoadMeshFromX function could not return ambient information for each material used by the mesh being loaded because the material data objects used to describe mesh materials in the X file have no ambient member.

The faceColor member of the Material template is equivalent to the Diffuse color member of the D3DMATERIAL9 structure. This is represented using the standard template ColorRGBA seen next. The specular and emissive members use the standard template ColorRGB, also shown next. We are already familiar with how the DirectX lighting pipeline deals with materials and, with the exception of the missing ambient component, the X file material data object describes material properties in the same way as its D3DMATERIAL9 counterpart. It is the data stored within these data objects that the D3DXLoadMeshFromX function returns in its D3DXMATERIAL array.

The ColorRGBA Template	The ColorRGB Template

`template ColorRGBA`
`{`
`<35FF44E0-6C7C-11cf-8F52-0040333594A3>`
`  float red;`
`  float green;`
`  float blue;`
`  float alpha;`
`}`
	`template ColorRGB`
	`{`
	`  <D3E16E81-7835-11cf-8F52-0040333594A3>`
	`   float red;`
	`   float green;`
	`   float blue;`
	`}`

We will now expand our X file example by adding a material data object as a child of the mesh.

X File Sample 2: Basic Mesh with Material

```
Xof 0303txt 0032

mesh{
    6;              // number of vertices
   -5.0;-5.0;0.0;,  // vertex list
   -5.0;5.0;0.0;,
    5.0;5.0;0.0;,
    5.0;-5.0;0.0;,
   -5.0;5.0;-5.0;,
   -5.0;5.0;5.0;;

    2;            // number of faces
    3;0,1,2;,     // face list
```

```
    3;3,4,5;;

    Material {     // child data object of mesh
      1.000000;1.000000;1.000000;1.000000;;
      0.000000;
      0.000000;0.000000;0.000000;;
      0.000000;0.000000;0.000000;;
    }
}
```

Here we see a top level object (the Mesh) with one child (the Material). The mesh is considered a top level object because it has no parent. That is to say, it is not embedded in any other data object.

Defining materials as direct children of objects like this means that this material object belongs to, and can only be referenced by, this mesh. While this is sometimes the case, most of the time X files will represent materials (and other children) as **data reference objects**. A data reference object is used to save space. If the X file contained five meshes that all required the same material, we can save space by creating the material once at the top of the X file as a top level data object and assigning it a name (a reference). All meshes that use the material can use the name as a reference, much like the concept of instances we looked at in previous lessons. This is obviously much more memory space efficient than defining the same material data object in each of the five separate meshes.

This next example uses the same basic X file, but this time the material is defined as a top level object and assigned a name so that any number of meshes in the file would be able to reference it.

X File Sample 2: Basic Mesh with Material Reference

```
Xof 0303txt 0032

Material WhiteMat {     // This is a Data Object
   1.000000;1.000000;1.000000;1.000000;;
   0.000000;
   0.000000;0.000000;0.000000;;
   0.000000;0.000000;0.000000;;
}

mesh{                   // This is a Data Object
    6;                  // number of vertices
   -5.0;-5.0;0.0;,      // vertex list
   -5.0;5.0;0.0;,
    5.0;5.0;0.0;,
    5.0;-5.0;0.0;,
   -5.0;5.0;-5.0;,
   -5.0;5.0;5.0;;
    2;             // number of faces
    3;0,1,2;,      // face list
    3;3,4,5;;

   {WhiteMat}     // Data Reference Object as a child of the mesh Data Object
}
```

We can use any top level data object as a child of another object (assuming we have given the data object a name) by placing the name in between two curly braces. In the previous example, the line '{WhiteMat}' signifies that WhiteMat is the first material used by this mesh. D3DX supplied loaders automatically handle cases for both child objects and child reference objects. However, the same rules still apply for closed and restricted templates. References will only be valid in open templates or if explicitly included in the type list for a restricted template.

In the previous examples, we saw both a material data object and a material data reference object being embedded as a direct child of the mesh object. While this was a nice illustration of the concept, most meshes will not assume either form. Meshes will often use multiple materials (recall the subset discussion from Chapter Eight), and they will need to be mapped to faces in the mesh. So instead, there will be a single material list data object stored inside each mesh and the material objects (or material references) will be stored inside this object. The MeshMaterialList standard template contains a list of materials used by the mesh as well as the face mapping information:

```
template MeshMaterialList
{
    < F6F23F42-7686-11cf-8F52-0040333594A3 >
        DWORD nMaterials;
        DWORD nFaceIndexes;
        Array DWORD FaceIndexes;
       [Material]
}
```

The first DWORD describes how many Material data objects are embedded as child data objects or child data reference objects of this material list object. This is followed by the number of faces the material list affects. This will usually be equal to the number of faces in the entire face list of the mesh unless there is only one material and then nFaceIndexes=1 (indicating that this single material should be applied to all faces in the mesh). Following this is an array of DWORDS describing which material is applied to which face. Each element in this array is a zero-based index describing a material from a list of child materials that will be embedded in this object. This is a restricted template that can only have Material objects as children.

X File Sample 3: Basic Mesh with Reference Based MeshMaterialList

Our next example will embed a MeshMaterialList in a Mesh object and the material list will have two Material children. We can see the way that X files work using a hierarchy of sorts, even when it is not a spatial one. Also note that the Mesh and the Materials are top level data objects and that we are **referencing** the materials from within the MeshMaterialList.

```
Xof 0303txt 0032

Material WhiteMat{  // Top Level Data Object
   1.000000;1.000000;1.000000;1.000000;;
   0.000000;
   0.000000;0.000000;0.000000;;
   1.000000;0.000000;0.000000;;
}
Material RedMat{    // Top Level Data Object
   0.000000;0.000000;1.000000;1.000000;;
```

```
   0.000000;
   0.000000;0.000000;0.000000;;
   0.000000;0.000000;1.000000;;
}
mesh{               // Top Level Data Object
   6;               // Number of vertices
  -5.0;-5.0;0.0;,   // Vertex list
  -5.0;5.0;0.0;,
   5.0;5.0;0.0;,
   5.0;-5.0;0.0;,
  -5.0;5.0;-5.0;,
  -5.0;5.0;5.0;;
   2;               // Number of faces
   3;0,1,2;,      // Face list
   3;3,4,5;;      // Second Face

   MeshMaterialList {   // child data object of Mesh
     2;                 // Two materials in the list
     2;                 // Two faces in the following material face list

     0,                 // the first face uses Material 0
     1;;                // the second face uses Material 1

     {WhiteMat}
     {RedMat}

   }// End Material list

}// end of mesh object
```

As we can see here, the mesh has as a child data object: the MeshMaterialList data object. As specified by the template, its first value describes the number of materials that will be assigned to this list (2). This is followed by the number of faces in the mesh which will have materials assigned to them (two in this example). Following this information is the index data that describes for each face, which material it uses in the list that follows. The first face index is zero which describes the first face in the mesh as having ‘WhiteMat’ (Material 0) assigned to it. The second face index is a value of 1 meaning it has been assigned the second material (Material 1) in the list ‘RedMat’. Following the index list is the list of materials belonging to the material list and for which the indices above it are relevant. In this example, the materials are referenced and are actually defined as top level objects at the head of the file. This will allow any other meshes which may also be represented in the file to reference these same materials in their material list data objects, thus saving storage space.

X File Sample 4: Basic Mesh with Reference Based MeshMaterialList

For the sake of completeness, let us see the same example again, but with the materials embedded in the MeshMaterialList data object rather than treated as top level data objects.

```
Xof 0303txt 0032

mesh{
 6;               // number of vertices
-5.0;-5.0;0.0;,   // vertex list
```

```
-5.0;5.0;0.0;,
 5.0;5.0;0.0;,
 5.0;-5.0;0.0;,
-5.0;5.0;-5.0;,
-5.0;5.0;5.0;;
 2;         // number of faces
 3;0,1,2;,  // face list
 3;3,4,5;;

 MeshMaterialList
 {    // child data object of Mesh
   2; // Two materials in the list
   2; // Two faces in the following material face list

       // material face list
   0,  // the first face uses Material 0
   1;; // the second face uses Material 1

   Material { // Material 0,child data object of MaterialList
   1.000000;1.000000;1.000000;1.000000;;
   0.000000;
   0.000000;0.000000;0.000000;;
   0.000000;0.000000;0.000000;;
   }
   Material { // Material 1, child data object of MaterialList
   1.000000;0.000000;0.000000;1.000000;;
   0.000000;
   0.000000;0.000000;0.000000;;
   0.000000;0.000000;0.000000;;
   }
 } // end material list

}// end of mesh object
```

The current example is a fairly complete X file. Indeed, if your meshes do not contain any textures, texture coordinates, or vertex normals, then your meshes might look very similar to this. You should try opening up some text based X files and examining them to get a better understanding of the format and the way that custom data objects have their templates listed at the top of the file.

To continue, let us look at how texture information would be stored for a mesh in an X file. We know from our last chapter that texture pixel data is not stored inside the X file (although you could create a custom template to store image data directly), only the file name is stored. Recall that D3DXLoadMeshFromX passed back a buffer of D3DXMATERIAL structures, where each element contained a D3DMATERIAL9 and a texture file name. We can assume then that in X files, texture and material data can somehow be paired together, and this is indeed the case -- instead of each face having a separate material and texture index, the Material object we just studied will now contain a TextureFilename child object. Material objects can still exist on their own without texture filename objects inside them (as seen previously), but often, a Material will describe a material/texture combination used by faces in the mesh.

The TextureFilename data object is a simple one that contains a string describing the name of the texture image file.

```
template TextureFilename
{
  < A42790E1-7810-11cf-8F52-0040333594A3 >
    string filename;
}
```

Let us now update our example to see what our mesh would look like in X file format if we now used materials that also referenced textures.

X File Sample 5: Materials storing Texture Filenames

```
Xof 0303txt 0032

Material BrickMat{            // Top Level Data Object
1.000000;1.000000;1.000000;1.000000;;
0.000000;
0.000000;0.000000;0.000000;;
1.000000;0.000000;0.000000;;
Texture Filename {“BrickWall.bmp”;}
}

Material WaterMat{            // Top Level Data Object
0.000000;0.000000;1.000000;1.000000;;
0.000000;
0.000000;0.000000;0.000000;;
0.000000;0.000000;1.000000;;
TextureFilename {“WaterTexture.bmp”;}
}

mesh{             // Top Level Data Object
  6;              // Number of vertices
 -5.0;-5.0;0.0;,  // Vertex list
 -5.0;5.0;0.0;,
  5.0;5.0;0.0;,
  5.0;-5.0;0.0;,
 -5.0;5.0;-5.0;,
 -5.0;5.0;5.0;;
  2;        // Number of faces
  3;0,1,2;, // Face list
  3;3,4,5;;

  MeshMaterialList {// Child data object of Mesh
   2;               // Two materials in the list
   2;               // Two faces in the following material face list

   0,               // the first face uses Material 0
   1;;              // the second face uses Material 1

   {WallMat}
   {WaterMat}

  }// End Material list
```

```
}// end of mesh object
```

When we look at the Material data objects which contain both color and texture information, we understand that it is exactly this information which the D3DXLoadMeshFromX function returns to our application in the D3DXMATERIAL array. Each element in this array describes the texture and material combination for a subset of faces in the mesh.

As we learned in Chapter Five, we will need vertex normals if we intend to use the DirectX lighting pipeline. While we know how to generate vertex normals manually with the D3DXComputeNormals function (after we have cloned the mesh to include space for normals), it is certainly nice when the X file can provide those normals directly. If a level editor or 3D modeling application exports vertex normal information, then this is often preferred because it gives the artist the ability to edit those normals to achieve custom lighting effects. Storing vertex normals in the X file is easy enough with the standard X File template called MeshNormals:

```
template MeshNormals
{
   < F6F23F43-7686-11cf-8F52-0040333594A3 >
     DWORD nNormals;
     array Vector normals[nNormals];
     DWORD nFaceNormals;
     array MeshFace meshFaces[nFaceNormals];
}
```

The first DWORD (nNormals) describes the number of normals in the normals array (an array of Vectors) that will follow. There are typically as many vertex normals in this list as there are vertices in the mesh, but sometimes a mesh may choose to save space by assigning the same normal to multiple vertices. If this is not the case, we can just read the normals in and assume that there is a one-to-one mapping of normals to vertices.

If the normal count is different from the number of vertices in the parent mesh vertex list, then this means that the normals are mapped to the vertices in the mesh using indices, similar to the face list. When this is the case, the bottom two members of this template are used. The DWORD nFaceNormals will equal the number of faces in the mesh, and thus the MeshFace array. Each MeshFace object in the array holds indices into the normal list for each vertex in the face. For example, if the first MeshFace contains the indices 10,20,30, then the first vertex of the face uses normal [10] in the normal list, the second vertex uses normal [20] and the third vertex uses normal [30]. More often than not, meshes contain per-vertex normals rather than the MeshFace index scheme and the last two members of this template are not used.

The next X file example adds vertex normals as a new child object for the Mesh.

X File Sample 6: Mesh with Vertex Normals (List Version)

```
Xof 0303txt 0032

mesh{
 6;              // number of vertices
```

```
-5.0;-5.0;0.0;,   // vertex list
-5.0;5.0;0.0;,
 5.0;5.0;0.0;,
 5.0;-5.0;0.0;,
-5.0;5.0;-5.0;,
-5.0;5.0;5.0;;
 2;          // number of faces
 3;0,1,2;,   // face list
 3;3,4,5;;

 MeshMaterialList {// child data object of Mesh
  2; //Two materials in the list
  2; //Two faces in the following material face list

      // material face list
  0,  // the first face uses Material 0
  1;; // the second face uses Material 1

  Material {            // Material 0,child data object of MaterialList
  1.000000;1.000000;1.000000;1.000000;;
  0.000000;
  0.000000;0.000000;0.000000;;
  0.000000;0.000000;0.000000;;
  TextureFilename {"example.bmp";} // child data object of Material
  }

  Material {           // Material 1, child data object of MaterialList
  1.000000;0.000000;0.000000;1.000000;;
  0.000000;
  0.000000;0.000000;0.000000;;
  0.000000;0.000000;0.000000;;
  }
 }

 MeshNormals {               // child data object of Mesh object
 6;                          // one for each vertex
 0.000000;1.000000;0.000000;, // Normal 1
 0.000000;1.000000;0.000000;, // Normal 2
 0.000000;1.000000;0.000000;, // Normal 3....
 0.000000;1.000000;0.000000;,
 0.287348;0.957826;0.000000;,
 0.287348;0.957826;0.000000;;
 2;               // number of faces
 3; 0,2,1;,       // indices of how the normals are mapped to each face
 3; 3,4,5;;
 }

}// end of mesh object
```

Notice that the MeshFace type contains the number of indices and then the indices themselves. In this particular example, the MeshFace list is not necessary since the number of vertices equals the number of normals, but we added the mapping list just to demonstrate the concept. Notice also that the MeshNormals data object is embedded as a child of the mesh object. This makes sense as this object contains the vertex normal information for that mesh.

If you take a look at the 'Mesh Normals' object above, you will see that the first value is 6, which indicates that there are six normals in the list that follows. This simple mesh only has two faces comprised of six vertices in total. After this normal count there follows a list of the six normals. Typically, this would be all the information stored as we have six vertices and six vertex normals and that is all we need to know. For completeness however, in this particular example we demonstrate how there may not be a one-to-one mapping between normals in the normal list and vertices in the vertex list. Following the normal list you can see a value of 2, which means that following this value will be an array of 'Mesh Face' objects used to describe how the normals in the normal list map to vertices in the mesh vertex list. We can see that the first face in this list has 3 indices (which happen to map to the first face in the mesh) and has indices 0, 2 and 1. This means the first vertex of the first face in the mesh should use the first normal in the normal list (normal[0]), the second vertex of the first face of the mesh should use normal[2] from the normal list and the third vertex in the first face of the mesh should use normal[1]. We can also see that the second 'Mesh Face' object has three indices and that the first, second and third vertices of this face use the fourth, fifth and sixth normals in the normal list respectively.

While we have seen how to pair a texture and a material together and assign the combination to faces in the mesh, there is currently no information in our X File example describing how the texture of a given material data object is mapped to a face. Thus, we need a way to store per vertex texture coordinates for the mesh. We do this by embedding another child object, called MeshTextureCoords, inside the mesh object. This standard template is shown below:

```
template MeshTextureCoords
{
  < F6F23F40-7686-11cf-8F52-0040333594A3 >
    DWORD nTextureCoords;
    array coords2d textureCoords[nTextureCoords] ;
}
```

The DWORD describes the number of texture coordinates in the following array of coord2d objects. Typically there will be a set of texture coordinates for each vertex in the mesh vertex list (provided the mesh is textured) and this is always a 1:1 mapping. For example, the first texture coordinate in the array is the texture coordinate set for the first vertex in the mesh vertex list, and so on. While there may be fewer texture coordinates in this list than there are vertices in the mesh, this will still be a 1:1 mapping. If a mesh has 50 vertices, but only the first 30 belong to textured faces and needed texture coordinates, only 30 texture coordinate sets might exist in this array, but they will map to the first 30 vertices in the parent mesh vertex list.

Each pair of texture coordinates in the MeshTextureCoords array are represented as the standard template Coords2d, shown below:

```
template Coords2d
{
   < F6F23F44-7686-11cf-8F52-0040333594A3 >
     float u;
     float v;
}
```

Finally, let's take a look at our X file example with texture coordinates added.

X File Sample 7: Mesh with Texture Coordinates

```
Xof 0303txt 0032

mesh{
 6;               // number of vertices
-5.0;-5.0;0.0;,   // vertex list
-5.0;5.0;0.0;,
 5.0;5.0;0.0;,
 5.0;-5.0;0.0;,
-5.0;5.0;-5.0;,
-5.0;5.0;5.0;;
 2;          // number of faces
 3;0,1,2;,   // face list
 3;3,4,5;;

 MeshMaterialList {// child data object of Mesh
  2; //Two materials in the list
  2; //Two faces in the following material face list

      // material face list
  0,  // the first face uses Material 0
  1;; // the second face uses Material 1

  Material {            // Material 0,child data object of MaterialList
  1.000000;1.000000;1.000000;1.000000;;
  0.000000;
  0.000000;0.000000;0.000000;;
  0.000000;0.000000;0.000000;;
  TextureFilename {"example.bmp";} // child data object of Material
  }

  Material {            // Material 1, child data object of MaterialList
  1.000000;0.000000;0.000000;1.000000;;
  0.000000;
  0.000000;0.000000;0.000000;;
  0.000000;0.000000;0.000000;;
  }
 }

 MeshNormals {               // child data object of Mesh object
 6;                          // one for each vertex
 0.000000;1.000000;0.000000;, // Normal 1
 0.000000;1.000000;0.000000;, // Normal 2
 0.000000;1.000000;0.000000;, // Normal 3....
 0.000000;1.000000;0.000000;,
 0.287348;0.957826;0.000000;,
 0.287348;0.957826;0.000000;;
 2;               // number of faces
 3;0,2,1;,        // indices of how the normals are mapped to each face
 3;3,4,5;;
 }
```

```
 MeshTextureCoords {// child data object of mesh object

 0.308594;0.152344;,    // texture coordinate 1
 0.007813;0.152344;,    // texture coordinate 2 ....
 0.007813;0.007813;,
 0.308594;0.007813;,
 0.328125;0.156250;,
 0.415681;0.156250;;
 }

}// end of mesh object
```

> **NOTE:** You may be wondering how to assign multiple textures (or materials) to a single face. Unfortunately, this is not possible using the standard templates. That is, multi-texturing is not supported as part of the X file standard, so custom templates would be required to remedy this situation.

There are still many standard templates we have yet to discuss. Some will be discussed later in the chapter, others in the next chapter. But for now, we have a good overall idea of how the X file format works. For a complete list of templates, please be sure to check the X file reference in the SDK documentation. The information we have just discussed will be very useful in the future, especially if you wish to read or write your own X file custom data objects. We do not, however, need to be fully versed in the X file format or its various templates to be able load a scene hierarchy. We demonstrated in Chapter 8 that we did not need to be aware of the way a mesh was laid out in an X file in order to load the mesh using the D3DXLoadMeshFromX function. Nevertheless, this X file discussion has set the stage for our return to frame hierarchies, which we will revisit in the next section in terms of their X file representation.

9.3.3 Hierarchical X Files and Frames

Our focus in this chapter will continue to be on scenes or objects that consist of multiple meshes. When this is the case, the X file will be stored as a frame hierarchy. As already discussed, the hierarchy is constructed using Frames, where a frame takes the form of a tree node in terms of implementation. From the perspective of an X file, these frames will include a transformation matrix stored as a child data object as well as any number of child mesh objects and/or child frame objects. When an X file contains many meshes, they will not generally be defined as top level objects. They are instead stored as frame child objects. It is typical for the X file to contain a single top level Frame (the root frame) and have all other meshes and frames defined either directly or indirectly as children of this root frame. The standard templates for defining hierarchies are Frame and FrameTransformMatrix.

```
template Frame
{
  < 3D82AB46-62DA-11cf-AB39-0020AF71E433 >
  […]
}
```

Frame is an open template that will usually have a FrameTransformMatrix, one or more Mesh objects, and/or other Frames as children. The D3DX loading functions D3DXLoadMeshHierarchyFromX and

the simpler D3DXLoadMeshFromX understand Mesh, FrameTransformMatrix, and Frame template instances as child objects when loading a Frame. These are usually the only objects stored in a frame.

```
template FrameTransformMatrix
{
   < F6F23F41-7686-11cf-8F52-0040333594A3 >
    Matrix4x4 frameMatrix;
}
```

FrameTransformMatrix contains a single member, a Matrix4x4 object, which is another standard template. It is an array of 16 floats describing each element of a 4x4 matrix in row major order:

```
template Matrix4x4
{
   < F6F23F45-7686-11cf-8F52-0040333594A3 >
   array float matrix[16];
}
```

With this information in mind, we now have a complete picture of the form a hierarchy takes inside an X file. The following example will use the automobile hierarchy discussed earlier, but we will leave out the bulk of the mesh data because we already know what mesh data in an X file looks like.. For now, just assume that the mesh data would be contained within the curly braces. Fig 9.4 is a reminder of the automobile hierarchy introduced earlier.

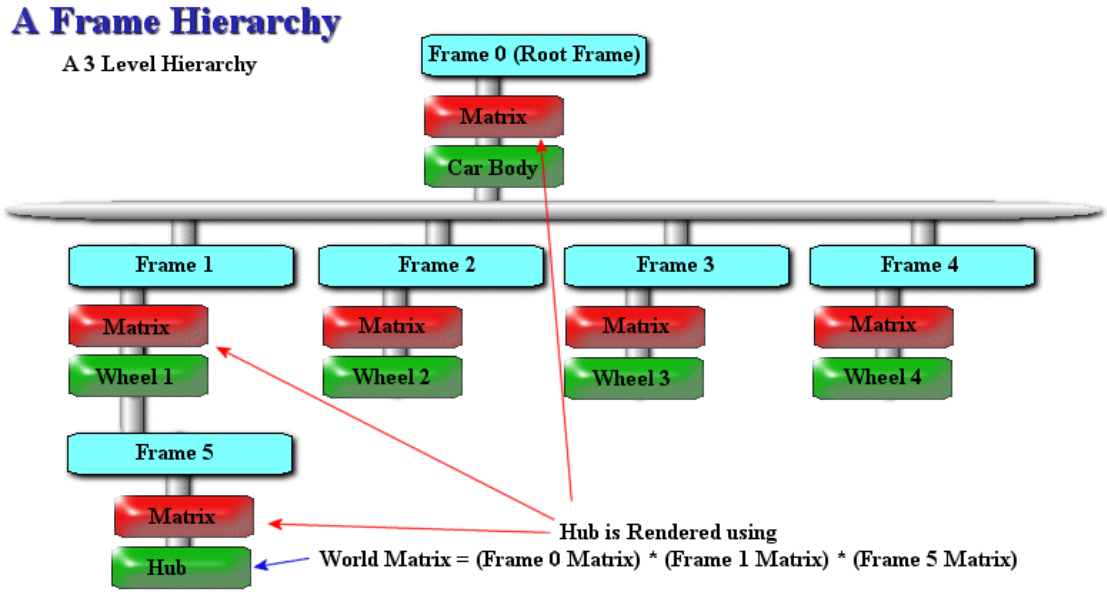

Figure 9.4

The wheel frames will be offset from the root frame at distances of 10 units along the X and Z axes. The root frame has a matrix which sets the object at position (50, 0, 50). Usually, the root frame matrix will either not exist or will be an identity matrix, allowing us to place the entire hierarchy where we want in the world by setting the world matrix and then rendering. However, in this example we will use a root

frame that is offset from the world space origin so that we can see the various matrices being stored in the X file.

Matrix Translation Vectors (Root Matrix now contains position 50,0,50)

Root Matrix	=	**50 , 0 , 50**	(The World Matrix of the Hierarchy)
Wheel 1 Matrix	=	**-10 , 0 , 10**	(RootMatrix * Wheel1Matrix = 40 , 0 , 60)
Wheel 2 Matrix	=	**10 , 0 , 10**	(RootMatrix * Wheel2Matrix = 60 , 0 , 60)
Wheel 3 Matrix	=	**-10 , 0 , -10**	(RootMatrix * Wheel3Matrix = 40 , 0 , 40)
Wheel 4 Matrix	=	**10 , 0 , -10**	(RootMatrix * Wheel4Matrix = 60 , 0 , 40)
Hub Matrix	=	**-5 , 0 , 10**	(Root Matrix * Wheel1Matrix * Hub Matrix = 35,0,10)

And finally, here is the X file that represents everything that we have learned thus far. You should be able to see how the X file is laid out exactly as described by the hierarchy diagram and how the matrices contained in the X file hierarchy are not world transform matrices but are instead relative matrices. Recall that they describe the position of a frame using the parent frame of reference.

X File Sample 8: Hierarchical X File

```
Xof 0303txt 0032

Frame Root
{
  FrameTransformMatrix
  {
    1.000000, 0.000000,  0.000000, 0.000000,
    0.000000, 1.000000,  0.000000, 0.000000,
    0.000000, 0.000000,  1.000000, 0.000000,
   50.000000, 0.000000, 50.000000, 1.000000;;
  }

  Mesh CarBody { mesh data would go in here }

  Frame Wheel1                // Child frame of Root
  {
    FrameTransformMatrix
    {
     1.000000,  0.000000, 0.000000,  0.000000,
     0.000000,  1.000000, 0.000000,  0.000000,
     0.000000,  0.000000, 1.000000,  0.000000,
    -10.000000, 0.000000, 10.000000, 1.000000;;
    }

    Mesh Wheel1 { mesh data would go in here }

    Frame Hub                 // Child frame of Wheel 1
    {
      FrameTransformMatrix
      {
       1.000000, 0.000000, 0.000000, 0.000000,
       0.000000, 1.000000, 0.000000, 0.000000,
       0.000000, 0.000000, 1.000000, 0.000000,
      -5.000000, 0.000000, 0.000000, 1.000000;;
```

```
      }

      Mesh Hub { Hub mesh data goes here }

    } // end child frame Hub

  } // end child frame Wheel 1

  Frame Wheel2                // Child frame of Root
  {
    FrameTransformMatrix
    {
     1.000000, 0.000000, 0.000000,   0.000000,
     0.000000, 1.000000, 0.000000,   0.000000,
     0.000000, 0.000000, 1.000000,   0.000000,
     10.000000, 0.000000, 10.000000, 1.000000;;
   }

   Mesh Wheel2 { mesh data would go in here}

  } // end child Wheel 2

  Frame Wheel3                      // Child frame of Root
  {
    FrameTransformMatrix
    {
     1.000000, 0.000000,   0.000000, 0.000000,
     0.000000, 1.000000,   0.000000, 0.000000,
     0.000000, 0.000000,   1.000000, 0.000000,
    -10.000000, 0.000000, -10.000000, 1.000000;;
    }

    Mesh Wheel3 { mesh data would go in here}

  } // end child frame wheel 3

  Frame Wheel4                      // Child frame of Root
  {
    FrameTransformMatrix
    {
     1.000000,  0.000000,   0.000000,  0.000000,
     0.000000,  1.000000,   0.000000,  0.000000,
     0.000000,  0.000000,   1.000000,  0.000000,
     10.000000, 0.000000, -10.000000,  1.000000;;
    }

    Mesh Whee4 { mesh data would go in here}

  }// end child frame wheel 4

} // end root frame
```

We now have a very solid understanding of how a hierarchy is stored inside an X file. What we will find is that this information is going to be very helpful to us when working with the frame hierarchy after it is loaded. This will be the subject of the sections that follow.

9.3.4 D3DXLoadMeshFromX Revisited

In Chapter Eight we learned how to load single meshes from an X file without making any effort to understand the internals of the file format. However, at the outset of this chapter we stated our concern about the limited nature of the D3DXLoadMeshFromX function. While D3DXLoadMeshFromX will collapse all of the data into a single mesh, it must of course account for the fact that those meshes are individually defined in parent-relative space. So it will need to traverse the hierarchy and cumulatively transform all child meshes using their Frame (and parent Frame) transformation matrices, so that the vertices of the mesh are transformed into the shared hierarchy/scene space. This happens before adding that data to the new D3DXMesh object (which is ultimately returned).

Again, this may be quite acceptable for certain applications that do not require those components to be independently manipulated. This might be the case, using our automobile example, for parked cars that are used as detail objects in a scene. But if we do want to treat those meshes independently, another solution is needed.

There are two ways to extract this hierarchy data from an X file, one more complex than the other. The easiest approach is to use the D3DXLoadMeshHierarchyFromX function, and we will look at this function shortly. The more difficult approach is to use the X file COM objects mentioned earlier in the text and parse the file manually. We will briefly review the COM objects first since this approach provides a more 'behind the scenes' look at the process. There will also be times when you will need to use some of the COM objects alongside the D3DXLoadMeshHierarchyFromX function in order for your application to parse custom data objects. Additionally, you may decide to write your own X File parser, perhaps because you do not want to use the D3DX library functions or because you may not have access to them (or perhaps you wish to write an X File loading module that will compile and work with earlier versions of DirectX). We will only briefly examine these X file interfaces: just enough to provide a high level understanding of the process and to get you started should you decide to pursue the concept on your own at a later date. There is plenty of good reference material in the 'X File Reference' section in the SDK documentation as well, so be sure to consult that documentation as needed.

9.3.5 Loading Hierarchies Manually

DirectX provides several COM objects and interfaces to deal with the manual reading and writing of X files. In order to use these objects and interfaces, we need to include three header files that ship with the SDK. They are contained in the 'Include' directory of the DirectX 9 SDK installation:

1. **dxfile.h** This file contains all the COM interfaces that we need to use to manually process X files.
2. **rmxftmpl.h** This file contains the template definitions for all of the standard X file templates that we have looked at previously, such as 'Frame', 'Mesh' and 'MeshMaterialList' for example.
3. **rmxfguid.h** This file contains all the GUID aliases for the templates so that we can identify object types when processing X file data objects.

NOTE: The X file COM objects are not part of the core DirectX and D3DX libraries. You must make sure that if you intend to use the X File interfaces that you also link the 'd3dxof.lib' file into your project. It can be found in the 'Lib' directory of your DirectX 9 SDK installation directory.

9.3.5.1 The IDirectXFile Interface

The 'd3dxof.lib' library exposes a single global function call to create our initial interface. This interface will serve as the gateway to the rest of the X file interfaces from within our application. This is similar to our use of Direct3DCreate9 to create our initial IDirect3D9 interface, which then serves as a means to create an IDirect3DDevice9. We call the DirectXFileCreate global function with the address of an IDirectXFile interface pointer. On function return, this will point to a valid DirectXFile object.

```
IDirectXFile * pDXFile = NULL;
DirectXFileCreate ( &pDXFile );
```

This simple interface contains three methods. One of those methods handles saving data to an X file and we will not concern ourselves with this for the time being. For now we will focus on the other two methods which are used in the file loading process.

HRESULT RegisterTemplates(LPVOID *pvData*, DWORD *cbSize*);

This method is the primary means by which we inform DirectX of the templates that we wish to parse in the X file. Each template must be registered with the loading system, or else data objects of that type inside the X File will not be recognized later during parsing. The first parameter points to a buffer that contains the template definitions we wish to register and the second parameter indicates the size (in bytes) of this buffer.

All of the standard templates that we looked at earlier (as well as many others) are already contained in a buffer called `D3DRM_XTEMPLATES` that is defined in 'rmxftmpl.h'. This is why we included this header file. The same header file defines the size of this buffer (3278 bytes) and assigns this value to `D3DRM_XTEMPLATE_BYTES`. To register the all of the standard X file templates, we would use code like this:

```
IDirectXFile * pDXFile = NULL;
DirectXFileCreate ( &pDXFile );
pDXFile->RegisterTemplates( (VOID*) D3DRM_XTEMPLATES, D3DRM_XTEMPLATE_BYTES );
```

At this point, if we were not using custom templates we could begin parsing immediately. If the X file does contain custom data objects (i.e. data objects which are not part of the X file standard), then their templates will also need to be registered. We can build the template string manually if we wish and pass it into the function as shown next:

```
char *szTemplates = "xof 0303txt 0032\
               template Contact { \
                  <2b934580-9e9a-11cf-ab39-0020af71e433> \
                  STRING Name ;\
```

```
                  STRING Address1;\
                  STRING Address2;\
                  STRING PostCode;\
                  STRING Country;\
               } \
            template Hobbies  { \
                  <2b934581-9e9a-11cf-ab39-0020af71e433> \
                   DWORD nItems;\
                   array STRING HobbyNames;\
            }";

IDirectXFile * pDXFile = NULL;
DirectXFileCreate( &pDXFile );
pDXFile->RegisterTemplates( (void *) szTemplates , strlen ( szTemplates ) );
```

In this example we have registered two custom templates, called ‘Contact’ and ‘Hobbies’, which could be used to store personal information about a person. Once these templates have been registered, if data objects of either type are found in the X file, the loading system will process them as valid objects.

The RegisterTemplates function will search the passed buffer for valid templates and register them with the loading system. Recall from our earlier discussion that it is common practice to define templates at the top of the X file itself, before the actual data object definitions. If this is the case, we could instead load the entire X file into a memory buffer (just performing a block read) and then pass this buffer (containing all X file data) into the RegisterTemplates function. The function will find the templates listed at the top of the file and will automatically register them. This means you will not have to hardcode template definitions into your project code and that you can easily change the template definitions just by altering the templates in the X file. They will automatically be registered each time the application is run. If the X file contained template definitions for all the standard templates that it uses, then registering the standard templates as a separate step would also be unnecessary.

After we have registered any standard and/or custom templates we intend to use, it is time to call the second function of the IDirectXFile interface. This function, IDirectXFile::CreateEnumObject, opens the X file and creates a top level data enumerator object which is returned as a pointer to an IDirectXFileEnumObject interface. We can use this interface to step through each top level data object in the X file one at a time and extract their data.

```
HRESULT CreateEnumObject( LPVOID pvSource,
                          DXFILELOADOPTIONS dwLoadOptions,
                          LPDIRECTXFILEENUMOBJECT *ppEnumObj );
```

The first parameter is a pointer to a buffer whose meaning depends on whether we are loading the X file from disk, resource, or memory buffer. This is specified by the second parameter which should be one of the DXFILELOADOPTIONS flags:

DXFILELOAD_FROMFILE - If this flag is used for the second parameter, then the first parameter to the CreateEnumObject function is a string containing the file name of the X file.

DXFILELOAD_FROMRESOURCE - If this flag is used as the second parameter, the first parameter should be a DXFILELOADRESOURCE structure. For more details on this structure, see the SDK documentation as we will not be covering it here.

DXFILELOAD_FROMMEMORY - If this flag is used as the second parameter, the first parameter should be a DXFILELOADMEMORY structure. For more details on this structure, check out the SDK documentation as we will not be using it in this chapter.

The complete process for registering the standard templates and then creating our enumeration object to process X file data would be as follows:

```
IDirectXFile            *pDXFile     = NULL;
IDirectXFileEnumObject  *pEnumObject = NULL;
DirectXFileCreate ( &pDXFile );
pDXFile->RegisterTemplates( (VOID*) D3DRM_XTEMPLATES ,
                                    D3DRM_XTEMPLATE_BYTES );

pDXFile->CreateEnumObject( "MyCube.x" , DXFILELOAD_FROMFILE, &pEnumObject );
```

> **Note:** This section is intended only as a brief introduction to the X file interfaces for those of you interested in parsing your X files manually. In this chapter, our demos will not be using these interfaces, and will instead be doing things the easy way using the D3DXLoadMeshHierarchyFromX function. This information is still useful though as later on we will discuss how we can use the D3DXLoadMeshHierarchyFromX function to parse custom X file templates. In that case, a thorough understanding of the X file format and the IDirectXFileData interface is necessary.

After the code shown above has been executed, the application has a pointer to an IDirectXFileEnumObject interface. This interface exposes methods which the application can use to start processing top level data objects stored in the X file.

9.3.5.2 The IDirectXFileEnumObject Interface

Once we have an IDirectXFileEnumObject interface, we can call its GetNextDataObject method to retrieve each top level data object stored in the X file, one at a time. Typically this will happen in a loop, where the data objects (returned to the application as DirectXFileData objects) are processed until no more top level data objects exist in the file.

For each top level data object that exists in the file (ex. Mesh, Frame, etc.), the data is returned to the application as an IDirectXFileData interface. The application can use the methods of this interface to extract the data as needed. Note that this function only returns top level objects, not child objects like, for example, a MeshMaterialList object which would be embedded as a child object inside a Mesh data object. Because all top level objects must be data objects, and not data reference objects, the enumerator can safely make this assumption.

The following code shows how we might set up a loop to process each top level object in the file.

```
LPDIRECTXFILE           pDXFile;
LPDIRECTXFILEENUMOBJECT pEnumObject;
LPDIRECTXFILEDATA       pFileData;
const GUID *pGuid;

DirectXFileCreate (&pDXFile);
pDXFile->RegisterTemplates( (VOID*) D3DRM_XTEMPLATES , D3DRM_XTEMPLATE_BYTES);
pDXFile->CreateEnumObject( "MyXFile.x" , DXFILELOAD_FROMFILE, & pEnumObject));

while ( SUCCEEDED ( pEnumObject->GetNextDataObject(&pFileData)))
{
     pFileData->GetType(&pGuid);
     if (*pGuid==TID_D3DRMMesh)     GetMeshData  ( pFileData );
     if (*pGuid==TID_D3DRMFrame)    GetFrameData ( pFileData );
     pFileData->Release();
}

pEnumObject->Release();
pDXFile->Release();
```

The code shows that once we have created the top level enumerator object, we repeatedly call its GetNextDataObject method to access the next top level data object in the X file. The actual data contained within the top level object is contained inside the returned IDirectXFileData interface.. Once we have an IDirectXFileData interface, we call its GetType function to test its GUID (i.e. the GUID of its template) against the ones we wish our application to support. In this example you can see that we are testing for top level Mesh and Frame objects only. The aliases for their GUIDs (and all of the standard template GUIDs) are listed in the 'rmxfguid.h' header file. TID_ is an abbreviation for Template ID.

Once we have identified a supported type in the above example code, we call some application defined functions to process the data stored in the returned IDirectXFileData object. In this example it is assumed that the GetMeshData and GetFrameData functions are application defined functions which will use the passed IDirectXFileData interface to extract the data into some meaningful structures (an ID3DXMesh for example). We will study the IDirectXFileData interface in a moment when we learn how to extract the data from a loaded data object.

There are three similar methods in the IDirectXFileEnumObject interface that we can use to access top level data objects defined in the X file. The first is called GetNextDataObject and is the one we have used in the above code example. All three data object retrieval methods of the enumerator interface are listed next:

```
HRESULT GetNextDataObject(LPDIRECTXFILEDATA *ppData);
HRESULT GetDataObjectByName(LPCSTR szName,LPDIRECTXFILEDATA *ppData);
HRESULT GetDataObjectById(REFGUID rguid, LPDIRECTXFILEDATA *ppData);
```

The **GetNextDataObject** function is called to fetch the next top level data object from the file. We saw this being used in the code example shown previously. The function is passed the address of an IDirectXFileData interface pointer which on function return will point to a valid interface which can be

used to extract the data from the data object. If the X file contains six top level data objects, this function would be called six times, each time fetching the next data object until it fails.

The **GetDataObjectByName** function lets us search the X file for an object with the name passed in. The second parameter is the address of an IDirectXFileData interface pointer which, if a top level object with a matching name exists in the file, will be used to extract data from the requested object. The example data object shown below, which is of type 'TestTemplate', would have the name 'MyFirstValues'. Fetching data objects by name is very useful if you know the name of a specific object you wish to load. This allows you to load this data object without having to step through all other top level data objects in the file.

The **GetDataObjectById** works in exactly the same way as the previous function, but searches on data object GUIDs rather than names. Although we have not mentioned it until now, each data object in an X file can also have its own **unique** GUID in addition to the template GUID. For example, let us say that we defined our data for a TestTemplate object as follows:

```
TestTemplate MyFirstValues {
  <78A5640B-1A66-4CD0-B1A4-3E2060429130>
  1.000000;
  2.000000;
  3.000000;
}
```

We have now added a GUID to the actual data object itself. The GUID that we included in the object above (remember this is not a template, but an actual instance of a TestTemplate object) can be used to identify this specific object in the file. Therefore, the template GUID can be used to identify all data objects of the same type in the X file and the data object GUID can be used to identify a single data object. This allows an application to find it easily even if the X file contains many data objects based on the same template.

9.3.5.3 The IDirectXFileData Interface

The IDirectXFileData interface encapsulates the reading and writing of X file data objects. This is true whether we are using the COM interfaces to manually parse the X file as discussed in the last section, or whether we use D3DXLoadMeshHierarchyFromX and custom data blocks have to be processed. Whether we intend to use the X File COM objects for loading X files manually, or intend to use the much easier D3DXLoadMeshHierarchyFromX function, exposure to this interface cannot be avoided. We will see shortly that when the D3DXLoadMeshHierarchyFromX function encounters a custom data object (for which D3DX has no knowledge of how to load), it will use a callback mechanism to send this data object to the application (as an IDirectXFileData). The application can then extract the data contained using the methods of this interface.

We saw earlier that when we use the IDirectXFileEnumObject interface to retrieve top level data objects in an X file, it actually returns this interface for each data object found. This interface encapsulates the data contained in the data object, such as the data for a mesh, frame or material object.

The IDirectXFileData interface exposes eight methods. Three of them are used primarily in the building and saving of X files and five are used for reading and processing the data stored in the X file data object. Since we are discussing loading X files at the moment, we will concentrate on these five methods for now. They are listed next with short descriptions. To make these functions easier to explain, we will use an example template and an object of that template type in our discussions:

```
template TestTemplate
{
  <A96F6E5D-04C4-49C8-8113-B5485E04A866>
  FLOAT TestFloat1;
  FLOAT TestFloat2;
  FLOAT TestFloat3;
}
```

This is a simple custom template with a GUID (which it must have) describing a data object that has three floats. Let us declare an instance of this template to work with:

```
TestTemplate MyFirstValues
{
   <78A5640B-1A66-4CD0-B1A4-3E2060429130>
  1.000000;
  2.000000;
  3.000000;
}
```

Note that this object also has its own GUID and no other object in the file will use this GUID. The template GUID describes the type of object this is (of which there may be many objects of this type in the file) and the object GUID identifies the exact instance of the template object. While per-object GUIDs are optional, it is a handy feature that you will no doubt see being used from time to time.

`HRESULT GetName( LPSTR pstrNameBuf, LPDWORD pdwBufLen );`

This function retrieves the name of the data object as specified in the X file. So in our example, because we specified "`TestTemplate MyFirstValues`" in the X file, the value returned would be "`MyFirstValues`". We are not required to specify a name when we instantiate an object in an X file; in fact, we saw examples earlier that simply instantiated an object using only a template name without assigning the object its own name. However, it can be handy to be able to reference the data later on elsewhere in the file, so it is good practice. Of course, this is often out of our hands as the X file will usually be created by some 3rd party modelling program for which we have no control over its X file export process. In the case of data reference objects, they naturally use per-object names so that they can be referenced by other data objects elsewhere in the file. Let us take a look at its two parameters.

LPTSTR pstrNameBuf
This first parameter is a pointer to a pre-initialised char buffer that should contain the resulting name on function return. It can be as large or small as you require. The name will be copied into this buffer.

LPDWORD pdwBufLen
This is a pointer to a `DWORD` which is used as both an 'In' and 'Out' parameter. The value, contained in the `DWORD` (that you pass in), must specify the maximum length of the string buffer that was passed in to

the previous parameter. When the function returns, this `DWORD` will be filled with the *actual* buffer length required to store the string, including the terminating character. If the original value you passed in specifies a value that is not large enough to return the entire string, then this function will return `D3DXFILEERR_BADVALUE`.

Passing NULL for the `pstrNameBuf` parameter will fill out the DWORD with the length of the buffer required to store the returned string (the complete name of the object). Note that the same rules still apply: the input value you pass in here must still be large enough (even if you do pass NULL as the string parameter). In both cases, an error will be returned if this is not the case. This allows you to test whether a certain buffer length will be large enough to store the returned string.

`HRESULT GetType (const GUID **ppguid);`

One of the first things we want to know about an IDirectXFileData interface is what type of data object it represents (Mesh, Frame, Material, etc.) so that we can select the appropriate processing path or determine if our application even wants to process it at all. GetType allows us to retrieve a pointer to the GUID of the template type for the data object. In our example, the GetType method would return the GUID of the TestTemplate type. We used this function earlier when enumerating through the file:

```
while ( SUCCEEDED ( pEnumObject->GetNextDataObject(&pFileData)))
{
     pFileData->GetType(&pGuid);
     if (*pGuid==TID_D3DRMMesh)  GetMeshData  ( pFileData );
     if (*pGuid==TID_D3DRMFrame) GetFrameData ( pFileData );
     pFileData->Release();
}
```

We pass in the address of a GUID pointer to retrieve a pointer to the GUID object itself. As you can see, this is a const pointer so we are not allowed to modify the GUID.

`HRESULT GetId( LPGUID pGuid );`

This method will retrieve the GUID for the object being referenced. Unlike the type GUID specified in a template declaration, this is the per-object GUID discussed previously. In our example object ('MyFirstValues'), we have included a GUID, so this is the value that will be retrieved here. We discussed earlier how to use the 'DEFINE_GUID' macro so that you can build aliases (such as TID_D3DRMMesh) for your own GUIDs and use them for type comparison.

LPGUID pGuid
This method takes a single parameter. A pointer to a GUID structure to be filled with the GUID data on function return. If no GUID exists in the data object, it will be filled with zeros.

`HRESULT GetData( LPCSTR szMember, DWORD *pcbSize, void **ppvData ) ;`

This is the primary method for retrieving the object data that was loaded from the file. If the data object represented by this interface was a Mesh object for example, the GetData method allows us to access the underlying vertex and index data stored within. It accepts three parameters which are described below.

LPCTSTR szMember

For this parameter, there are two options. The first option is to pass in the name of a member variable in the data object that you wish to retrieve the value for (ex. "`TestFloat1`" in our current example). This allows us to retrieve the variables of a data object one at a time, or get the values only for specific variables that we may be interested in. The second option is to pass NULL, which indicates that all of the data for the entire data object should be retrieved.

DWORD *pcbSize

On function return, this `DWORD` pointer will contain the total size of all of the data retrieved.

void **ppvData

As the third parameter, the application should pass the address of a void pointer. On function return this will point to the start of the data buffer we requested. Whether this buffer contains just a single member variable of the object or the entire data set itself depends on whether or not NULL was passed as the first parameter. The application never gets to own this data as it is issued a pointer to the API's own internal data. For this reason, we must copy the information pointed at into memory that our application does own so that we can modify it and rely on its persistence.

If we request a pointer for the entire data buffer, then the template itself should be our guide for determining the offsets for where each variable is stored in that buffer. Look again at our example template:

```
template TestTemplate
{
  <A96F6E5D-04C4-49C8-8113-B5485E04A866>
  FLOAT TestFloat1;
  FLOAT TestFloat2;
  FLOAT TestFloat3;
}
```

We can see that the buffer will contain three floats. Note that the GUID is *not* part of the data buffer, as there are separate methods for accessing the GUID as previously discussed. Using the above example, we know that the pointer would initially point to the float value 'TestFloat1'. Assuming 32-bit floating point precision is being used, we know that incrementing a BYTE pointer by four bytes would now point it at the value assigned to 'TestFloat2', and so on. Of course, the most common and easiest ways to access the data would be to either use a float pointer to step though the values with a simple pointer increment (for this example) or to build a three float structure that mirrors the data area and do a block copy. The returned void pointer could then be cast to a pointer of this type and the members accessed/copied intuitively. We might imagine we have defined a 3 float structure called 'MyXStruct'. We could then cast the returned void pointer and extract the data into three application owned variables (called foo1, foo2 and foo3) as shown below. vpPointer is assumed to be the void pointer to the data buffer returned by the GetData method:

```
MyXStruct *data = vpPointer;
foo1 = MyXStruct->TestFloat1;
foo2 = MyXStruct->TestFloat2;
foo3 = MyXStruct->TestFloat3;
```

This method is inadvisable however because the compiler may insert extra padding into your structures to make the members 32-bit aligned for increased performance. As this invisible padding is not inserted into the retrieved data object buffer, a mismatch can occur between the offsets of each member in the structure and their corresponding offsets in the data buffer. We will have more discussion about this problem a bit later.

The previous four methods of the IDirectXFileData interface that we have discussed demonstrate how to identify a data object and extract its data. We have discovered however, that a data object in an X file, like Meshes for example, may also contain child data objects. Thus, the IDirectXFileData interface may point to a data object that has child objects. We need a way to not only to process its data as previously discussed, but also a way to perform the same processing on any child objects it may contain. This is definitely necessary as the IDirectXFileEnumObject interface (which we have used for data object retrieval thus far), only retrieves top level data objects. This would leave us no way to access any embedded child objects should they exist.

The IDirectXFileData interface has a method that works very much like the IDirectXFileEnumObject::GetNextDataObject function. It allows us to step through its child objects one at a time retrieving IDirectXFileData interfaces for each of its children. This final method (called GetNextObject) provides the ability for our application to reach any object in a complete hierarchy of X file data objects. Not surprisingly, it is common for the loading of an X file to be done as a recursive process.

```
HRESULT GetNextObject( LPDIRECTXFILEOBJECT *ppChildObj );
```

The GetNextObject method allows us to iterate through all the child objects just as we did earlier for top level objects. We will continue to call this method until it returns `DXFILEERR_NOMOREOBJECTS`. Essentially, the interface maintains an internal ‘current object’ pointer so that it knows how far through the list it is. Note that this is a one-time only forward iteration process; once we have traversed the list, we cannot restart from the beginning.

This function has a single parameter:

LPDIRECTXFILEOBJECT *ppChildObj
This pointer will store the address of the current child to be processed. We might expect that the child data object would be returned via an IDirectXFileData interface (as with top level objects) but we are actually returned an IDirectXFileObject interface instead. This is because, unlike top level data objects which are always explicit data objects, child data objects may be specified as either actual data objects or data *reference* objects. You will recall from our earlier X file examples that we showed a top level material object being referenced using a child data reference object in a Mesh. The `IDirectXFileObject` interface is actually the base class for three derived classes: `IDirectXFileData` (which we are now familiar with), `IDirectXFileDataReference`, and `IDirectXFileBinary`. We are not told what type of derived interface this object is via this function, so we must `QueryInterface` the base pointer to find out. The GUIDs for the three types of derived interfaces that may be returned by this function are:

```
IID_IDirectXFileData
IID_IDirectXFileDataReference
IID_IDirectXFileBinary
```

If the IDirectXFileData::GetNextObject method returns a data reference object, we can determine this by calling QueryInterface on the base pointer and passing in IID_IDirectXFileDataReference as the interface GUID. If it is a data reference object, a valid IDirectXFileDataReference interface will be returned for the object. If we do find a child data reference object (instead of a normal child data object), we have to handle it slightly differently. A data reference object does not actually contain data. It is analogous to a pointer in many ways, pointing to a data object elsewhere in the file. We must use the IDirectXFileDataReference interface to resolve this reference and point us at the actual data object which contains the data we need to extract.

We have already discussed the first interface type (IDirectXFileData) and know how to extract the data for a child data object. Let us now look at the other two interfaces which may be returned.

9.3.5.4 The IDirectXFileDataReference Interface

While the top level enumerator will always return an IDirectXFileData interface (remember, top level objects cannot be data reference objects or binary objects) this is not the case for child objects. If the IDirectXFileData::GetNextObject function returns a data reference object, then we know that it does not contain data, but rather acts like a pointer to a data object elsewhere in the file. To access the actual data, we will use the following method:

```
HRESULT Resolve( LPDIRECTXFILEDATA * ppDataObj );
```

This function resolves the reference by returning an `IDirectXFileData` interface to the actual data of the object being referenced. From our application's perspective, from this point on, we are dealing with a normal data object. We can work with the IDirectXFileData interface to extract the data as discussed previously, knowing that it is a child of the outer data object.

There are two other methods exposed by this interface: GetID and GetName. They are identical to the calls of the same name that were discussed when we studied the IDirectXFileData interface (both classes derive them from the same base class).

9.3.5.5 The IDirectXFileBinary Interface

This interface allows us to retrieve any binary data objects that may be stored in the X file, even in cases where the file is a formatted text version. We will not be using this at interface at all, so be sure to study the SDK documentation for more information.

You now have more than enough information to get started on your own X file parser if you care to write one. Again, with DirectX 9, there is probably little need given the utility functions provided. But if this is so, you might be wondering why we just spent so much time examining the X file format in such detail. As it turns out, understanding the X file format is still very useful, even when using the D3DXLoadMeshHierarchyFromX function. This is especially true if we need to parse custom objects. Furthermore, if you wanted to write a level editor or an X file exporter in the future, perhaps as a plug-in or tool for a game that you were developing, you would want to have at least this level of familiarity with X files so that you can write your file data correctly. And not to be overlooked, now that you understand how to construct X files manually, you could build simple frame hierarchies using a text editor like Notepad in the absence of an available scene editor.

> **Note:** While we are not going to look at a complete source code example of loading an X file using the 'X File' interfaces discussed, the DirectX SDK ships with source code to a mesh loading class in CD3DFile.h and CD3DFile.cpp which you can use in your own applications. CD3Dfile.cpp can be found in the 'Samples\C++\Common\Src' folder of your DirectX 9 installation. Here you will see all of the interfaces we have discussed being used to manually load an X file and maintain its hierarchical structure.

9.4 D3DXLoadMeshHierachyFromX

D3DXLoadMeshHierarchyFromX is very similar to the D3DLoadMeshFromX function studied in the last chapter. The key difference is that it supports the loading of multiple meshes and creates an entire frame hierarchy in memory. While this function removes the burden of having to become familiar with the X file format and process them using the COM objects discussed in the last section, we still need to understand the X file interfaces if we wish to process custom objects. We will look at some custom objects later in the course, but for now we will concentrate on loading hierarchies that use only the standard templates.

As you can see in the declaration that follows, there are some new D3DX structures and classes we will need to learn about before we can use this function. Furthermore, we must also learn how to derive a COM interface so that we can provide the function with application-defined memory allocation routines for mesh and frame data.

```
HRESULT D3DXLoadMeshHierarchyFromX
(
    LPCTSTR                     Filename,
    DWORD                       MeshOptions,
    LPDIRECT3DDEVICE9           pDevice,
    LPD3DXALLOCATEHIERARCHY     pAlloc,
    LPD3DXLOADUSERDATA          pUserDataLoader,
    LPD3DXFRAME*                ppFrameHierarchy,
    LPD3DXANIMATIONCONTROLLER*  ppAnimController
);
```

We will discuss the parameter list slightly out of order so that we can have a better idea of how it all works.

LPCTSTR Filename
This is a string containing the name of the X file we wish to load. This X file may contain multiple meshes and/or a frame hierarchy. This function will always create at least one frame (the root frame), even if the X file contains only a single top level mesh and no actual frames. In such a case, the mesh will be an immediate child of the root frame (also returned by this function in the sixth parameter).

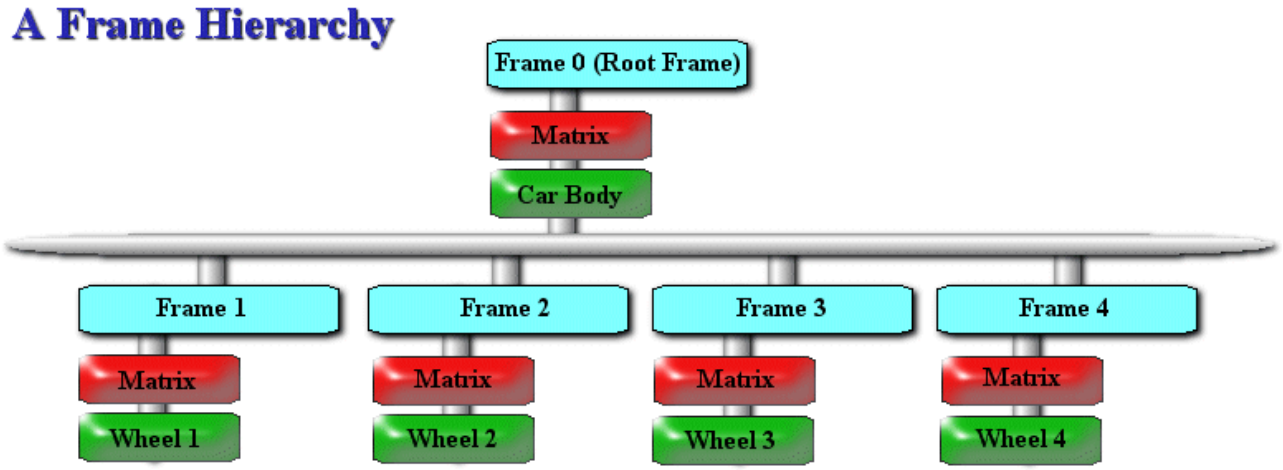
DWORD MeshOptions
These are the standard mesh options that we pass to mesh loading functions. We use a combination of zero or more members of the D3DXMESH enumerated type to specify the memory pools for mesh data, dynamic buffer status, etc.

Note that these flags may be ignored or altered by D3DX, and meshes may be created in a different format. Shortly we will see that during the loading of each mesh, we get a chance to test them (via a callback mechanism) for the desired options. If the mesh format that D3DX has chosen is not what we want, we can clone another mesh and then attach it to the parent frame instead.

LPDIRECT3DDEVICE9 pDevice
This is a pointer to the device that will own the resource memory.

LPD3DXFRAME *ppFrameHeirarchy
The sixth parameter to the D3DXLoadMeshHierachyFromX function is vitally important, since without it we would not be able to access the loaded hierarchy. We pass in the address of a pointer to a D3DXFRAME structure and on function return this will point to the root frame of the hierarchy. We can then use this pointer to access the root frame, its child frames and any child meshes it contains. This will be the doorway to our loaded hierarchy, allowing us to completely traverse the hierarchy to any level we desire.

The D3DXFRAME structure is used by D3DX to store the information for a single frame in the loaded hierarchy. A hierarchy will consist of many of these structures linked together. If you look at the following diagram of a hierarchical X file, followed by the D3DXFRAME structure definition, you will see that the structure itself mirrors the information that the diagram would suggest a frame would need to store.



```
typedef struct _D3DXFRAME
{
    LPTSTR                  Name;
    D3DXMATRIX              TransformationMatrix;
    LPD3DXMESHCONTAINER     pMeshContainer;
    struct _D3DXFRAME *     pFrameSibling;
    struct _D3DXFRAME *     pFrameFirstChild;
} D3DXFRAME, *LPD3DXFRAME;
```

We see that a frame includes a name as its first member. This can certainly be useful if needed to search for a specific component in your hierarchy or if you wanted to use it for display purposes.

The 4x4 D3DXMATRIX member stores the parent-relative transformation we discussed in the early part of the chapter. This is a relative matrix describing the position and orientation of the frame using its parent frame (if one exists) as its frame of reference.

The D3DXMESHCONTAINER structure stores a single set of mesh data (geometry, material, etc.) local to this node. It stores all the data for a single mesh. Note that we will see momentarily that this structure is capable of serving as a node in a linked list of mesh containers (via a pNext pointer) should multiple meshes actually need to be stored in a single frame in the hierarchy. The mesh container pointer in the D3DXFrame structure then is potentially the head of that linked list. It is more typical for a single mesh to be stored in a frame (if any) and therefore this pointer will often point to a single D3DXMESHCONTAINER structure whose next pointer is NULL. We will examine this structure in more detail in a moment.

The last two members are both pointers to other D3DXFRAME structures. The pFrameSibling pointer points to frame structures that are at the same level in the hierarchy as the current frame (i.e., they share the same parent frame). This pointer will be set to NULL for the root frame. If you recall our automobile example, all four of the wheel frames were child frames of the root frame and they are therefore sibling frames. The pFrameFirstChild pointer is essentially the head of a linked list of sibling frames. In the automobile example, the root frame pFrameFirstChild pointer would point at the first wheel frame. That wheel frame would then be linked together with its siblings using the pFrameSibling pointers. So the root frame (Frame 0) will have its pFrameFirstChild pointing at Frame 1. Frame 2 would be pointed to by Frame 1's pFrameSibling pointer. Frame 3 would be linked using Frame 2's pFrameSibling pointer, and so on. Thus the pFrameSibling pointer acts like the generic 'next' pointer in a standard linked list implementation. To traverse the hierarchy from the root down, we start at the pFrameFirstChild after processing the root, step through the sibling linked list, and then process the next set of children in the same fashion, and so on.

So, we have seen that when we use the D3DXLoadMeshHierarchyFromX function, D3DX will construct an entire hierarchy of D3DXFRAME structures in memory. The root frame is returned by the function which can then be used by the application to traverse and render the hierarchy. Wherever a mesh is attached to a frame in the hierarchy, the corresponding D3DXFRAME structure will have a valid pointer to a D3DXMESHCONTAINER structure. This structure contains all of the information for the mesh that D3DX has loaded and attached to the frame on our behalf. It also contains the actual ID3DXMesh interface for the mesh.

The D3DXMESHCONTAINER is defined as follows:

```
typedef struct _D3DXMESHCONTAINER
{
      LPTSTR                      Name;
      D3DXMESHDATA                MeshData;
      LPD3DXMATERIAL              pMaterials;
      LPD3DXEFFECTINSTANCE        pEffects;
      DWORD                       NumMaterials;
      DWORD                       *pAdjacency;
      LPD3DXSKININFO              pSkinInfo;
      struct _D3DXMESHCONTAINER   *pNextMeshContainer;
} D3DXMESHCONTAINER, *LPD3DXMESHCONTAINER;
```

LPTSTR Name

Like a frame in the hierarchy, we can assign a name to the mesh stored in the container. This is almost always the name of the actual mesh (e.g. 'Door Hinge 01') that is assigned to the mesh inside the 3D modeller.

D3DXMESHDATA MeshData

This structure stores the mesh object that D3DX has loaded/created. It contains either a pointer to a regular ID3DXMesh, an ID3DXPMesh, or an ID3DXPatchMesh (which we will not discuss until later in the curriculum). Since the mesh can only be one of these types at any given moment, the pointers can share the same memory by specifying them as a union.

```
typedef struct _D3DXMESHDATA
{
   D3DXMESHDATATYPE     Type;
   union
   {
      LPD3DXMESH        pMesh;
      LPD3DXPMESH       pPMesh;
      LPD3DXPATCHMESH   pPatchMesh;
   } // End Union
} D3DXMESHDATA, *LPD3DXMESHDATA;
```

The Type member allows us to determine which of the three mesh pointers is active. It will be set to one of the following values:

```
D3DXMESHTYPE_MESH
D3DXMESHTYPE_PMESH
D3DXMESHTYPE_PATCHMESH
```

LPD3DXMATERIAL pMaterials

This is an array of `D3DXMATERIAL` structures which store the material and texture data used by the mesh object specified by the previous member. This is identical to the information returned by the D3DXLoadMeshFromX function. Each D3DXMATERIAL structure in this array describes the texture and material for the corresponding subset in the mesh. This array is unique to this mesh container and information is not shared between separate containers in the hierarchy. Therefore, we must make sure when processing this data that we do not load the same texture

multiple times. This is easy enough to address as D3DX will provide our application with the ability to process each mesh container before its gets added to the frame hierarchy. This is accomplished via a callback mechanism that D3DX uses to communicate with the application during the hierarchy construction process.

LPD3DXEFFECTINSTANCE pEffects
Just as the D3DXLoadMeshFromX function returned a buffer of effect instances (one for each subset in the mesh), this array represents the same information for the mesh attached to this mesh container. Effects will be covered in the next module in this series.

DWORD NumMaterials
This variable contains the number of subsets in the mesh attached to this mesh container. This tells us both the number of D3DXMATERIAL structures in the pMaterials array and the number of D3DXEFFECTINSTANCEs in the pEffects array.

DWORD *pAdjacency
This is the standard array describing the face adjacency within the mesh.

LPD3DXSKININFO pSkinInfo
This member stores the skin information for the mesh if the mesh uses the skinning technique for animation. We will cover skinning in detail when we discuss skinning and skeletal animation in Chapter 11. We will ignore this parameter at this time.

struct _D3DXMESHCONTAINER *pNextMeshContainer
The mesh container can act as a node in a linked list. This is a pointer to the next mesh container in the list should multiple meshes be assigned to a single frame in the hierarchy.

So we can see that a mesh container stores what is essentially all of the information that we retrieve in a single call to `D3DXLoadMeshFromX`. In effect, D3DX is doing exactly this, with the exception that instead of collapsing all of the mesh data into a single mesh object, this process is performed for each mesh in the hierarchy. Each mesh's materials, effects, adjacency, and other data is loaded into this container, almost as if we had loaded numerous separate single mesh .X files ourselves into a hierarchy of D3DXFRAME structures.

Fig 9.5 gives us another look at our simple automobile hierarchy, using the structures we have discussed thus far. This diagram demonstrates the hierarchy that would be created by the D3DXLoadMeshHierarchyFromX function if the X file being loaded contained our multi-mesh automobile. This is the version that has a hubcap mesh connected to the first wheel to better show a multi-level hierarchy. In the following example, no two meshes share the same immediate parent frame, but if multiple meshes were immediate children of the same parent frame, the parent frame would point to the first of these mesh containers, and then all the remaining mesh containers of this frame would be linked together (much like sibling frames) using their pNextMeshContainer pointers. Pay special attention to how the frames are linked together. Notice how frames 1-4 are linked by their sibling pointers. This entire row of children is attached to the parent via the root node's child pointer (points to frame 1). Also notice how each frame has a mesh container attached which describes all the information and contains all the data associated with that mesh. The root frame would be returned to the calling

application by the loading function. The application can use this root frame to traverse the hierarchy and access and render its mesh containers.

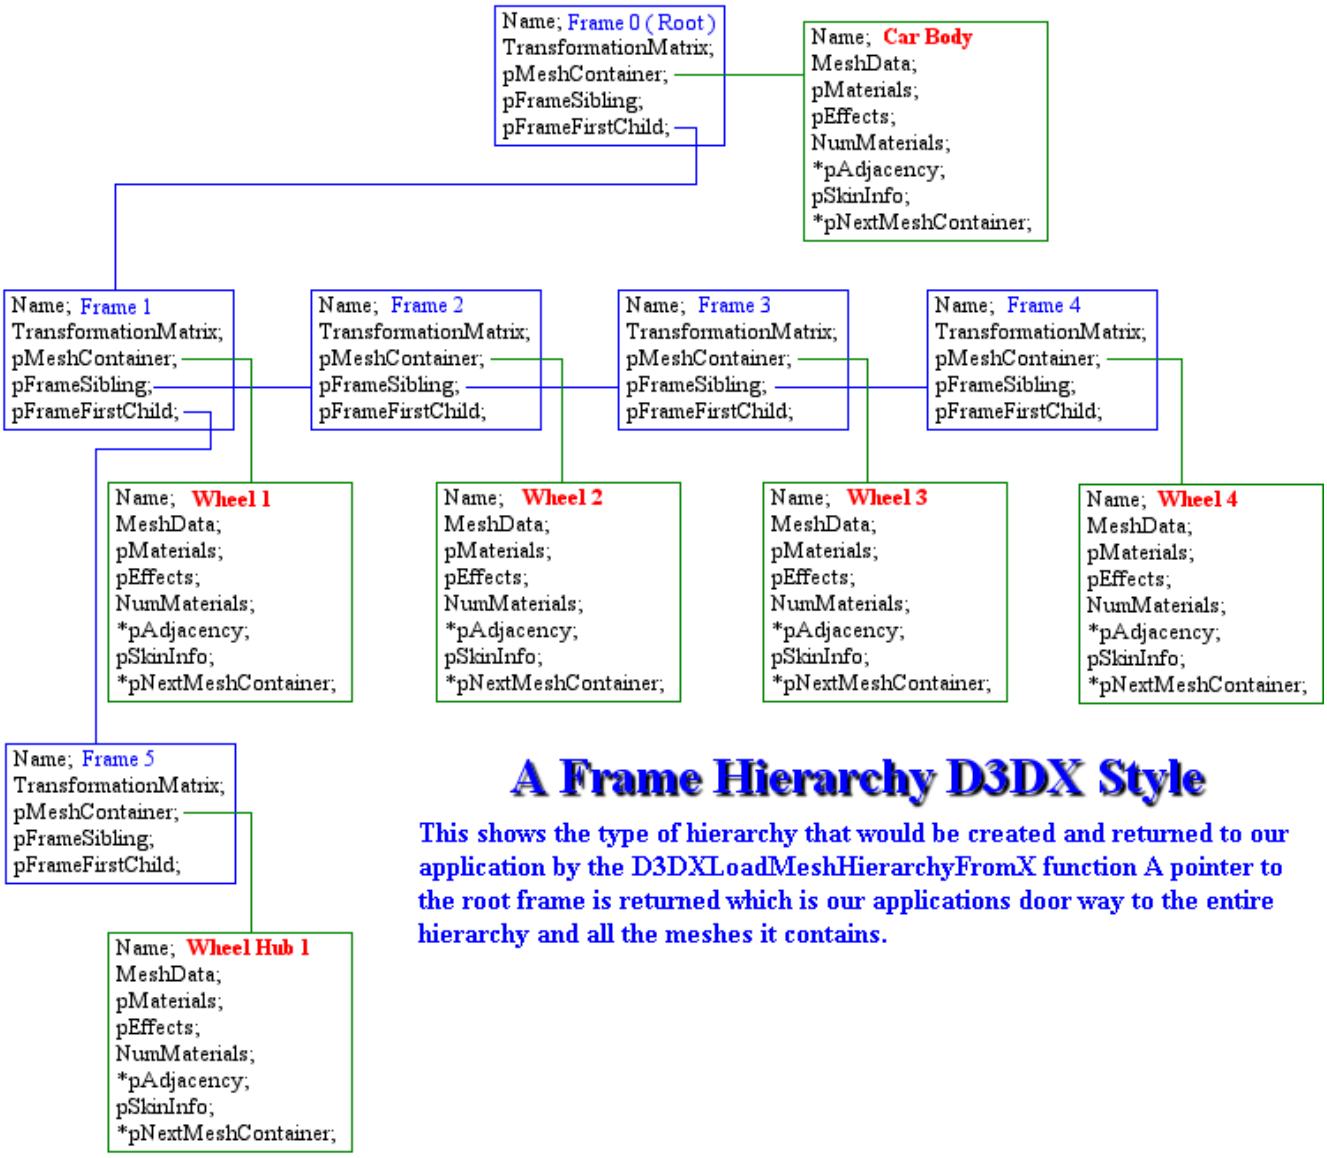


Figure 9.5

While we now know what the hierarchy will look like when the function returns, we still need to finish our examination of the parameters for D3DXLoadMeshHierarchyFromX. As it turns out, hierarchy construction is not completely automated. The application will need to play a role in the allocation of resource data (frames and mesh containers) as the hierarchy is assembled. This is important because we want the application to own the memory used by the hierarchy. If this were not the case, then routine hierarchy alterations or de-allocation of hierarchy components by the application would result in exceptions being generated.

LPD3DXALLOCATEHIERARCHY *pAlloc*

As the fourth parameter to the D3DXLoadMeshHierarchyFromX function, we must pass in a pointer to an application defined class that is derived from the ID3DXAllocateHierarchy interface. It is this parameter which is in many ways the key to the whole loading process. This interface cannot be instantiated on its own because its four member functions are pure virtual functions (they contain no function bodies). We must derive from it, and overload several functions in order to plug our application specific functionality into the D3DX hierarchy loading process.

> **Note:** Some versions of the DirectX 9 SDK suggest that this interface derives from IUnknown (much like the other COM interfaces we have seen in DirectX). This is not the case. It is more correct to think of this interface as being just a pure virtual C++ base class.

This interface is declared using all the standard interface macros to provide C and C++ development environment support (which we will discuss in a moment), so we need to be aware of these macros so that we can derive our interface using them too.

The next code listing is for ID3DXAllocateHierarchy as declared in d3dx9Anim.h.

```
DECLARE_INTERFACE( ID3DXAllocateHierarchy )
{
    // ID3DXAllocateHierarchy
    STDMETHOD(CreateFrame)        ( THIS_ LPCSTR Name,  LPD3DXFRAME *ppNewFrame) PURE;

    STDMETHOD(CreateMeshContainer)( THIS_ LPCSTR Name,
                                    LPD3DXMESHDATA pMeshData,
                                    LPD3DXMATERIAL pMaterials,
                                    LPD3DXEFFECTINSTANCE pEffectInstances,
                                    DWORD NumMaterials,
                                    DWORD *pAdjacency,
                                    LPD3DXSKININFO pSkinInfo,
                                    LPD3DXMESHCONTAINER *ppNewMeshContainer) PURE;

    STDMETHOD(DestroyFrame)       ( THIS_ LPD3DXFRAME pFrameToFree ) PURE;

    STDMETHOD(DestroyMeshContainer)( THIS_ LPD3DXMESHCONTAINER pMeshContToFree ) PURE;
};
```

> **Note:** If you ever have occasion to browse through any of the DirectX header files, you will see that virtually all interfaces are declared just like C++ classes. The difference is that they never have member variables, only member functions. This is exactly what an interface is (for those of you who don't know). The interface exposes only methods to the user of the API and keeps the data and private functionality nicely tucked away. Refer back to our COM discussion in Chapter Two for a refresher if needed.

The declaration may look a little strange, but do not be distracted by the macros, which will be built out during our compiler's pre-process. We will discuss those macros in the next section and it will all become clear. First we will look at how to derive our own class from this interface, which is something we *must* do. It is this derived object that we will pass to the D3DX loading function. D3DX will use the methods of our class to allocate the frames and mesh containers it created in application memory. This allows the application to chose how and where these resources should be allocated.

As the following code shows, deriving a class from an interface is quite similar to normal inheritance models.

```
class CAllocateHierarchy: public ID3DXAllocateHierarchy
{
public:

    // Constructor
    CAllocateHierarchy( int var ) : m_TestVar(var) {}

    STDMETHOD(CreateFrame)           ( THIS_ LPCTSTR Name,   LPD3DXFRAME *ppNewFrame);

    STDMETHOD(CreateMeshContainer)   ( THIS_ LPCTSTR Name,  LPD3DXMESHDATA pMeshData,
                                       LPD3DXMATERIAL pMaterials,
                                        LPD3DXEFFECTINSTANCE pEffectInstances,
                                       DWORD NumMaterials, DWORD *pAdjacency,
                                       LPD3DXSKININFO pSkinInfo,
                                        LPD3DXMESHCONTAINER *ppNewMeshContainer );

    STDMETHOD(DestroyFrame)          ( THIS_ LPD3DXFRAME pFrameToFree );

    STDMETHOD(DestroyMeshContainer)  ( THIS_ LPD3DXMESHCONTAINER pMeshContainerBase );

    // Public Variables for This Class
    int   m_TestVar
};
```

Our derived class adds a constructor and a public member variable (m_TestVar). The four functions of the ID3DXAllocateHierarchy base class have the ‘PURE’ macro at the end of each function prototype. This macro expands to ‘=0’, which means the function is pure virtual and must be implemented in the derived class. That is all there is to deriving from an interface. In truth, this is not something that you will usually want or need to do, but it is required in this particular case. Of course, we do have to implement these four methods in our derived class to provide memory allocation and deallocation functions that D3DX can use during hierarchy construction. We will discuss the implementation of these four methods shortly. If you would like to better understand the macros seen above, read the next section. It is not vital that you understand these macros in order to use them, but we will discuss them anyway for those students who are interested. For those who are not, feel free to skip this next section on move straight on to discuss implementing the four methods of our ID3DXAllocateHierarchy derived class.

9.4.1 The COM Macros

When deriving a class from the ID3DXAllocateHierarchy interface, our derived class methods seem to be using quite a few strange looking macros: STDMETHOD and THIS_ for example. Technically speaking, we do not have to use them in order to derive a class from an interface, but it does make life easier when matching prototypes for base class functions. We want to ensure that they overload correctly in our derived class.

Let us start by looking at what these macros resolve to in the pre-processor at compile time. They can be found in the header file ‘objbase.h’ and are part of the standard COM development semantics. As you might suspect, DirectX follows the COM development guidelines and uses these macros throughout its interface declarations.

When we call the STDMETHOD macro, we pass in the name of the class method like so:

```
STDMETHOD( method )
```

When the pre-processor encounters this macro it resolves to:

```
virtual HRESULT STDMETHODCALLTYPE method
```

This expanded macro in turn contains the 'STDMETHODCALLTYPE' macro, which resolves to:

```
__stdcall
```

This declares the standard COM function calling convention. That is, the STDMETHOD fully resolves to the following, where 'method' is the name of the function passed into the macro.

```
virtual HRESULT _stdcall method
```

Thus, the CreateFrame function for our CAllocateHierarchy test class would be defined like so when processed by the compilers pre-processor:

```
virtual HRESULT _stdcall CreateFrame
```

So the macro is used to quickly define overridable interface functions that return an HRESULT. This is the standard COM style as we learned way back in Chapter Two.

The other macro we see used in the ID3DXAllocateHierarchy interface declaration (and every COM interface declaration) is the 'THIS_' macro. It is inserted before the first parameter of each method. This macro makes it possible to use the interface in a C environment that would otherwise have no concept of objects or methods. There are two versions of the 'THIS_' macro, wrapped by a compile time directive. If we remove some of the bits that are not relevant to this discussion, we end up with the following:

```
#if defined(__cplusplus) && !defined(CINTERFACE)
      #define     THIS_
#else
      #define     THIS_       INTERFACE FAR *This,
#endif
```

This is actually quite clever and is not something you will likely see very often, but it is worth discussing.

All of the macros (such as DECLARE_INTERFACE, STDMETHOD, etc.) allow for C style interface declaration and expansion, even if the application is being compiled in a C++ environment. Although all of these macros have been around forever, and are actually defined by the underlying COM object mechanism (objbase.h), DirectX follows them strictly, to allow a C environment to use the COM objects exposed.

As we can see, the expansion of the above 'THIS_' macro, in a C++ compiler (ignoring the && case for a moment), would result in absolutely nothing being injected into the portions of code by the pre-

processor. In other words, nothing would be inserted before the first parameter of each method. We know that with C++ classes, the 'this' pointer is implicitly inserted as the first parameter of all class member functions by the compiler. In a C environment however, this is not the case. This leads to the second case above, where a 'This' pointer is injected by the macro pre-processor during a compile as the first parameter to each method. But how does it know what type the 'This' parameter inserted into the method parameter list should be? We can see right at the start of the inserted code that there is another macro being used: `INTERFACE`. What we also see, is that at the start of every interface declaration in DirectX (or more specifically in this example, just prior to the declaration of the `ID3DXAllocateHierarchy` interface) the following lines of code which assigns a value to the INTERFACE definition:

```
#undef      INTERFACE
#define     INTERFACE   ID3DXAllocateHierarchy
```

If we look at the expansion of the `CreateFrame` member of the ID3DXAllocateHiearchy interface:

```
STDMETHOD (CreateFrame)( THIS_ LPCSTR Name,  LPD3DXFRAME *ppNewFrame)   PURE;
```

in a C environment, we get the following:

```
virtual HRESULT __stdcall CreateFrame(ID3DXAllocateHierarchy FAR *This,
                                      LPD3DXFRAME * ppNewFrame) = 0;
```

As you can see, as the first parameter to each method, a pointer to the actual structure that contains the member variables is inserted so the function can access them in C. This is exactly what the COM object exports, allowing us to use DirectX in a C environment. There is of course a little extra work to do, because we must remember to always explicitly pass the 'this' pointer when calling an interface method and we have to address some of the C++ specific concepts like 'virtual' and '=0'.

If you look at any of the DirectX header files that declare interfaces you will see, before the DECLARE_INTERFACE macro, the lines

```
#undef      INTERFACE
#define     INTERFACE   NameOfInterface
```

This means that when we use the 'THIS_' macro in a 'C' environment, a far pointer of the correct interface type is inserted at the head of each method's parameter list. You will see these lines of code before each interface declaration where 'NameOfInterface' would of course be replaced by the interface about to be declared. This allows for the behavior of the _THIS macro to be altered on a per interface basis.

Looking again at the compile time directives for the '`THIS_`' macro, we see the "`&& !defined(CINTERFACE)`" portion of the first if statement. This define is available for us to use from inside our C++ environment. We can '`#define CINTERFACE`' right at the start of the logical compile path, and develop using the C language thereafter even when using a C++ compiler. This is a nice additional level of portability.

Before moving on, there is one last issue to cover: how to access interfaces or classes in a C program when the language does not support these concepts. The key is the '`DECLARE_INTERFACE`' macro.

As you know, C++ defines structs and classes similarly. One might consider a struct in C++ as the equivalent of a public class (classes are private by default). Since structs in C are data containers that cannot include member functions, the DECLARE_INTERFACE macro helps bridge the gap.

DirectX uses the '`DECLARE_INTERFACE`' macro wherever it needs to declare an interface. If we imagine we declare a simple interface called ID3DXAllocateHierarchy with a single member function, it would be declared in the DirectX header files something like this:

```
DECLARE_INTERFACE( ID3DXAllocateHierarchy )
{
   STDMETHOD(CreateFrame) (THIS_ LPCSTR Name, LPD3DXFRAME * ppNewFrame) PURE;
};
```

If we look in objbase.h (in your C++ include directory) you will see that the interface declaration shown above is expanded differently depending on whether we are using a C or C++ environment.

```
#if defined(__cplusplus) && !defined(CINTERFACE)

      #define interface                                  struct

      #define DECLARE_INTERFACE(iface)                   \
        interface iface

      #define DECLARE_INTERFACE_(iface, baseiface)       \
              interface iface : public baseiface

            #define STDMETHOD(method)                          \
                    virtual HRESULT STDMETHODCALLTYPE method

            #define PURE                                       = 0

#else
      #define interface                                  struct

      #define DECLARE_INTERFACE(iface)                   \
        typedef interface iface {                  \
          struct iface##Vtbl FAR*lpVtbl;           \
        } iface;                                   \
        typedef struct iface##Vtbl iface##Vtbl; \
        struct iface##Vtbl

      #define DECLARE_INTERFACE_(iface, baseiface)       \
              DECLARE_INTERFACE(iface)

      #define STDMETHOD(method)                          \
              HRESULT (STDMETHODCALLTYPE * method)

      #define PURE

#endif
```

Notice that there are two separate DECLARE_INTERFACE macros, one with an underscore at the end, and one without. The one with the underscore is used wherever a base interface is required.

The above conditional code shows that in the C++ environment, the DECLARE_INTERFACE macro is simply replaced with the keyword 'struct' and, together with the macros used to declare the method (_THIS and STDMETHOD), would expand to a structure called ID3DXAllocateHierarchy which has a single virtual function as its only method. It is a regular structure that has a virtual function which uses the standard COM calling convention and returns an HRESULT as shown below:

```
struct ID3DXAllocateHierarchy
{
   virtual HRESULT __stdcall CreateFrame(LPCSTR Name,LPD3DXFRAME *ppNewFrame) = 0;
};
```

This is perfectly legal C++ and by studying the expansion code above you can see how this structure definition was arrived at.

If a C environment is being used, the DECLARE_INTERFACE macro is expanded to something a bit more cryptic: This is because structures can not have methods in C, so a workaround is put in place. The C section of the expansion would create the following:

```
typedef struct ID3DXAllocateHierarchy
{
  struct ID3DXAllocateHierarchyVtbl FAR * lpVtbl;
} ID3DXAllocateHierarchy;

struct ID3DXAllocateHierarchyVtbl
{
  HRESULT (__stdcall * CreateFrame ) (ID3DXAllocateHierarchy FAR * This,
                                      LPCSTR Name, LPD3DXFRAME * ppNewFrame);
};
```

The C case creates two structures instead of one. The first is the actual ID3DXAllocateHierarchy structure and it contains a single member variable. This is a pointer to the second structure type created by the macro (called ID3DXAllocateHierarchyVtbl). This structure is referred to as the VTABLE and as you can see, it contains one or more pointers to functions as its members. The names of the structures are the same with the exception of the Vtbl appended to the end of the second structure. The Vtable is essentially where functions that were part of the class in the C++ case will be stored. If we were to carry on declaring methods in our interface, this second structure would end up containing callbacks for all of the interface methods. Therefore, we can think of the Vtable structure as being linked to the first structure as a container of function pointers.

In C++ the methods of this interface can be called like so:

```
pAllocHierarchy->CreateFrame (…) ;        // Calling interface methods in C++
```

In C, the function pointers are stored in the Vtable structure which is accessible via the first structure's lpVtbl member. Therefore, we must take this into account when calling member functions of the interface in the C development environment.

```
pAllocHierarchy->lpVtbl->CreateFrame (…); // Calling interface methods in C
```

Inheritance is not implicitly or automatically supported in a C environment. We see this in the **DECLARE_INTERFACE** macro. The two sections (C/C++) of the DECLARE_INTERFACE_ macro (note the underscore) are used to declare an interface that has a base class. The two macros are shown again next:

The C++ case:

```
#define DECLARE_INTERFACE_(iface, baseiface )interface iface : public baseiface
```

This resolves the standard class/struct inheritance code for a declaration:

```
struct iface : public baseiface
```

The C case ignores the base interface:

```
#define DECLARE_INTERFACE_(iface, baseiface)  DECLARE_INTERFACE(iface)
```

This resolves to:

```
struct iface
```

This is unfortunate, but is something that we certainly can live without. All DirectX interfaces re-declare their base class functions anyway, so they are explicitly supported in derived interfaces. We still get access to all of the base class functionality via the VTable callbacks, even if we cannot cast between types in ways that we might take for granted in C++. If you have ever wondered why all of the interfaces in the DirectX header files re-declare all of their base class methods (which should automatically be inherited from the base interface), now you know -- it is for C environment access compatibility where method inheritance is not supported.

Bear in mind that the compiler will automatically assume that it is to compile code for a C environment when the '.c' file extension is used. So be aware of this if you use DirectX in a project which mixes '.c' files, with '.cpp' files.

9.4.2 The ID3DXAllocateHierarchy Interface

The fourth parameter to the D3DXLoadMeshHierachyFromX function is a pointer to an application defined class derived from the ID3DXAllocateHierarchy interface. The derived class must implement the four functions of the base interface so that D3DXLoadMeshHierarchyFromX can call them when mesh containers and frames need to be allocated and de-allocated. This process of calling back out to the application allows for application resource ownership during hierarchy construction. This is important for applications that want to add additional functionality to the interfaces that are provided.

Let us look at an example of an interface derived class:

```
class CAllocateHierarchy: public ID3DXAllocateHierarchy
{
public:

    STDMETHOD(CreateFrame)          ( THIS_ LPCTSTR Name,  LPD3DXFRAME *ppNewFrame);

    STDMETHOD(CreateMeshContainer)  ( THIS_ LPCTSTR Name,  LPD3DXMESHDATA pMeshData,
                                      LPD3DXMATERIAL pMaterials,
                                      LPD3DXEFFECTINSTANCE pEffectInstances,
                                      DWORD NumMaterials, DWORD *pAdjacency,
                                      LPD3DXSKININFO pSkinInfo,
                                      LPD3DXMESHCONTAINER *ppNewMeshContainer );

   STDMETHOD(DestroyFrame)          ( THIS_ LPD3DXFRAME pFrameToFree);

   STDMETHOD(DestroyMeshContainer)  (THIS_ LPD3DXMESHCONTAINER pMeshContainerBase);
};
```

Because this is a class and not merely an interface (a pure abstract base class) we can now add any number of additional methods and member variables to enhance the functionality of the original ID3DXAllocateHierarchy. The above example does not add any new member variables or methods, but it must implement the four base class methods. This allows D3DXLoadMeshHierarchyFromX to use them like callbacks.

9.4.2.1 Allocating Frames

HRESULT CreateFrame(LPCSTR *Name*, LPD3DXFRAME **ppNewFrame*)

This function is called when a new frame is encountered in the X file. The application is responsible for allocating a new D3DXFRAME and then returning it to D3DXLoadMeshHierrachyFromX by means of the second parameter. D3DX will populate the frame we return with data from the X file and attach it to the hierarchy in the correct position. At its simplest, this function just has to allocate a new D3DXFRAME structure and point the second parameter passed in to point at it.

LPCSTR Name
This first parameter is the name of the frame being created and will be passed into the function by D3DXLoadMesHierarchyFromX when it encounters a frame in the X file that is about to be loaded. Recall that there is storage for a string pointer in the base frame structure. In the case of a character model for example, the artist or 3D modeller might name the frames with descriptive labels such as “Left Arm”, “Right Leg” or “Torso” within the X file.

When we allocate the D3DXFRAME structure inside this function, we will want to store this name in the D3DXFRAME::Name member variable so that we can access the frame by name later. However it is important to realize that the memory of the string we are passed is not owned by the application, it is owned by D3DX. As such, we cannot simply store the string pointer we are passed in our D3DXFRAME structure because we cannot make assumptions about what D3DX will do with the memory once we return from the function. For example, if D3DX were to free it, our frame structure

would contain a dangling pointer to a string that no longer exists. Therefore this string must be duplicated in any way you see fit (i.e. strdup or _tcsdup if you want to be Unicode compliant) and stored in the D3DXFRAME structure you create. Remember that if you duplicate the name, you must make sure that when the frame is destroyed you also free the string memory that you created during the frame creation process. We will examine how frames are destroyed in a moment.

LPD3DXFRAME *ppNewFrame

The second parameter to this function is the address of a D3DXFRAME pointer (i.e. a pointer to a pointer). This time the application is being passed a pointer by D3DX, not the other way round as is usually the case with D3DX function calls. The de-referenced pointer should contain `NULL` at this point, although it may not. We use this pointer to return the pointer to the frame that we create, back to the D3DXLoadMeshHierarchyFromX function.

The following code snippet is a simple version of a CreateFrame function implementation. It does everything D3DX requires and a bit more. It allocates a new D3DXFRAME, copies the name passed into the function, sets the frame transformation matrix to an identity matrix, and assigns the passed pointer to the newly created frame. Setting the transformation matrix to identity is purely a safety precaution as it will most likely be overwritten with the matrix data extracted from the X file when the frame data is loaded. However, this is a nice default state.

```
HRESULT CAllocateHierarchy::CreateFrame( LPCTSTR Name, LPD3DXFRAME *ppNewFrame )
{
    D3DXFRAME  *pNewFrame = NULL;

    // Clear out the passed frame pointer (it may not be NULL)
    *ppNewFrame = NULL;

    // Allocate a new frame
    pNewFrame = new D3DXFRAME;
    if ( !pNewFrame ) return E_OUTOFMEMORY;

    // Clear out the frame
    ZeroMemory( pNewFrame, sizeof(D3DXFRAME_MATRIX) );

    // Store the passed name in the frame structure
    // and set the new frame transformation matrix
    // to an identity matrix by default
    if ( Name ) pNewFrame->Name = _tcsdup( Name );
    D3DXMatrixIdentity( &pNewFrame->TransformationMatrix );

    // Assign the D3DX passed pointer to our new application allocated frame
    *ppNewFrame = pNewFrame;

    // Success!!
    return D3D_OK;
}
```

When we examine how to derive from these structures a little later on, you will see that these Create functions can and do serve a greater purpose, allowing us to store other data in our frame objects. When the above function returns, the passed pointer will point to our application allocated frame structure and it will contain the frame's name and an identity matrix. D3DX will then load the frame data from the X

file for this frame and store it in the structure before inserting the frame into its correct place in the hierarchy. This function will be called once for every frame in the hierarchy.

9.4.2.2 Deallocating Frames

If D3DX does not own the frame hierarchy memory, then how can it deallocate that memory when the hierarchy needs to be destroyed? In fact, since our application will only ultimately get back a root frame pointer from the D3DXLoadMeshHierarchyFromX function, how can we ourselves deallocate the hierarchy?

It just so happens that the D3DX library exposes a global function called D3DXFrameDestroy that will help with this process. When we have finished with our frame hierarchy we will call this function to cleanup the memory. We will discuss this function in detail at the end of this section. For now you should know that the D3DXFrameDestroy call takes two parameters. This first parameter is a pointer to a frame. This input frame and all of its descendants in the hierarchy will be destroyed. This would include the deallocation of any meshes as well. To release the whole hierarchy, we would pass in the root frame; to release only a sub-tree in the hierarchy, we would pass the appropriate node.

Because the memory is application owned, the application is responsible for actually physically releasing that memory. The second parameter to the D3DXFrameDestroy function is a pointer to an ID3DXAllocateHierarchy derived object (just as we saw for allocation). The function will step through each frame in the hierarchy and call ID3DXAllocateHierarchy::DestroyFrame. This gives control back to the application defined class for memory release.

HRESULT DestroyFrame(LPD3DXFRAME *pFrameToFree*);

The single function parameter is a pointer to the frame that D3DX would like released. This function will be called once for every frame in the hierarchy when the hierarchy is destroyed. The destruction of the full hierarchy is set in motion by the application calling the global D3DXFrameDestroy function with a pointer to the root frame.

Next we see a quick example implementation that matches up with the CreateFrame example we wrote earlier. Notice how the function frees the passed frame and the frame name as well. The name was allocated in the CreateFrame function when _tcsdup was called to make a copy of the passed name. Just as the CAllocateHierarchy::CreateFrame function is called by D3DX for each frame that needs to be created during X file loading, the CAllocateHierarchy::DestroyFrame function is called when the memory for each frame in the hierarchy needs to be released.

```
HRESULT CAllocateHierarchy::DestroyFrame( LPD3DXFRAME pFrameToFree )
{
     // Validate Parameters
    if ( !pFrameToFree ) return D3D_OK;

    // Release memory for name and frame
    if ( pFrameToFree->Name ) free( pFrameToFree->Name ); // '_tcsdup' allocated.
    delete pFrameToFree;                                  // 'new' allocated.
```

```
    // Success!!
    return D3D_OK;
}
```

Note that we used ‘free’ and not ‘delete’ to free the string memory because the _tcsdup function used in the CreateFrame method uses a C memory allocation function (alloc or malloc, etc.). The frame itself was allocated using ‘new’, so we free it with ‘delete’.

9.4.2.3 Allocating Mesh Containers

To handle allocation of meshes and related resources stored in the X file, our application-derived class must override the ID3DXAllocateHierarchy::CreateMeshContainer function. This function is similar to CreateFrame. It is called by D3DX so that the application can allocate and initialize a D3DXMESHCONTAINER structure and return it to the file loading function. Recall that D3DX can automate the loading of the mesh geometry, but it does not manage resources such as materials, textures, or effects (the application is responsible for that task). We saw this in the last chapter when we loaded the textures for the passed texture filenames and stored them in our CScene class.

The initialization and validation code is a bit laborious -- we have to copy, validate, and potentially manipulate all of the mesh related data passed in before we return the mesh container to D3DX. The concept is very similar to what we did in the last chapter when loading meshes using D3DXLoadMeshFromX. Recall that we are passed a loaded mesh and buffers filled with mesh related assets such as materials and texture filenames and we must process those resources ourselves. This function will be called once for each mesh in the X File hierarchy.

```
HRESULT CreateMeshContainer
(
    LPCSTR           Name,
    LPD3DXMESHDATA   pMeshData,
    LPD3DXMATERIAL   pMaterials,
    LPD3DXEFFECTINSTANCE pEffectInstances,
    DWORD            NumMaterials,
    DWORD *          pAdjacency,
    LPD3DXSKININFO   pSkinInfo,
    LPD3DXMESHCONTAINER *ppNewMeshContainer
);
```

LPCTSTR Name
This string stores the name of the mesh as defined inside the X file. We will often want to store this name along with our mesh so we can identify it later. Like the name in the frame structure, we must free the name when the mesh container is destroyed.

LPD3DXMESHDATA pMeshData
D3DX passes us the relevant mesh object using this structure pointer. It will either contain an ID3DXMesh, an ID3DXPMesh, or an ID3DXPatchMesh. We can do whatever we like with the mesh - clone it, manipulate it and then store it in the mesh container that we allocate, or we can simply store the passed mesh in the D3DXMESHCONTAINER structure immediately. It is important to understand that

eventually D3DX will Release() the interface to the mesh passed into this function. Therefore, if you are going to store away the mesh interface and you would like it to be persistent, you must call AddRef().

LPD3DXMATERIAL **pMaterials**
LPD3DXEFFECTINSTANCE **pEffectInstances**
DWORD **NumMaterials**
DWORD * **pAdjacency**
LPD3DXSKININFO **pSkinInfo**

These parameters are essentially carbon copies of the information you are required to store in the D3DXMESHCONTAINER structure. They are very similar to the information we get back when we call D3DXLoadMeshFromX. Again, we do not own the memory for these input parameters, and they will be destroyed by the caller (D3DX), so we must duplicate them if we wish to store the resources in the mesh container.

LPD3DXMESHCONTAINER * ppNewMeshContainer

As with the CreateFrame function, this pointer allows us to return our newly allocated mesh container back to D3DX after it has been populated with data passed into the function that we want to retain. For now, let us just look at a quick example that deals with the basics of mesh allocation. We will look at a more complete implementation that handles materials and textures in the workbook accompanying this chapter.

```
HRESULT CAllocateHierarchy::CreateMeshContainer( LPCTSTR Name, LPD3DXMESHDATA pMeshData,
                                                 LPD3DXMATERIAL pMaterials,
                                                 LPD3DXEFFECTINSTANCE pEffectInstances,
                                                 DWORD NumMaterials, DWORD *pAdjacency,
                                                LPD3DXSKININFO pSkinInfo,
                                                 LPD3DXMESHCONTAINER *ppNewMeshContainer )
{
    HRESULT            hRet;
    LPD3DXMESH         pMesh = NULL;
    D3DXMESHCONTAINER *pMeshContainer = NULL;

    // We only support standard meshes in this example (no patch or progressive meshes)
    if ( pMeshData->Type != D3DXMESHTYPE_MESH ) return E_FAIL;

    // We require FVF compatible meshes only
    if ( pMesh->GetFVF() == 0 ) return E_FAIL;

    // Allocate a new mesh container structure
    pMeshContainer = new D3DXMESHCONTAINER_DERIVED;
    if ( !pMeshContainer ) return E_OUTOFMEMORY;

    // Clear out the structure to begin with
    ZeroMemory( pMeshContainer, sizeof(D3DXMESHCONTAINER_DERIVED) );

    // Copy over the name. We can't simply copy the pointer here because the memory
    // for the string belongs to the caller (D3DX)
    if ( Name ) pMeshContainer->Name = _tcsdup( Name );

    // Copy over passed mesh data structure into our new mesh contain 'MeshData' member
    // Remember, we are also copying the mesh interface stored in the 'MeshData' structure
    // so we should increase the ref count
    pMeshContainer->MeshData = *pMeshData;
    pMeshContainer->MeshData.pMesh->AddRef();
```

```
    // Attempt to optimize the new mesh
    pMeshContainer->MeshData.pMesh->OptimizeInPlace(D3DXMESHOPT_VERTEXCACHE ,
                                                    pAdjacency , NULL , NULL , NULL);

    // Store this new mesh container pointer
    *ppNewMeshContainer = (D3DXMESHCONTAINER*)pMeshContainer;

    // Success!!
    return D3D_OK;
}
```

Studying the previous example function shows us that the process is not very complicated. It basically just creates a new mesh container and copies the passed mesh into it. The input pointer is assigned so that D3DX can insert the mesh into the hierarchy. Processing materials and textures will make the function longer, but no more difficult. The same is true if we need to change the mesh format to accommodate data required by the application, such as vertex normals if they are not included in the X file. In this case we would simply clone the passed mesh and store the newly cloned mesh in the mesh container. When this function returns the newly created mesh container to D3DX, it will be attached to the correct parent frame in the hierarchy. This function will be called for every mesh contained in the X file.

9.4.2.4 Deallocating Mesh Containers

During hierarchy destruction, ID3DXAllocateHierarchy::DestroyMeshContainer is called by D3DXFrameDestroy for each mesh container in the hierarchy. This allows the application to free the mesh containers and any application-defined content in an appropriate way. This parallels the requirement to implement a DestroyFrame function for frame cleanup.

`HRESULT DestroyMeshContainer( LPD3DXMESHCONTAINER pMeshContToFree );`

DestroyMeshContainer takes a single parameter: a pointer to the mesh container that D3DX would like us to free from memory. Here is an example that works in conjunction with the CreateMeshContainer function just discussed:

```
HRESULT CAllocateHierarchy::DestroyMeshContainer(LPD3DXMESHCONTAINER pContToFree)
{
    // Validate Parameters
    if ( !pContToFree ) return D3D_OK;

    // Release data
    if ( pContToFree->Name ) free( pContToFree->Name );
    if ( pContToFree->MeshData.pMesh)
         pContToFree->MeshData.pMesh->Release();

    delete pContToFree;

    // Success!!
    return D3D_OK;
}
```

9.4.2.5 The D3DXFrameDestroy Function

Most of the resource deallocation was handled in the DestroyFrame and DestroyMeshContainer functions we just examined. Initiating the destruction of the hierarchy, or a subtree thereof, is done with the following global D3DX function:

```
HRESULT D3DXFrameDestroy
(
    LPD3DXFRAME pFrameRoot,
    LPD3DXALLOCATEHIERARCHY pAlloc
);
```

LPD3DXFRAME pFrameRoot
This frame is the starting point for the destruction process. D3DX will start deallocation here at this node and then work its way through all subsequent child frames and mesh containers, cleaning up the resources as it goes. To destroy the entire hierarchy, just pass the root frame that was returned via the call to `D3DXLoadMeshHierarchyFromX`. Be sure to set your root frame variable to `NULL` after calling this function, to ensure that you do not try to access invalid memory later on.

LPD3DXALLOCATEHIERARCHY *pAlloc*
The second parameter is an instance of our derived `ID3DXAllocateHierarchy` class. It does not have to be the same physical object that was passed into the D3DXLoadMeshHierarchyFromX function, and it does not have to be allocated in any special way. For example, this object could be temporarily instantiated on the stack and it will work just as well. This will be the object D3DX calls to access the two Destroy functions (DestroyFrame and DestroyMeshContainer). Be sure to pass in the same type of derived class that was used to create the hierarchy in the first place.

Here is an example of a call that creates a local allocator and then cleans up the entire hierarchy:

```
CAllocateHierarchy Allocator;

if (m_pFrameRoot) D3DXFrameDestroy(m_pFrameRoot, &Allocator);
m_pFrameRoot = NULL;
```

9.4.3 Extending the D3DX Hierarchy

At first it may seem that hierarchy loading is more complicated than is called for. After all, D3DX should certainly be perfectly capable of doing everything itself. But by managing much of the process at the application level, we gain a significant advantage: the ability to extend the data structures stored in the hierarchy.

D3DX will concern itself only with the core navigation components of the hierarchy (`D3DXFRAME::pFrameSibling`, `D3DXFRAME::pFrameFirstChild`, `D3DXFRAME::pMeshContainer` and `D3DXMESHCONTAINER::pNextMeshContainer`), the frame transformation matrix (when working with

animation) and the frame name (when working with skinned meshes). The rest of the data structure can be used at our discretion.

As a result, we can derive our own structures from both `D3DXFRAME` and `D3DXMESHCONTAINER` and store whatever additional information we require. Since we are responsible for both the creation and destruction of these structures, as long as we cast it correctly in all of the right places, D3DX will work correctly without requiring knowledge of our additional structure members.

There are a number of cases where this proves to be useful. Some examples would include:

1) Caching the world matrix. Because the frame matrices are relative to their respective parent's space, they can be quite difficult (and potentially expensive) to work with when it comes to rendering the hierarchy. This is especially true in cases where multiple frames exist at the same level (as a sibling linked list).

   To expedite the process, each derived frame can store a new matrix that is a combination of all parent frame transformation matrices and its own relative matrix. We can build these matrices in a single hierarchy update pass. Then, when we render each mesh in the hierarchy, we can just use this matrix (assigned to its owner frame) as the mesh world matrix and avoid having to combine relative matrices for each mesh that we render.

   So we might derive a structure from D3DXFRAME similar to the following:

```
struct D3DXFRAME_DERIVED : public D3DXFRAME
{
      D3DXMATRIX  mtxCombined;
};
```

2) Hierarchical intersection testing. We can add bounding volume information to our frame structures so that hierarchical tests can be performed. For example, we might choose to store an axis aligned bounding box for collision testing, frustum culling, etc.:

```
struct D3DXFRAME_DERIVED : public D3DXFRAME
{
      D3DXMATRIX  mtxCombined;
      D3DXVECTOR3 aabb_min, aabb_max;
};
```

   The bounding volume at each frame in the hierarchy would be a combination of the frame's immediate bounding volume (built using all of the bounding volumes for meshes stored in the frame) plus the bounding volumes for its list of direct children (which themselves are calculated in the same way). These bounding volumes would all be world space volumes, and the bounding volume hierarchy would be built from the bottom up. If a node animates or changes in some way that would affect position, orientation, or scale, we can just recalculate its bounding volume and propagate that change up the tree to the root, starting from the node that changed. The significant advantage here is that the parent bounding volume totally encloses its children. Thus, if the parent is not visible (via an AABB/Frustum test for example) then none of its children could possibly be visible either. This minimizes rendering calls and is a common optimization in 3D

engines. The same holds true for other collision tests as well. If something cannot collide with the parent volume, it cannot possibly collide with any of its children either. This is one of the most beneficial aspects of a spatial hierarchy and we will encounter it again and again in our 3D graphics programming studies (including later in this very course).

3) Application specific mesh management. Rather than use the provided D3DXMESHDATA structure, we can derive our own mesh container to suit our needs:

```
struct D3DXMESHCONTAINER_DERIVED : public D3DXMESHCONTAINER
{
      CTriMesh    *pMesh;
};
```

Here we can store the mesh as we require and work directly within our engine's pre-established framework. This allows us to plug our mesh class directly into the D3DX hierarchy and store it in a mesh container. The CTriMesh listed above would be an example of a proprietary application mesh class that you might write to manage your triangle based mesh data.

One thing to make sure that you do straight away is update the destroy functions in your hierarchy allocation class. If you are working with a derived structure, you must make sure that you cast the pointer that was passed to the destroy functions to the derived structure type before you `delete` it. If you do not, you risk important destructors not being called, memory not being freed, or any manner of potential general protection faults.

There are some important exceptions to the above cases, where overriding the default behaviour may cause problems. For example, not storing the mesh in the provided D3DXMESHDATA structure can lead to one issue. Consider the function `D3DXFrameCalculateBoundingSphere`. This is a very nice function that iterates through the frame hierarchy starting from a passed frame and tests the mesh data stored there to return a bounding sphere that encapsulates all of the meshes that are children (both immediate and non-immediate). This function will expect the mesh data to be stored in the standard place (inside the D3DXMESHDATA structure of the mesh container) and will not be able to calculate a bounding sphere unless this is the case. Another example is `D3DXSaveMeshHierarchyToFile`. This function iterates through the hierarchy and writes mesh, material, effect, and texture data out to an X file. Note that in both of these cases there is a simple solution -- we can store a reference to the mesh in both the provided data structure (D3DXMESHDATA) and our custom mesh class (CTriMesh in our example above).

9.4.4 D3DXLoadMeshHierarchyFromX Continued

There are still two parameters left to discuss before we use D3DXLoadMeshHierarchyFromX.

```
HRESULT D3DXLoadMeshHierarchyFromX
(
    LPCTSTR                 Filename,
    DWORD                   MeshOptions,
    LPDIRECT3DDEVICE9       pDevice,
```

```
    LPD3DXALLOCATEHIERARCHY       pAlloc,
    LPD3DXLOADUSERDATA            pUserDataLoader,
    LPD3DXFRAME*                  ppFrameHeirarchy,
    LPD3DXANIMATIONCONTROLLER*    ppAnimController
);
```

We will address the animation controller type in the next chapter. For now, we will just assume that the X file contains no animation and we will set this parameter to NULL. This tells the function that we are not interested in getting back animation data, even if it exists in the file.

LPD3DXLOADUSERDATA pUserDataLoader

The fifth parameter is a pointer to an ID3DXLoadUserData interface. Much like ID3DXAllocateHierarchy, this parameter is also going to be passed as an application-defined class that is derived from the ID3DXLoadUserData interface. The methods of this object will be called (by the D3DX loading function) whenever data objects built from custom templates are encountered in the X file.

If you are not using custom data objects, then D3DX will not require this pointer and you can simply pass NULL. In fact, even if the X file does contain custom data objects you can still pass in NULL. In this case, D3DX will simply ignore custom information and just load the standard data objects.

Our ID3DXLoadUserData derived object must implement three functions: LoadTopLevelData, LoadFrameChildData, and LoadMeshChildData. In order to properly derive from this class and process custom data objects, we must be familiar with all the X file topics we discussed earlier. Specifically, we need to be comfortable with the IDirectXFileData interface. While we will not need to use this interface, D3DX will pass our callback functions an ID3DXFileData interface for each custom data object it encounters. This interface is almost identical to the IDirectXFileData interface we discussed earlier. It is a newer interface however that has been wrapped up in the D3DX library to make accessing the data a little simpler. If you understand the IDirectXFileData methods, you will understand how to use all of the analogous methods exposed by the ID3DXFileData interface.

9.4.4.1 The ID3DXLoadUserData Interface

The ID3DXLoadUserData interface is declared in d3dx9anim.h. This is another pure abstract non-COM interface just like ID3DXAllocateHierarchy. However, if we look at the following interface declaration we will notice something different about this declaration when compared to all others.

```
DECLARE_INTERFACE(ID3DXLoadUserData)
{
    STDMETHOD(LoadTopLevelData)   ( LPD3DXFILEDATA pXofChildData) PURE;

    STDMETHOD(LoadFrameChildData) ( LPD3DXFRAME pFrame, LPD3DXFILEDATA pXofChildData) PURE;

    STDMETHOD(LoadMeshChildData)  ( LPD3DXMESHCONTAINER pMeshContainer,
                                    LPD3DXFILEDATA pXofChildData) PURE;
};
```

Compare this to the following interface that more closely follows the rules we discussed earlier about declaring interfaces: (It is probably how ID3DXLoadUserData should have been defined.)

```
#undef INTERFACE
#define      INTERFACE ID3DXLoadUserData

DECLARE_INTERFACE(ID3DXLoadUserData)
{
    STDMETHOD(LoadTopLevelData)   ( THIS_ LPD3DXFILEDATA pXofChildData) PURE;

    STDMETHOD(LoadFrameChildData) ( THIS_ LPD3DXFRAME pFrame,
                                    LPD3DXFILEDATA pXofChildData) PURE;

    STDMETHOD(LoadMeshChildData)  ( THIS_ LPD3DXMESHCONTAINER pMeshContainer,
                                    LPD3DXFILEDATA pXofChildData) PURE;
};
```

So there are two key differences (perhaps by design, perhaps an oversight) -- the interface is not defined before the declaration and the methods have not had the 'THIS_' macro inserted at the head of their parameter lists. As a result, this interface cannot be used in a C environment.

In fact, there are two interfaces in this header file (d3dx9anim.h) where the same declaration style is presented. The other is the declaration of the ID3DXSaveUserData interface. If you need to use either interface in a C environment, your only option is to alter the interface declaration in d3dx9anim.h to the format seen above.

Deriving a class from the ID3DXLoadUserData interface in a C++ environment is straightforward:

```
class CLoadUserData : public ID3DXLoadUserData
{
public:
    STDMETHOD(LoadTopLevelData)   (LPD3DXFILEDATA pXofChildData);
    STDMETHOD(LoadMeshChildData)  (LPD3DXMESHCONTAINER pMeshContainer,
                                   LPD3DXFILEDATA pXofChildData);
    STDMETHOD(LoadFrameChildData) (LPD3DXFRAME pFrame, LPD3DXFILEDATA pXofChildData);
};
```

If you are using a C environment and you have edited and corrected the ID3DXLoadUserData declaration in the d3dx9anim.h header file as mentioned above, then your derived class declaration would look something like this:

```
class CLoadUserData : public ID3DXLoadUserData
{
public:
    STDMETHOD(LoadTopLevelData)  (THIS_  LPD3DXFILEDATA pXofChildData);
    STDMETHOD(LoadMeshChildData) (THIS_  LPD3DXMESHCONTAINER pMeshContainer,
                                  THIS_  LPD3DXFILEDATA pXofChildData);
    STDMETHOD(LoadFrameChildData)(THIS_  LPD3DXFRAME pFrame, LPD3DXFILEDATA pXofChildData);
};
```

9.4.4.2 Loading Custom Top Level Data

HRESULT LoadTopLevelData(LPD3DXFILEDATA *pXofChildData*);

Recall that a top level data object is not defined inside any other data object (i.e., it does not have a parent) in the X file. When the D3DXLoadMeshHierarchyFromX function encounters a top level data object that is not one of the data objects based on a standard template, it calls the LoadTopLevelData function of your passed ID3DXLoadUserData derived object so that the application can process the data as it deems appropriate.

The function receives a pointer to an ID3DXFileData interface which provides all of the methods we need to identify the custom object (GetName, GetType, and GetID) and also allows us to retrieve a pointer to the actual data of the object for extraction (via its Lock and Unlock methods). We discussed the IDirectXFileData interface in detail earlier in this chapter and the ID3DXFileData interface is very similar. Its methods are shown below:

```
GetChildren ( SIZE_T *puiChildren );
GetChild    ( SIZE_T uiChild, ID3DXFileData **ppChild );
GetEnum     ( ID3DXFileEnumObject **ppObj );
GetId       ( LPGUID pId );
GetName     ( LPSTR szName, SIZE_T *puiSize );
GetType     ( const GUID *pType );
IsReference ( VOID );
Lock        ( SIZE_T *pSize, const VOID **ppData );
Unlock      ( VOID );
```

To see how we might implement such a function to handle the processing of top level custom data objects, let us go back to our earlier example using a custom template.

```
template TestTemplate
{
  <A96F6E5D-04C4-49C8-8113-B5485E04A866>
  FLOAT TestFloat1;
  FLOAT TestFloat2;
  FLOAT TestFloat3;
}
```

Let us assume that the X file we are loading has at least one of these objects as a top level object. In this example we will include an object called MyFirstValues:

```
TestTemplate MyFirstValues
{
  1.000000;
  2.000000;
  3.000000;
}
```

In order to store and manage this type of data in our application, we would probably define a structure in our code that mirrors the template definition in the X file:

```
struct TestTemplate
{
    float TestFloat1;
    float TestFloat2;
    float TestFloat3;
};
```

Somewhere else in our code, before we load the X file, we would want to define a GUID that mirrors the values stored in the template. This will allow us to compare GUIDs when we need to determine custom object types when the function is called.

```
// The GUID used in the file for the template, so we can identify it
const GUID IID_TestTemplate = {0xA96F6E5D, 0x4C4, 0x49C8, {0x81, 0x13, 0xB5, 0x48,
0x5E, 0x4, 0xA8, 0x66}};
```

You could also create this GUID using the DEFINE_GUID macro:

```
DEFINE_GUID ( IID_TestTemplate , 0xA96F6E5D, 0x4C4, 0x49C8, 0x81, 0x13, 0xB5, 0x48,
0x5E, 0x4, 0xA8, 0x66 };
```

Now let us look at our LoadTopLevelData function:

```
HRESULT CLoadUserData::LoadTopLevelData(LPD3DXFILEDATA pXofChildData)
{
    // First retrieve the name of the data object
    TCHAR DataName[256];
    ULONG StringSize = 256;
    pXofChildData->GetName( DataName, &StringSize );

    // Next retrieve the GUID of the data object if one exists
    GUID DataUID;
    pXofChildData->GetId( &DataUID );

    // Next up, retrieve the GUID of the template which defined it.
    const GUID * pTypeUID;
    pXofChildData->GetType(&pTypeUID );

    // Ensure that we are importing the type that we expect
    if ( memcmp( pTypeUID, &TestTemplateUID, sizeof(GUID) ) != 0 )
        return D3D_OK;

    // OK, we know it's our type, import and process the data
    TestTemplate * pData;
    ULONG DataSize;
    pXofChildData->Lock( &DataSize, ( const void**)&pData );

    // We can now use the data
    DO SOMETHING WITH DATA HERE (ex. COPY AND STORE IT SOMEWHERE);

    PXofChildData->Unlock();

    // Success!!
    return D3D_OK;
}
```

This is the core of our custom data processor. We retrieve the type via a call to `GetType`, the data itself via a call to `GetData`, and then depending on the value of the type `GUID` returned, we cast and process the data pointed to by the returned pointer. If we were using multiple custom templates, a switch statement or some other conditional would probably be in order, but the concept is the same.

Note: Remember that IDirectXFileData::GetID returns the GUID of the object, not the template.

Do not forget that if you are processing data objects that have child data objects (or child data reference objects) then you will want to call IDirectXFileData::GetNextObject to retrieve and process those as well. As the child objects may themselves have child objects, suffice to say, this could be a deeply recursive process which requires some thought on how best to implement this code. Using closed or restricted templates can help minimize code complexity and recursion.

It should be noted that the code example above was written a little bit dangerously in an effort to improve clarity of the process. It assumes that any padding added to the structure TestTemplate by the compiler would also be mirrored in the X file data object, which is not usually the case. Therefore, because file data is not guaranteed to be aligned properly with byte boundaries in your C++ structure, you should access *data* with unaligned pointers. For example, you could step through the data with a BYTE pointer and extract each member by correctly offsetting and casting the de-referenced pointer into another variable type.

Refer to the CD3Dfile.cpp file that ships with the DirectX SDK (Samples\C++\Common\Src) to see how IDirectXFileData can be used to recursively process a hierarchy.

9.4.4.3 Loading Custom Child Data

When a top level object based on one of the open standard templates includes a custom child, D3DX must call out to the application to deal with this data. There are two important functions we must be prepared to implement in our derived ID3DXLoadUserData class. The first function will handle custom children found when processing a frame and the second handles custom children found when processing a mesh.

```
HRESULT LoadFrameChildData(LPD3DXFRAME pFrame,
                           LPD3DXFILEDATA pXofChildData);
```

LoadFrameChildData will be called by D3DXLoadMeshHierarchyFromX whenever an unknown object is encountered by the loading code that is an immediate child of a frame being processed. In addition to the expected ID3DXFileData type that allows us to extract the custom data, the function also takes a pointer to the frame in the hierarchy for which the custom data object is a child. This is useful if our application is using a derived D3DXFRAME structure with additional members that might be needed to store this custom data in some meaningful way. For example, the custom object might contain a string that describes what the frame is used for and whether or not it should be animated. If we were using a derived D3DXFRAME class, we could copy this string into a member variable in the frame structure. Thus each frame would contain a description that could be used for printing out debug information.

The following snippet shows our custom template embedded inside a standard frame object as an immediate child:

```
Xof 0303txt 0032

Frame Root
{
      FrameTransformMatrix
      {
        1.000000, 0.000000, 0.000000,  0.000000,
        0.000000, 1.000000, 0.000000,  0.000000,
        0.000000, 0.000000, 1.000000,  0.000000,
       50.000000, 0.000000, 50.000000, 1.000000;;
      }

      Mesh CarBody { mesh data would go in here }

      TestTemplate MyFirstValues
      {
            1.000000;
            2.000000;
            3.000000;
      }
}
```

When D3DXLoadMeshHierarchyFromX encounters a custom data object as an immediate child of a mesh object, the LoadMeshChildData method is called to facilitate processing. Like its predecessor, the function provides access to the parent mesh in addition to the custom child data.

HRESULT LoadMeshChildData(LPD3DXMESHCONTAINER *pMeshContainer*,
LPD3DXFILEDATA *pXofChildData*);

The following X file snippet demonstrates a custom template embedded in a standard mesh object.

```
Xof 0303txt 0032

Frame Root
{
  FrameTransformMatrix
  {
    1.000000, 0.000000, 0.000000,  0.000000,
    0.000000, 1.000000, 0.000000,  0.000000,
    0.000000, 0.000000, 1.000000,  0.000000,
   50.000000, 0.000000, 50.000000, 1.000000;;
  }

  Mesh MyMesh
  {
    6;                  // Number of vertices
   -5.0;-5.0;0.0;,      // Vertex list ( Vector array )
   -5.0;5.0;0.0;,
    5.0;5.0;0.0;,
    5.0;-5.0;0.0;,
```

```
   -5.0;5.0;-5.0;,
   -5.0;5.0;5.0;;

    2;            // Number of faces
    3;0,1,2;,     // MeshFace Array
    3;3,4,5;;

    TestTemplate MyFirstValues
    {
      1.000000;
      2.000000;
      3.000000;
    }
  } // end mesh
} // end frame ( top level object )
```

9.4.5 Using D3DXLoadMeshHierarchyFromX

Our previous discussions may lead you to believe that D3DXLoadMeshHierarchyFromX is dreadfully complicated. While it is certainly more involved than D3DXLoadMeshFromX, it is still relatively straightforward, especially when you are not processing custom data objects. Once you have derived a suitable ID3DXAllocateHierarchy class to handle frame and mesh allocation, you can load a frame hierarchy stored in a file like so:

```
CAllocateHierarchy Allocator;
D3DXFRAME *pRootFrame = NULL;

D3DXLoadMeshHierarchyFromX("Example.x", D3DXMESH_MANAGED,
                           pDevice, &Allocator,
                           NULL, &pRootFrame, NULL );
```

When this function returns, pRootFrame will point to the root frame of the hierarchy contained in "Example.x". We passed NULL for the pUserDataLoader parameter so that custom data objects will be ignored. We also passed NULL for the ppAnimController parameter since we will not require animation data in this example. We will discuss the ID3DXAnimationController in the next chapter. Note that we have passed D3DXMESH_MANAGED for the mesh creation flag to indicate our desire for managed resources.

> **Note:** The Options passed to D3DXLoadFrameHierarchyFromX are not adhered to as closely as you might like. For example, in one of our testing scenarios, passing D3DXMESH_MANAGED resulted in meshes created with the D3DXMESH_SOFTWARE option (with a dramatic performance hit). To work around this, as you will see in the workbook source code, we forcibly set the Options inside the derived CreateMeshContainer method by cloning the mesh when the options passed by D3DX are not what we asked for.

It is also worth noting that there is a D3DXLoadMeshHierarchyFromXInMemory function available as well. As we have come to expect from the D3DX library, any function that loads data from a file usually has sibling functions that have the same semantics, but different data sources (memory, resources).

9.5 X File Notes

Before wrapping up our X file discussions, there are a few things to keep in mind when working with X files:

- You **must** include the decimal point when working with floating point values in a template. For example, specify '2.' or '2.0' but not '2'. If you do not, the value will be imported incorrectly.

- Be aware of structure padding for byte alignment. This is important to bear in mind when copying data from an IDirectXFileData object into an application defined structure. For example, consider the following structure:

```
struct TestStruct{
    UCHAR foo;
    ULONG bar;
};
```

  You might expect that if we were to do sizeof(TestStruct) that it would return 5, because the structure contains a single ULONG (4 bytes) and a single UCHAR (1 byte). In fact, sizeof would return 8 because by default, structures are byte aligned to make them more efficient. So in memory, our structure looks more like:

```
struct TestStruct{
    UCHAR foo;
    // Three Padding Bytes Here
    ULONG bar;
};
```

  Thus, when laid out in a format similar to the current example, structures are aligned based on the largest member contained therein. Another example:

```
struct TestStruct{
    UCHAR foo;
    // Seven Padding Bytes Here
    __int64 bar;
};
```

  The above structure would return a value of 16 from sizeof, even though we only directly use 9 bytes with our member variables. This is in contrast to our templates -- when D3DX loads a template with members similar to the above structures, it will not pad the data. This means that in some cases we can not simply 'memcpy' the data over, but will need to copy the members individually.

- The SDK documentation states (in places) that restricted template declarators should specify a GUID within square brackets. This is not true -- they should in fact be enclosed in 'less than' and 'greater than' chevron symbols as explained earlier.

9.6 Rendering the Hierarchy

Rendering a D3DX based hierarchy requires stepping through the frames in a particular order. Our function will iterate recursively from frame to frame, combining frame matrices as it goes. We can render meshes stored in the frame in this recursion, or we can alternatively choose to separate the world matrix update pass from the rendering pass. Here is an example of both updating the matrices and rendering in a single pass through the hierarchy:

```
void RenderFrame ( LPD3DXFRAME pFrame, const D3DXMATRIX * pParentMatrix )
{
    // Used to hold world matrix for immediate child meshes of this frame
    D3DXMATRIX WorldMatrix;

    // If there is a parent matrix then combine this frame's relative matrix with it
    // so we get the complete world transform for this frame.
    // Otherwise, this is the root frame so this frame's matrix is
    // the world matrix for the frame (just copy it)
    if ( pParentMatrix != NULL)
      D3DXMatrixMultiply(&WorldMatrix, &pFrame->TransformationMatrix, pParentMatrix);
    else
      WorldMatrix = pFrame->TransformationMatrix;

    // Now we need to render the linked list of meshes using this transform
    pD3DDevice->SetTransform( D3DTS_WORLD, &WorldMatrix );
    for ( pMeshContainer = pFrame->pMeshContainer;  pMeshContainer;
          pMeshContainer = pMeshContainer->pNextMeshContainer )
    {
         RenderMesh ( pMeshContainer );
    }

    // Process Sibling Frame with the same parent matrix
    if ( pFrame->pFrameSibling )
        RenderFrame (pFrame->pFrameSibling, pParentMatrix);

    // Move onto first child frame
    if ( pFrame->pFrameFirstChild )
        RenderFrame ( pFrame->pFrameFirstChild, &WorldMatrix);
}
```

In the above code, the RenderMesh() function is assumed to be a function that handles the actual drawing of the mesh. This can be a function that loops through each subset of the mesh, sets the relevant textures and material for that subset and then calls DrawSubset, or one that sets aside the mesh in some sort of render queue for additional sorting prior to the actual polygon drawing routines. If you choose the latter approach, just remember to store the world matrix for later access (and skip the SetTransform call since it is an unnecessary expense in that case).

To kick off the process above, we would call the function from our application render loop, passing in a pointer to our hierarchy root frame and NULL for the initial matrix pointer.

```
RenderFrame (pRootFrame, NULL);
```

Alternatively, we could pass in a standard world matrix (assuming the root frame matrix is set to identity by default – often a good idea) to move or orient the hierarchy in the world or with respect to some other parent if desired (like our car transporter example discussed earlier). Assuming our hierarchy was wrapped in some application defined object:

```
RenderFrame (object->pRootFrame, &object->world_matrix);
```

Also keep in mind our earlier discussion regarding intersection testing (ex. frustum culling). As mentioned, intersection testing is much more efficient when we use hierarchical spatial data structures due to the bounding volume relationship that ensues (parents completely enclose their children).

Let us look at dividing our rendering strategy into two passes. The first pass will update the world matrices for each frame. This would also be an ideal place to run any animation controllers if they were attached directly to nodes, but we will not worry about that for the moment. The second pass will handle the actual drawing calls, but will include simple visibility testing. Note that because we are separating the two passes, we will need to store the world matrix generated during the initial pass. Otherwise the render pass will not be able to properly transform the child meshes. We will assume in our example that we have derived our own frame type from D3DXFRAME called CMyFrame which adds a WorldMatrix D3DXMATRIX member for this purpose.

```
void Update ( LPD3DXFRAME pFrame, const D3DXMATRIX * pParentMatrix )
{
    // Cast to a pointer to our derived frame type
    CMyFrame *myFrame = (CMyFrame *)pFrame;

    // Could process local animations here…
    //(D3DX does things differently though as we will see)

    // If there is a parent matrix then combine this frame relative matrix with it
    // so we get the complete world transform for this frame.
    // Otherwise, this is the root frame, so this frame's matrix is
    // the world matrix for the frame -- so just copy it
    if ( pParentMatrix != NULL)
           D3DXMatrixMultiply(&myFrame->WorldMatrix, &myFrame->TransformationMatrix,
                              pParentMatrix);
    else
           myFrame->WorldMatrix = myFrame->TransformationMatrix;

     // Process Sibling Frame with the same parent matrix
     if ( myFrame->pFrameSibling )
          Update ( myFrame->pFrameSibling, pParentMatrix );

     // Move onto first child frame
     if ( myFrame->pFrameFirstChild )
           Update ( myFrame->pFrameFirstChild, &myFrame->WorldMatrix);
}
```

With our hierarchy now updated in world space, we can proceed to render it in a separate pass using the following function. Note that because the hierarchy has been updated for this render pass, all the frame structures now contain the actual world transformation matrices in their (newly added) WorldMatrix member. This function does not have to do any matrix concatenation; it just has to set the world matrix for any frame that contains meshes, and then render those meshes.

```
void Render ( LPD3DXFRAME pFrame, Camera  *pCamera )
{
     // Cast to a pointer to our derived frame type
     CMyFrame *myFrame = (CMyFrame *) pFrame;

     // If frame is not visible, neither are its children… just return
     if ( !pCamera->FrustumSphereTest( myFrame->center, myFrame->radius ))
            return;

     // Now we need to render the linked list of meshes using this transform
     pD3DDevice->SetTransform( D3DTS_WORLD, &myFrame->WorldMatrix );
     for ( pMeshContainer = myFrame->pMeshContainer;  pMeshContainer;
           pMeshContainer = pMeshContainer->pNextMeshContainer )
     {
           RenderMesh ( pMeshContainer );
     }

     // Process Sibling Frame with the same parent matrix
     if ( myFrame->pFrameSibling ) Render ( myFrame->pFrameSibling, pCamera );

     // Move onto first child frame
     if ( myFrame->pFrameFirstChild ) Render ( myFrame->pFrameFirstChild, pCamera );
}
```

In this code example, our visibility test is just about the simplest one possible. It is a very rough cull that considers partial intersections to be visible. We could instead implement a more robust system that accounts for cases where the bounding volume is fully outside, fully inside, or partially intersecting the frustum. When the volume is fully inside, no additional tests are needed for the children – they can simply be rendered directly without them having to do tests of their own. When the volume is partially inside, we can run additional tests with tighter fitting bounding volumes (perhaps an AABB) if desired. We will discuss Bounding Volume/Frustum tests again later in this course.

There are other optimizations that can be done with frustum culling as well. For example, given what we know about our parent-child relationship, we can further speed up our routine by tracking which frustum planes the parent tested against and letting the children know this during the traversal (a bit flag works nicely here). If the parent was completely inside the left frustum plane for example, so are its children and they will not need to run that test again -- only partial intersections need to be tested. This reduces the number of tests that need to be run at each node in the tree. Again, a parent being fully outside any single plane means all of its children are as well and traversal stops at that point as we saw above.

Another popular optimization is frame-to-frame coherency which adds even more value to the previous two optimizations. A simple implementation of this requires that we keep track of the last failed frustum plane tested between render calls (usually as a data member in our derived frame class). It is likely that on the next render pass, that frame will fail against the same frustum plane, so we can test it first. If the frame fails that same frustum plane test, we can immediately skip the remaining 5 (out of 6) frustum plane tests and return immediately, letting the caller know the frame is still not visible. We will be incorporating all of these concepts and more into our game engine design during the next course in this series, but you should feel free to try your hand at them sooner if you like. They really can make a big difference in engine performance.

Conclusion

This chapter has certainly been tough going, due mainly in part to the fact that the loading of data is rarely considered very engaging subject matter. We have not even learned anything that will give us instant visual gratification. However, as virtually all game engines arrange their data hierarchically, what we have learned in this chapter is a foundation upon which everything else we do will be built from this point on. Animated game characters for example (Chapter 11) will be represented as frame hierarchies, where each frame in the hierarchy represents an animation-capable joint of the character's skeleton.

As we have now learned how to load, construct, traverse, and render frame hierarchies, we now finally have the ability to load and represent entire scenes as independent objects that can be manipulated as needed.

We will use hierarchies to spatially subdivide the world to make efficient rendering possible as we will see later. In fact, frame hierarchies serve as a great introduction to the topic of scene graphs. Scene graphs are basically a more complex and fleshed out frame hierarchy implementation. We will be discussing them in module III of this course series when we leave our framework behind and migrate towards larger scale graphics engine technologies.

Simply put, you will find that we will be using frame hierarchies almost everywhere from now on. Indeed, we will begin with the very next chapter. In Chapter Ten, we will learn how to use the D3DX animation system to animate our scene hierarchies. The D3DX animation system allows us to perform some very complex tasks, from playing cut scenes using our in game graphics engine, to performing real time animation blending. Hierarchies play a pivotal role in these tasks, so you are now well equipped to move forward with confidence.

Workbook Nine:
Frame Hierarchies

Lab Project 9.1: Multi-Mesh Hierarchies

The focus of this lab project will be on loading and rendering multi-mesh frame hierarchies. Many of the topics discussed in the accompanying textbook will be demonstrated as we progress. For example, we will implement a class called CActor which encapsulates hierarchies and provide the application with an easy means to update and render them. We will also derive our own class from ID3DXAllocateHierarchy to facilitate the automated loading of multi-mesh X files within CActor. In addition, we will explore the relative nature of frame hierarchies by creating a simple animation class (called CAnimation). As discussed in the textbook, objects of this type can be attached to frames in the hierarchy and used to animate/update their matrices in a local fashion. While the demonstration application we create (Figure 9.1) may appear to be a simple mesh viewer, the car is actually a multi-mesh representation. This allows us to apply animations to the wheels separately from the rest of the hierarchy. Finally, the frames in our hierarchy will store pointers to meshes of type CTriMesh. As a result, we can continue to use the mesh resource management system we developed in the previous chapter and render our meshes using the class interface we are now familiar with.

Figure 9.1

This lab project will teach you how to do the following:

- Populate a frame hierarchy from an X file.
- Derive your own class from the ID3DXAllocateHierarchy interface.
- Populate the frame hierarchy from external references inside an IWF file.
- Animate individual frames in the hierarchy.
- Traverse and render a hierarchy.
- Represent meshes in the hierarchy using our own object type (CTriMesh).

Introducing CActor

To encapsulate hierarchies (loaded from an X file in this case), the CActor class will be implemented and employed. If multiple hierarchical X files need to be loaded (e.g., multiple game characters) then a separate CActor object will be instantiated to wrap the frame hierarchy and mesh data for each one. The term 'Actor' is commonly used in many game development SDKs to represent an animation capable object or hierarchy of objects that plays a part in the scene. This is not unlike the way an actor in Hollywood plays a part in a movie. While this is exactly the context in which we are using the name Actor, it should be made clear that our CActor class need not just represent the frame hierarchy for a single multi-mesh model (e.g., a character or an automobile) but may represent an entire scene hierarchy loaded from a single X file.

The CActor class will wrap the call to the D3DXLoadMeshHierarchyFromX function with its own method called LoadActorFromX. This is the function that our application will call to load the X file into the actor. When it returns control back to the application, the hierarchy and mesh data that was contained in the file will be loaded and the CActor will contain a D3DXFRAME derived pointer to the root frame of the hierarchy. The CActor class will also expose functions to traverse the hierarchy and update the frame matrices to generate the absolute matrices for each frame prior to rendering its meshes. Additionally, the interface will expose functions to render the hierarchy and its contained meshes.

In the textbook we learned that in order to use the D3DXLoadMeshHierarchyFromX function, we must derive a class from the ID3DXAllocateHierarchy interface. You will recall that the four member functions of this interface are used as callbacks by the D3DX loading function to allow the application to allocate the memory for the hierarchy frames and mesh containers in the appropriate way. Our ID3DXAllocateHierarchy derived class will be a standalone class that is instantiated and used by the CActor object to pass into the D3DXLoadMeshHierarchyFromX function. The CreateMeshContainer callback function of the CAllocateHierarchy class that we derive will also need access to the CActor object which is currently using it. Therefore, when we derive our class, we will also add a pointer to a CActor object that will be set by its constructor.

The reason the CAllocateHierarchy::CreateMeshContainer function needs to know about the CActor object using it harkens back to the previous lesson where we wanted to have texture and material management for all meshes (contained in all actors) handled at the scene level. You will recall that we implemented a callback mechanism for our CTriMesh class so that when it loaded data from an X file, the returned texture and material buffer was passed off to the scene (via the scene callback functions that had been registered with the mesh) to add the textures and materials to the scene's texture and material arrays. With meshes in non-managed mode, this meant that multiple CTriMeshes in the scene shared the same resources and needed to be rendered by the scene itself. This provided better batching potential. Even in non-managed mode (where the CTriMesh stored its own texture and material information) the textures were still loaded and stored in the scene object to minimize redundancy when multiple managed meshes used the same texture resources. We very much wish to use our CTriMesh class to represent the various meshes stored in our D3DX frame hierarchies so that we can work with an interface that we are comfortable with and continue to benefit from its cloning and optimization functions. Furthermore, we definitely want our meshes to benefit from the managed and non-managed mode resource management systems implemented by that class.

Unlike using our CTriMesh class in isolation, where creation is basically performed by the D3DXLoadMeshFromX function, our meshes will now need to be created manually inside the CreateMeshContainer function of the CAllocator object. Recall that this function is called for each mesh in the hierarchy by D3DX and it is passed the ID3DXMesh interface and the materials the mesh uses. Therefore, we do not wish to use the CTriMesh::LoadMeshFromX function (as we did in the previous lesson) to create our CTriMesh data because the mesh data has already been loaded by D3DX. Instead, our CTriMesh instances will need to be created inside the CreateMeshContainer function and attach the ID3DXMesh data that we are passed. This presents a small problem because previously our application would instantiate a CTriMesh, register the material callbacks, and then call the CTriMesh::LoadMeshFromX function which triggered these callbacks. But now that the CTriMesh::LoadMeshFromX function will no longer be used, our CTriMesh is not created until the hierarchy is being loaded. Therefore, the application cannot register callbacks with meshes that do not yet exist prior to the D3DXLoadMeshHierarchyFromX call made by CActor. The simple solution is to duplicate some of this callback functionality inside CActor. This will allow the application to register the same three callback functions with the CActor instead of CTriMesh. When the CreateMeshContainer function is called, because the CAllocateHierarchy object has a pointer stored for the CActor for which it is being used, it can access the actor's function callback array and perform the same task (handing resources for each mesh off to the scene).

The basic task of the CAllocateHierarchy::CreateMeshContainer function will be as follows:

- Allocate a new CTriMesh object and attach it to the ID3DXMesh that it is passed by D3DX
- If the CActor is in managed mode, allocate space in the CTriMesh's internal attribute table to store the texture pointer and material for each subset that we are passed by D3DX. Copy the material data into the CTriMesh's internal attribute table and use the CActor's registered texture callback function to load the texture and return a texture pointer. These texture pointers are also stored inside CTriMesh's attribute table.
- If the CActor is in non-managed mode then the function will simply send the passed material data to the actor's registered attribute callback function which will store the texture and material data for each subset at the scene level. This function will return a new global attribute ID for each subset in the mesh which the function can use to lock the CTriMesh's index buffer and remap its attribute buffer.
- Store the newly created CTriMesh in the mesh container and return it to D3DX so that it can be attached to the frame hierarchy.

All of the above steps should seem very familiar. This code was seen in the previous chapter inside the CTriMesh::LoadMeshFromX function. All we have done is essentially duplicated it inside the CreateMeshContainer method of the CAllocateHierarchy object. This same code still exists in the CTriMesh::LoadMeshFromX function so that it can continue to be used as a standalone mesh object that does not have to be used with CActor or frame hierarchies. However, when the CTriMesh is part of the CActor's internal hierarchy, their own callback system will not be used and the CActor will manage the callbacks instead.

It is also worth noting that our CActor class can still be used to load an X file even if that X file does not contain a frame hierarchy and contains only a single mesh. In such a case, the CActor's hierarchy will consist of just a single frame (the root) with the mesh attached as an immediate child

object. Single mesh CActors can be rendered and updated in exactly the same way, so the difference is invisible to the application using the CActor class.

Application Design

An understanding of the relationships between our various classes is vital. So let us break down the responsibilities for each object:

CScene

As we have come to expect, the scene object handles the loading of scene data and the rendering of that data at a high level. The application uses the CScene::LoadSceneFromX or CScene::LoadSceneFromIWF functions to load the data and set it up correctly. The scene loading methods have now been modified to be aware of actors.

The CScene::LoadSceneFromX function will now allocate a new CActor and register any resource callback functions with the actor before calling the LoadActorFromX function to populate the frame hierarchy with X file data. Each call to this function made by the application will load a new X file and will create a new CActor in the scene's CActor array. In our application, this function is called once to load the automobile representation from the X file.

The CScene::LoadSceneFromIWF (and all its support functions) are largely unchanged. In the previous chapter, it searched for external references stored inside the IWF file and used their names to load an X file into a CTriMesh. Now, this same function will allocate a new CActor when an external reference is found instead. It will then register the scene's resource callbacks with the newly created actor before calling the CActor::LoadActorFromX function to load the X file data.

All the other scene methods that are part of the framework still exist (AnimateObject, Render, etc.) and will be changed slightly to work with actors.

CActor

The CActor class encapsulates the loading, updating, and rendering of a hierarchy.

Its loading function CActor::LoadActorFromX will instantiate a temporary CAllocateHierarchy object and pass it into the D3DXLoadMeshHierarchyFromX function. When this function returns, the CActor's root frame pointer will point to the root frame of the newly loaded frame hierarchy. Any meshes attached to frames in the hierarchy will be of type CTriMesh. The scene will call this function to load any X files (either directly or via external references in an IWF file).

The CActor::RegisterCallback function is virtually identical to its cousin in the CTriMesh class. It allows the application to register callback function pointers. We covered the code to the scene's three resource callback functions in the previous workbook and these are unchanged. This CActor method simply stores the passed function pointers in an array so that they are accessible from the CAllocateHierarchy::CreateMeshContainer function (via its CActor pointer) when the hierarchy is being loaded.

This class will also have a method called DrawActorSubset which will be called by the scene to render **all** CTriMesh subsets in its hierarchy with a matching attribute ID. This function will traverse the hierarchy calling CTriMesh::DrawSubset for each of its contained meshes.

CTriMesh

This class is unchanged from our previous workbook. However, now objects of this type will be stored in the frame hierarchies of the actors to which they belong. In our application, we will be using all the meshes in non-managed mode, so the scene class will be responsible for setting the states before calling CActor::DrawSubset. This allows us to benefit from greater batching potential using global attribute IDs across all CTriMeshes in all CActors currently being used by the scene.

Although not demonstrated in this demo, it is also perfectly legal to use the CActor in managed mode. This is actually the default case when the attribute callback has not been registered with the CActor. When this is the case, each CTriMesh in the frame hierarchy will internally store the material and texture pointer used by the mesh for each of its subsets.

CAllocateHierarchy

The CAllocateHierarchy object is also introduced in this application. It is derived from the ID3DXAllocateHierarchy interface and is instantiated by CActor and passed into the D3DXLoadMeshHierarchyFromX function.

This object will contain four callback functions (CreateFrame, CreateMeshContainer, DestroyFrame, and DestroyMeshContainer) which will be called by the D3DX loading function to allocate the memory for the various hierarchy components as the hierarchy is being constructed. This allows us to customize the mesh and frame data that we are passed. For example, the CreateMeshContainer method provides us the flexibility to store the passed mesh data in a CTriMesh and add that to the mesh container instead. It also allows us to clone the mesh data into another format or optimize its vertex and index data.

Our CAllocateHierarchy class will also have a single member variable: a pointer to a CActor. When the CAllocateHierarchy object is instantiated by the CActor, the pointer to the actor is passed into the constructor and stored in the object. It will be used in the CreateMeshContainer function to access the resource callback functions that have been registered with the actor. This will allow the array of material and texture data that we are passed by D3DX for a given mesh to be registered and stored at the scene level. It will also allow for the re-mapping of each mesh's attribute buffer into global attribute IDs.

CObject

The CObject class as been used in nearly all of our previous lab projects to represent meshes in the scene. This was necessary because a mesh itself does not store a world matrix. For example, in the last workbook, this object coupled together a CTriMesh with its assigned world matrix. CObject will now have a new member pointer added: a pointer to a CActor. Usually, only one of the pointers will be active at once (either the CActor pointer or the CTriMesh pointer) depending on whether the object represents just a single CTriMesh or a CActor. Although making these two pointers a union would seem the logical choice, there may be times when we might wish the CObject to represent

both an actor and a separate mesh that both use the same world matrix. So the design decision was made to allow both pointers to exist simultaneously.

When the application uses the CScene::LoadSceneFromX function, a new CObject will be added to the scene. That object will contain a matrix and an actor. When the application calls CScene::LoadSceneFromIWF, several CObjects will typically be added to the scene. Meshes stored internally in the IWF (such as brushes from GILES™) will be loaded into a CTriMesh and attached to a new CObject and added to the scene's CObject array. Any external references stored in the IWF file will be loaded into a CActor, attached to a new CObject, and added to the scene CObject array. Therefore, when the scene is loaded from an IWF file, multiple CObjects will be added to the scene. Some objects in this array may contain actors (i.e., mesh hierarchies) while other objects may contain only simple CTriMesh pointers. Our scene rendering function will need to be able to render both types of CObject.

We know from previous lessons that the matrix stored in the CObject represents the world matrix that will be sent to the device before rendering the contained mesh. This behavior is still true when the CObject is being used to represent only a single mesh. However, when a CActor is encountered, this matrix is not used in quite the same way. Instead, this matrix will be used to position and orient the root frame of the hierarchy. The scene object will not simply set this matrix as the world matrix on the device since we know that would not work -- the actor might contain multiple meshes which all need to have their absolute world matrices generated and set separately before they are rendered.

The scene object will instead call the CActor::SetWorldMatrix method, passing in the matrix stored in CObject. The CActor will use this passed matrix to combine with the root frame matrix and traverse the tree, generating all absolute world matrices for each frame. As we know from our textbook discussions, combining the CObject matrix with the root frame matrix will affect all the world matrices that are generated below the root frame in the hierarchy. Once all absolute matrices in the hierarchy have been updated, we have all the matrices we need to render any mesh in the hierarchy. When we render a mesh, we simply use the absolute matrix stored in its owner frame as the world matrix that we set on the device. This is done in a separate rendering pass through the hierarchy.

From the application's perspective, things are no different with respect to moving objects around in our scene. When we pass the CObject's matrix into CActor::SetWorldMatrix, we are applying a transformation to the root frame which filters down to all other frames in the hierarchy. Therefore, we can still move the object around in our scene using only the CObject matrix.

The following diagram shows the relationships that exist between the various classes in our application. Notice that the scene stores a list of objects, each object stores an actor and each actor stores the root frame to an entire frame and mesh hierarchy.

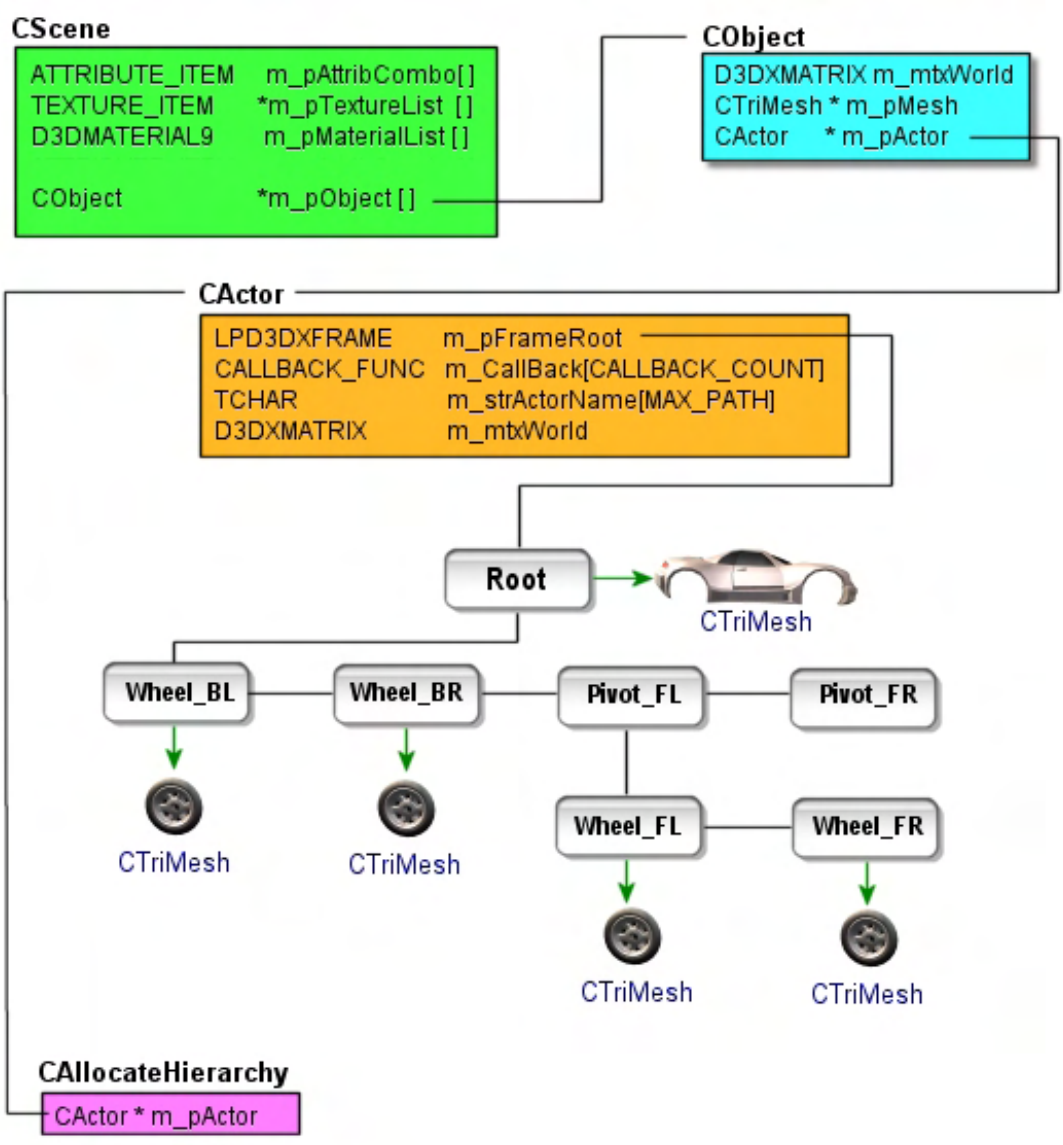

Figure 9.2

The CAllocateHierarchy object in Figure 9.2 is only instantiated temporarily (on the stack) by CActor for the call to D3DXLoadMeshHierarchyFromX.

Notice how the CActor itself also stores its own matrix. In fact, when we call CActor::SetWorldMatrix and pass in the CObject's matrix, this matrix is cached internally by the actor. The reason we do this is that many of the methods exposed by CActor (Draw, UpdateFrames, SetWorldMatrix, etc.) would usually require a total traversal of the hierarchy and a rebuilding of the absolute frame matrices stored in each frame. You may for example, issue several function calls to the actor which would cause the hierarchy to be traversed each time. To rid ourselves of unnecessary traversals, each function (such as SetWorldMatrix) will also except a Boolean parameter indicating whether we wish the function to update the matrices in the hierarchy immediately or whether we simply wish to store the state such that it can be used to update the hierarchy later via another function. This allows us to set the actor world matrix, apply some animation to the relative frame matrices, and then later call

CActor::UpdateFrameMatrices to traverse the hierarchy and rebuild the absolute matrices using the world matrix that was set in a previous call . Using this technique, the first two function calls would not update the hierarchy, but would simply set states. The final call would use these states to update the hierarchy in a single pass using those caches states. Without this mechanism, every call that alters the hierarchy would cause a hierarchy traversal and a rebuild of all absolute frame matrices.

Another thing that may seem strange in the above diagram is that our automobile frame hierarchy looks rather different from the diagrams we looked at in the textbook. There is another level of frames (called *pivots*) between the root and the front wheels. The reason these pivots are necessary is clear when we establish what our application will do. Every time the scene is rendered, the wheel frames of the car will be rotated around their local X axis. We will discuss the class that performs this task in a moment. The process is basically one of building an X axis rotation matrix that rotates some small number of degrees and multiplying it with the relative frame matrices for each wheel. This accumulative step will rotate the wheels a little more around their **local** X axis every cycle of the game loop. This will cause them to spin around like the wheels on a real automobile. The local X axis of each wheel can be perceived as sticking out of the page directly at you if you were viewing the wheel face on (Figure 9.3).

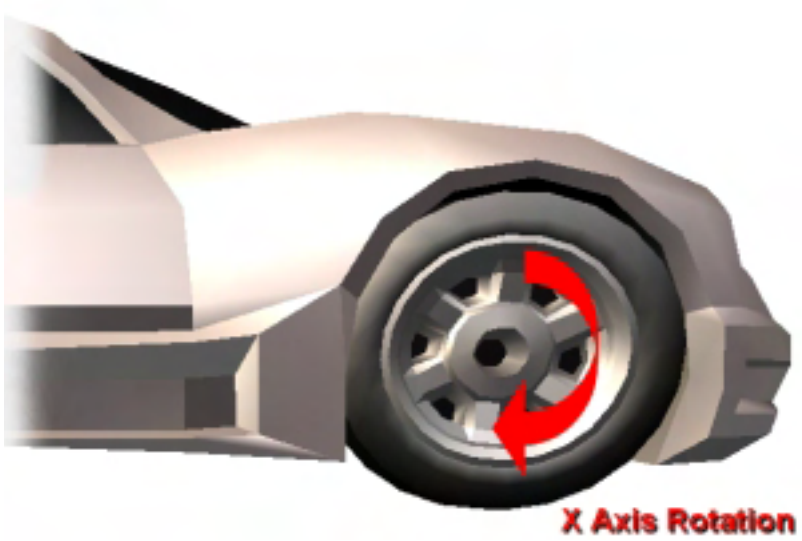

Figure 9.3

The red arrow shows the rotation around the X axis (which we cannot see in this diagram because we would be looking directly down it). It should be clear why rotating the wheel frame matrix X axis is the desired choice. The textbook taught us that applying rotations to the relative matrix of a frame causes a local rotation. Therefore, however much we rotate the root frame and change the orientation of each wheel in the world, each wheel will always rotate around the correct axis: the local X axis.

The problem we have is when we introduce the need for additional local rotations for that wheel frame. In our application, we also wish to give the user the ability to press the comma and period keys to steer the wheels left or right. If we look at Figure 9.4 we can see the local Y axis prior to any local rotations. It is clear that this is the axis we would wish to use for left/right wheel rotation.

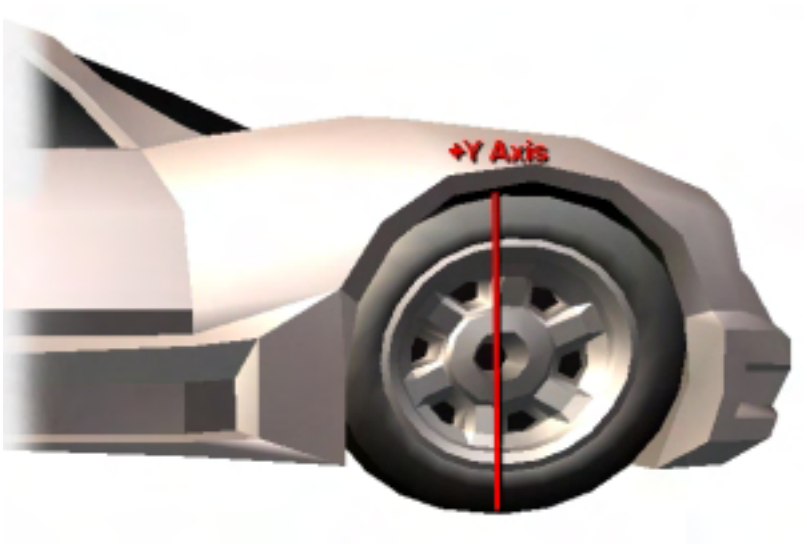

Figure 9.4

In Figure 9.4 we see the local Y axis of the wheel frame prior to any rotation. Just as the local X axis can be thought of as the wheel's right vector, this axis describes the wheels up vector. So far it all looks very promising.

So it would seem at first that our task is a simple one. For every update, we build an X axis rotation matrix and combine it with the wheel matrix causing the wheel to revolve. Then, when the user presses a comma or period key, we simply build a Y axis rotation matrix (with either a negative or positive degree value for left and right respectively) and apply that to the frame matrix of the wheel as well. Right?

Actually, no! The problem is that when we combine matrices with a relative frame matrix we are dealing with its local coordinate system. Imagine for example that the wheel has been rotated 45 degrees about its X axis and we then, based on user input, wanted to apply a Y rotation to make the wheel turn. The problem is, at this point, the entire local coordinate system has been rotated about the local X axis. So the local Y axis (the wheel up vector) is no longer pointing straight up relative to the car body. Instead it is oriented at an angle of 45 degrees around the wheel's local X axis (Figure 9.5). It is clear that applying a Y rotation to this matrix would not have the correct effect at all.

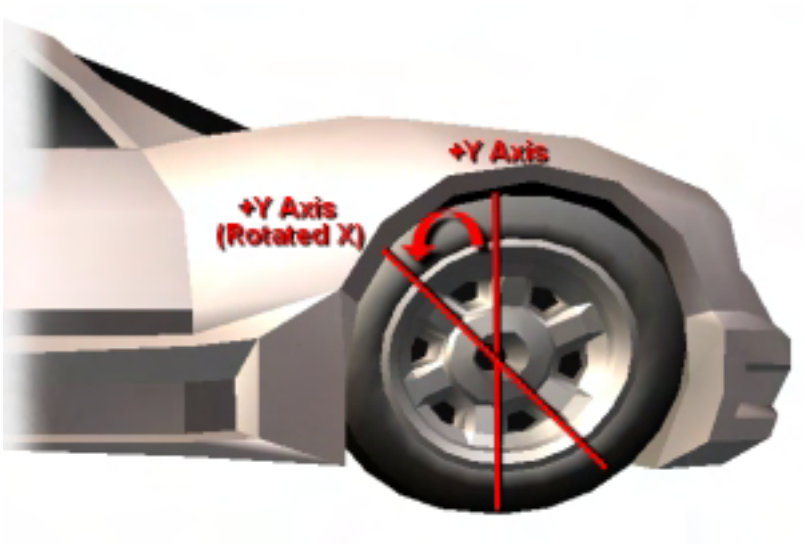

Figure 9.5

So, it seems we cannot use the frame matrix for both X *and* Y rotation. Maybe we could apply the Y rotation to the parent frame instead? No, that would not work either because the parent frame in this case would be the root frame which represents a position at the center of the automobile. While the orientation of the root frame's Y axis absolutely is the axis we need to rotate about, the wheel is offset in this frame of reference from that origin. We would not want the wheel to rotate about the center of the automobile instead of around its own center point. Applying a rotation to the parent would actually rotate the whole car about its Y axis, so that definitely is not the way to go either. We need these wheels to rotate about their own coordinate origins, but using the automobile up vector.

As it happens, there is a very simple way to do what we need and it is commonly used by artists to help game programmers with such tasks. The use of *dummy frames* in the hierarchy, which to the uninitiated may seem to prove no purpose, solves the problem. Two dummy frames exist in our automobile representation and they are positioned above the two front wheels in the hierarchy. Let us examine their purpose.

Figure 9.6 shows the position of the two dummy frames (Pivot_FL and Pivot_FR) in the hierarchy. These frames are positioned in the root frame of reference such that they describe a position at the center of the wheels. They have no default orientation (i.e., identity). In other words, these pivot frames describe the position of the wheels themselves (like the diagrams in the textbook). However, each pivot frame has a child wheel frame. These wheel frames also initially start out with an identity orientation but (and this is the important point) they also have a *zero translation vector*. Since they are defined as children in the pivot frame of reference, but with zero offset, this means that for each front wheel we have two frames on top of each other sharing the same space. To demonstrate this important point, if we were to also assign a wheel mesh to Pivot_FL and render this hierarchy, the mesh at Pivot_FL and the mesh at Wheel_FL would be in the exact same position.

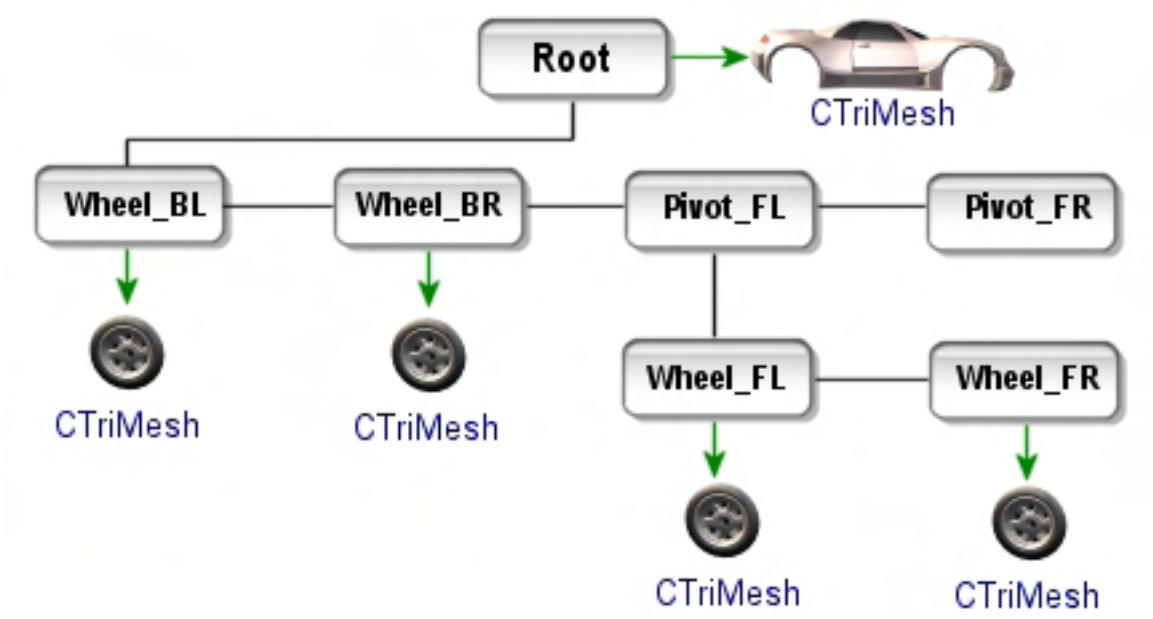

Figure 9.6

The usefulness of these seemingly redundant frames becomes clear when we consider the very important fact that Wheel_FL is defined in the Pivot_FL frame of reference.

If we apply a Y axis rotation to the Pivot_FL frame, we know that any child frames will inherit this rotation. We know for example that when we apply a rotation to the root frame, the four wheel frames will rotate about the root frame Y axis at a radius consistent with their specified offsets. In this case however, the Wheel_FL frame has not been offset from its parent frame. Therefore, we can think of the Pivot_FL frame's Y axis as also passing through the origin of the wheel frame's local coordinate system. Applying a rotation to the pivot will cause the wheel frame (and its mesh) to rotate about its own center point but also around the parent axis. The great thing is that because we have applied the Y axis rotation to the parent frame, we are free to rotate the wheel frame about its local X axis without any fear that its orientation will interfere with (or be corrupted by) other rotation operations.

Our task is simple then. During every update we will apply an X axis rotation to each of the wheel frame matrices, and when the user presses either the comma or period key, we will apply a Y axis rotation to the pivot frames. Problem solved.

CAnimation

The last new class we will introduce in this lesson is called CAnimation. This is a very simple object that will be used to explore hierarchical animation and prepare you for the following chapter where we will explore the DirectX animation controller in detail. The job of this object will be to apply rotations to frames in the hierarchy. There will be one CAnimation object created for each frame that needs to be animated.

The scene will create six animation objects (one for each of the wheels and two more for the pivot frames) and will use the CAnimation::Attach method to attach frame matrices in the hierarchy to the individual animation objects. The CAnimation object simply stores this matrix internally so that it

knows which matrix to update when the scene object calls its RotationX, RotationY and RotationZ methods. It is these methods that build a rotation matrix and multiply it with its associated frame matrix. As you can probably imagine, the code to this class is extremely small.

> **Note**: Using this naming convention, an animation is assumed to be either an object or dataset that animates a single frame in the hierarchy. In our example X file, the car has six frames that need to be animated. Therefore, our demo contains six animations.

Source Code Walkthrough – CActor

With a high level discussion of this lab project behind us, we will now examine the code sections that we are not yet familiar with. We will start by looking at the CActor class, which is where most of the stuff that is new to us will be hiding. The class definition is contained in CActor.h and is shown below in its entirety. This should give you a feel for the interface it exposes to the application and the member variables it contains. This will be followed with a description of its member variables.

```
class CActor
{
public:
    enum CALLBACK_TYPE { CALLBACK_TEXTURE=0,
                         CALLBACK_EFFECT = 1,
                         CALLBACK_ATTRIBUTEID = 2,
                         CALLBACK_COUNT = 3 };
    // Constructor
             CActor( );
    virtual ~CActor( );

    bool      RegisterCallback   ( CALLBACK_TYPE Type, LPVOID pFunction, LPVOID pContext );
    HRESULT   LoadActorFromX     ( LPCTSTR FileName, ULONG Options,
                                   LPDIRECT3DDEVICE9 pD3DDevice );
    void      Release            ( );
    void      SetWorldMatrix     ( const D3DXMATRIX * mtxWorld = NULL,
                                          bool UpdateFrames = false );
    void      DrawActor          (  );
    void      DrawActorSubset    ( ULONG AttributeID );

    // Accessor functions
    LPCTSTR       GetActorName      ( ) const;
    CALLBACK_FUNC GetCallback       ( CALLBACK_TYPE Type ) const;
    ULONG         GetOptions        ( ) const;
    LPD3DXFRAME   GetFrameByName    ( LPCTSTR strName, LPD3DXFRAME pFrame = NULL ) const;

    // Private Functions
    private:
    void    DrawFrame           ( LPD3DXFRAME pFrame, long AttributeID = -1 );
    void    DrawMeshContainer   ( LPD3DXMESHCONTAINER pMeshContainer,
                                  LPD3DXFRAME pFrame, long AttributeID = -1 );
    void    UpdateFrameMatrices ( LPD3DXFRAME pFrame, const D3DXMATRIX * pParentMatrix );

    // Member Variables for This Class
    LPD3DXFRAME                  m_pFrameRoot;
    LPDIRECT3DDEVICE9            m_pD3DDevice;
    CALLBACK_FUNC                m_CallBack[CALLBACK_COUNT];
    TCHAR                        m_strActorName[MAX_PATH];
    D3DXMATRIX                   m_mtxWorld;
    ULONG                        m_nOptions;
};
```

LPD3DXFRAME m_pFrameRoot

When the actor's hierarchy is constructed in the CActor::LoadActorFromX method, this pointer is passed into the D3DXLoadMeshHierarchyFromX function and used to store the address of the root frame that is returned. This single pointer is the actor object's doorway to the hierarchy and the means by which it begins hierarchy traversal.

Below, you are reminded of the layout of the D3DXFRAME structure:

```
typedef struct _D3DXFRAME
{
    LPSTR Name;
    D3DXMATRIX TransformationMatrix;
    LPD3DXMESHCONTAINER pMeshContainer;
    struct _D3DXFRAME *pFrameSibling;
    struct _D3DXFRAME *pFrameFirstChild;
} D3DXFRAME, *LPD3DXFRAME
```

Because we need to store additional information in our frame structure, such as the absolute world matrix of a frame (and not just the relative matrix provided by the vanilla D3DX version shown above), we will derive our own structure from D3DXFRAME to contain this additional matrix information. The frame structure used throughout our actor's hierarchy is shown below.

```
struct D3DXFRAME_MATRIX : public D3DXFRAME
{
    D3DXMATRIX  mtxCombined;    // Combined matrix for this frame.
};
```

In the textbook, we also covered the D3DXMESHCONTAINER structure that is used throughout the hierarchy to contain mesh data for a frame. You are reminded of this structure again below. It should be very clear to you what each member of this structure is used for after our discussion in the textbook.

```
typedef struct _D3DXMESHCONTAINER
{
    LPSTR Name;
    D3DXMESHDATA MeshData;
    LPD3DXMATERIAL pMaterials;
    LPD3DXEFFECTINSTANCE pEffects;
    DWORD NumMaterials;
    DWORD *pAdjacency;
    LPD3DXSKININFO pSkinInfo;
    struct _D3DXMESHCONTAINER *pNextMeshContainer;
} D3DXMESHCONTAINER, *LPD3DXMESHCONTAINER
```

We will also wish to derive from this structure because we want to represent our meshes in the hierarchy using the CTriMesh object we created in the previous workbook. You will recall that the D3DXMESHDATA member of this structure would normally contain the ID3DXMesh interface for the mesh being stored here. The structure that we will use is derived from this one, with a single extra member added: a CTriMesh pointer:

```
struct D3DXMESHCONTAINER_DERIVED : public D3DXMESHCONTAINER
{
    CTriMesh * pMesh;          // Our wrapper mesh.
};
```

As you can see, our mesh container now contains a pointer to a CTriMesh. The CAllocateHierarchy::CreateMeshContainer function will take the passed ID3DXMesh, create a CTriMesh from it and attach it to the mesh container, instead of storing the ID3DXMesh pointer directly in the mesh container's D3DXMESHDATA member.

> **Note:** In our application we also store the CTriMesh's underlying ID3DXMesh interface pointer in the mesh container's D3DXMESHDATA member. While there might seem little point in doing this, D3DX provides many helper functions that calculate things like the bounding volume of a frame. These functions expect the mesh data to be stored in the D3DXMESHDATA member of the frame as they have no knowledge that we are now using our own CTriMesh object to store and render mesh data. Without us also storing the mesh interface used by the CTriMesh in this member, these functions will not work correctly.

The remaining member variables of the CActor class will now be discussed.

LPDIRECT3DDEVICE m_pD3DDevice

When the application calls the CActor::LoadActorFromX function it must also pass a pointer to the Direct3D device which will be the owner of any meshes in that hierarchy. The CActor passes this device pointer into the D3DXLoadMeshHierarchyFromX function and also stores the address in this member variable. It will need access to this pointer during rendering traversals of the hierarchy so that the absolute world matrices of each frame can be set as the device world matrix prior to rendering any of its attached mesh containers.

CALLBACK_FUNC m_CallBack[CALLBACK_COUNT]

As with the CTriMesh class, the actor has a static array that can be used to store pointers to resource callback functions. The CALLBACK_TYPE enumeration is also familiar to us because the CTriMesh class used this same enumeration within its namespace. The members of this enumeration describe the three possible callback functions which can be registered with the actor. The value of each member in this enumeration also describes the index in the callback array where the matching function pointer will be stored. For example, the CALLBACK_ATTRIBUTEID function pointer will be stored in m_CallBack[2].

TCHAR m_strActorName[MAX_PATH]

This string is where the name of the actor will be stored. This name is the name of the X file passed into the LoadActorFromX method. The actor's name will often be retrieved by the scene object to make sure that the same hierarchical X file does not get loaded more than once. When an external reference is found in an IWF file for example, a search of all the currently loaded actor names will be performed to make sure it does not already exist. If it does, then we will not create a new actor, but will simply point the new CObject's CActor pointer at the one that already exists. When we do this we are referencing the actor with multiple CObjects.

D3DXMATRIX m_mtxWorld

This is where the CActor will cache a copy of the matrix passed into its SetWorldMatrix function. This is the matrix that is used to perform updates to the hierarchy. This matrix will contain the world space position and orientation of the actor.

ULONG m_nOptions

This member will contain a combination of D3DXMESH creation flags used to create the meshes in the hierarchy. The application will pass these flags into the LoadActorFromX function where they will be stored and used later in the CAllocateHierarchy::CreateMeshContainer function to create the ID3DXMesh data in the application requested format. This is another reason why the CAllocateHierarchy object will need access to the CActor which is using it.

CActor::CActor()

The CActor constructor takes no parameters and initializes the object's member variables to zero. Its internal world matrix is set to an identity matrix, essentially describing this actor as currently existing at the origin of world space. The callback array is also initialized to zero.

```
CActor::CActor()
{
    // Reset / Clear all required values
    m_pFrameRoot      = NULL;
    m_pD3DDevice      = NULL;
    m_nOptions        = 0;

    ZeroMemory( m_strActorName, MAX_PATH * sizeof(TCHAR) );
    D3DXMatrixIdentity( &m_mtxWorld );

    // Clear structures
    for ( ULONG i = 0; i < CALLBACK_COUNT; ++i )
       ZeroMemory( &m_CallBack[i], sizeof(CALLBACK_FUNC) );
}
```

CActor::~CActor()

As with many of our classes, the destructor does not actually perform the cleanup code itself but rather calls the object's Release function to perform this task. This is beneficial, as the Release function can be used to wipe the information from a CActor without destroying it. This would allow us to use the same CActor object to load another X file once we are finished with the data it currently contains. As the Release function is going to have to be written anyway, let us not duplicate this same cleanup code in the destructor. So we simply call it:

```
CActor::~CActor( )
{
    // Release the actor objects
    Release();
}
```

CActor::Release()

A couple of items are quite interesting about this cleanup code. Firstly, notice the use of the D3DXFrameDestroy function to destroy the actor's entire frame and mesh hierarchy. This function was discussed in the textbook. We pass it an ID3DXAllocateHierarchy derived object and the root frame of the hierarchy to be destroyed. D3DX will then step through each frame in the hierarchy and call the DestroyFrame and DestroyMeshContainer callback methods of the passed allocator object. We will see that it is these callback functions that we must implement to perform the actual removal of frame and mesh data from memory. We will cover the CAllocateHierarchy class next.

So, this function instantiates a CAllocateHierarchy object and passes it into the global D3DXFrameDestroy function. The instance of the allocation object used to destroy the hierarchy does not need to be the same one used to create it, which is why we can create a temporary allocation object on the stack in this way. Notice the passing of the **this** pointer into the constructor, so that the allocation object can store a pointer to the actor which is using it.

```
void CActor::Release()
{
    CAllocateHierarchy Allocator( this );

    // Release objects (notice the specific method for releasing the root frame)
    if ( m_pFrameRoot      ) D3DXFrameDestroy( m_pFrameRoot, &Allocator );
    if ( m_pD3DDevice      ) m_pD3DDevice->Release();

    // Reset / Clear all required values
    m_pFrameRoot      = NULL;
    m_pD3DDevice      = NULL;
    m_nOptions        = 0;

    ZeroMemory( m_strActorName, MAX_PATH * sizeof(TCHAR) );
    D3DXMatrixIdentity( &m_mtxWorld );

    // Callbacks NOT cleared here!!!
}
```

When the D3DXFrameDestroy function returns, the entire frame hierarchy and all its meshes will be removed from memory. The Release function then relinquishes its claim on the device and sets its member variables to their initial values.

Notice however that the Release function does not clear the actor's resource function callback array. This is very convenient when you wish to re-use the object. Usually, even if you want to erase the actor's data and reuse it, the same callback functions can be used to load textures and materials. This allows us to release the actor's data without have to re-register the same callback functions. As the callback array is a statically allocated array, it will naturally be destroyed when the object is destroyed.

CActor::RegisterCallback

This function is called by the application to register any of three types of resource callback functions prior to calling the LoadActorFromX method. The passed function pointers and their associated contexts (in our demo, a CScene pointer) are simply stored in the callback array. These callback functions

essentially describe whether the actor is in managed or non-managed mode. If the function callbacks CALLBACK_TEXTURE or CALLBACK_EFFECT are being used, then all the meshes in the hierarchy will be created in managed mode. We are currently not using the CALLBACK_EFFECT callback until Module III when we cover effect files. If the CALLBACK_ATRIBUTEID callback is registered, all meshes in the hierarchy will be created in non-managed mode.

```
bool CActor::RegisterCallback( CALLBACK_TYPE Type, LPVOID pFunction, LPVOID pContext )
{
    // Validate Parameters
    if ( Type > CALLBACK_COUNT ) return false;

    // Store function pointer and context
    m_CallBack[ Type ].pFunction = pFunction;
    m_CallBack[ Type ].pContext  = pContext;

    // Success!!
    return true;
}
```

These function pointers are not actually used directly by CActor, but are accessed by the CAllocateHierarchy object each time a mesh container is to be created. If the CALLBACK_TEXTURE function pointer exists (m_Callback[0]), then the texture filenames for each material in the mesh being created will be passed to this callback. The callback is responsible for creating the texture and returning a pointer back to the CAllocateHierarchy::CreateMeshContainer function. The texture pointer and the material will be stored inside the CTriMesh, which will then manage its own state changes and have the ability to render itself in a self-contained manner.

If the CALLBACK_ATTRIBUTEID function has been registered (m_CallBack[2]) then the CAllocateHierarchy::CreateMeshContainer function will create all CTriMeshes in the hierarchy in non-managed mode. The texture and material information passed to the CreateMeshContainer function by D3DX will simply be dispatched to this callback. The scene will create and store the textures and materials in its own arrays and return a global attribute ID back to the CreateMeshContainer function for that texture and material combination. The CreateMeshContainer function will then lock the attribute buffer of the CTriMesh and re-map its attribute IDs to this new value. When in this mode, the scene object will be responsible for the state management and subset rendering of each actor's meshes.

CActor::LoadActorFromX

You would be forgiven for thinking that it is in the CActor::LoadActorFromX function that all the hard work happens, and therefore it is expected to be quite large in size. But as you can see, this function is actually very small since it uses the D3DXLoadMeshHierarchyFromX function to handle most of the heavy lifting. Indeed, it is in the CAllocateHierarchy::CreateMeshContainer function that most of the loading code is situated. We will take a look at that class next.

This function should be called by the application only after the resource callback functions have been registered. It will be passed the name of the X file that needs to be loaded along with any mesh creation flags. These mesh creation flags are a combination of D3DXMESH options, which we have used for mesh creation throughout the last lesson. They describe the resource pools we would like the mesh index

and vertex buffers created in. The function should also be passed a pointer to the Direct3D device which will own the meshes.

The first thing the function does is instantiate an object of type CAllocateHierarchy. The **this** pointer is passed into the constructor so that its CreateMeshContainer callback function will be able to access the actor's resource callback functions and the mesh creation flags for mesh container creation.

The passed device pointer is stored in the actor's member variable and the reference count incremented. The mesh creation options are also stored by the actor.

Next we call the function that kick starts the whole loading process, D3DLoadMeshHierarchyFromX.

```
HRESULT CActor::LoadActorFromX(LPCTSTR FileName,ULONG Options,LPDIRECT3DDEVICE9 pD3DDevice)
{
    HRESULT hRet;
    CAllocateHierarchy Allocator( this );

    // Validate parameters
    if ( !FileName || !pD3DDevice ) return D3DERR_INVALIDCALL;

    // Store the D3D Device here
    m_pD3DDevice = pD3DDevice;
    m_pD3DDevice->AddRef();

    // Store options
    m_nOptions = Options;

    // Load the mesh heirarchy
    hRet = D3DXLoadMeshHierarchyFromX( FileName, Options, pD3DDevice, &Allocator,
                                       NULL, &m_pFrameRoot, NULL );
    if ( FAILED(hRet) ) return hRet;

    // Copy the filename over
    _tcscpy( m_strActorName, FileName );

    // Success!!
    return D3D_OK;
}
```

We pass the D3DX loader function the name of the file, the mesh creation options, the device, and a pointer to our ID3DXAllocateHierarchy derived object. The four member function of this object will be used as callback functions by D3DXLoadMeshHierarcdhyFromX. NULL is passed in as the fifth parameter, as we have no need to parse custom data objects. If we did, this is where we would pass in a pointer to our ID3DXLoadUserData derived object. For the sixth parameter, we pass in the address of the actor root frame pointer. On function return, this will point to the root frame of the hierarchy. Finally, we pass in NULL as the last parameter as we have not yet covered the ID3DXAnimationController interface. This will be covered in the next chapter.

If the D3DXLoadMeshHierarchyFromX function is successful, this function copies the filename passed in and stores it in the CActor::m_strActorName member variable. This will be used for actor lookups by the scene to avoid loading multiple actors with the same X file data.

CActor::SetWorldMatrix

Once the CActor has had its data loaded via the above function, it is ready to be positioned in the world. We can set the world space orientation and position of the actor (and all its child frames and meshes) using the SetWorldMatrix function.

This function should be passed a matrix describing the new world space transformation matrix for the actor. We can think of this as actually positioning the root frame in the world. Essentially, the passed matrix will become the root frame's parent frame of reference.

Our CScene class will store each CActor pointer in a CObject along with a world matrix. Therefore, when the scene updates the position of the CObject, its world matrix is passed into its CActor's SetWorldMatrix function to generate all the absolute world matrices for each frame. If no valid matrix is passed, then we will set the actor's matrix to identity, for safety.

```
void CActor::SetWorldMatrix( const D3DXMATRIX * mtxWorld, bool UpdateFrames  )
{
    // Store the currently set world matrix
    if ( mtxWorld )
        m_mtxWorld = *mtxWorld;
    else
        D3DXMatrixIdentity( &m_mtxWorld );

    // Update the frame matrices
    if ( UpdateFrames ) UpdateFrameMatrices( m_pFrameRoot, mtxWorld );
}
```

The function also takes a Boolean parameter called UpdateFrames which tells it whether you would like the traversal of the hierarchy and the updating of frame matrices to be performed immediately. If you pass 'true' then the CActor::UpdateFrameMatrices method will be called to traverse the hierarchy and update all the absolute world matrices of each frame. After the call to UpdateFrameMatrices, the absolute matrix in each frame contains the world matrix that should be set on the device in order to render any attached meshes. If 'false' is passed, the input matrix is simply stored in the actor's member variable and the update process can be deferred until a later time.

CActor::UpdateFrameMatrices

This function is responsible for stepping through the hierarchy in a recursive fashion and generating the absolute world matrices for each frame (stored in D3DXFRAME_MATRIX::mtxCombined). It can be called by the application, but is usually called by the SetWorldMatrix function above to recalculate the frame matrices when a new world matrix has been set.

The function is usually passed a pointer to the root frame as its first parameter. Its second parameter is the world space transformation matrix to be applied. The function recursively calls itself, so the changes filter down the hierarchy.

If you examine the SetWorldMarix call above, you can see that it calls this function passing in the root frame and the new world space transformation for the root frame (essentially the position of the actor in the scene). Let us now see what the function does with that information.

```
void CActor::UpdateFrameMatrices( LPD3DXFRAME pFrame, const D3DXMATRIX * pParentMatrix )
{
    D3DXFRAME_MATRIX * pMtxFrame = (D3DXFRAME_MATRIX*)pFrame;

    if ( pParentMatrix != NULL)
        D3DXMatrixMultiply( &pMtxFrame->mtxCombined,
                            &pMtxFrame->TransformationMatrix,
                            pParentMatrix);
    else
        pMtxFrame->mtxCombined = pMtxFrame->TransformationMatrix;

    // Move onto sibling frame
    if ( pMtxFrame->pFrameSibling )
         UpdateFrameMatrices( pMtxFrame->pFrameSibling, pParentMatrix );

    // Move onto first child frame
    if ( pMtxFrame->pFrameFirstChild )
         UpdateFrameMatrices( pMtxFrame->pFrameFirstChild, &pMtxFrame->mtxCombined );
}
```

First, the function casts the passed D3DXFRAME to its correct derived type. This is D3DXFRAME_MATRIX, which you will recall contains an extra matrix member (mtx_Combined) to store the world matrix for each frame during update traversals.

The function recursively calls itself until every frame in the hierarchy has been visited and its absolute world matrix (stored in mtx_Combined) has been calculated. After the function has returned program flow back to the caller, the combined matrix stored in each frame structure will contain the world matrix of that frame that should be set on the device in order to render any meshes attached to that frame.

The passed matrix is combined with the relative matrix stored in that frame to calculate its world matrix. If the frame has a sibling, then the function is called for its sibling too, so that it has a chance to combine its relative matrix with the passed matrix also. As the siblings are stored as a linked list, this causes all siblings of the frame to be visited and have their world matrices generated.

The next and final line of the function is very important to understanding the matrix concatenation process. If the frame has a child frame, then the function is called again for the child frame. Only this time, the matrix passed in is the world matrix that has just been generated for the current frame (i.e., mtx_Combined). It is the world matrix of the parent frame which describes the child frame's frame of reference. In the instance of the function that processes the child, its relative matrix is combined with the parent's **world** matrix, generating the world matrix for the child frame also. As the child position and orientation is described by its relative matrix in the parent's frame of reference, this will correctly position the child frame in world space such that it is correctly offset from its parent. If the parent matrix had more than one child frame, then the children will be connected in a linked list by their sibling pointers. In this case, the instance of the function processing the child will also cause each sibling to be processed using the same parent world matrix.

This function is actually very small but does a lot of work due to its recursive nature. Study this code and make sure you understand it.

CActor::DrawActorSubset

Because the CActors in our application have their AttributeID callback function registered, all CTriMeshes in the hierarchy are created in non-managed mode. This means the CTriMeshes in the scene have their attribute buffers filled with scene global attribute IDs. As the CTriMeshes themselves do not contain an attribute table in this mode, it is the responsibility of the scene object to render any CActors. This is done in the CScene::Render method which we will look at in a moment.

The scene must loop through all attributes it has in its attribute array and call the CActor::DrawSubset method for each actor. The scene must make sure that before it does, it sets the correct texture and material that is mapped to that attribute ID. This is virtually no different from how the scene rendered standalone CTriMeshes in non-managed mode in the previous lesson. The only difference is that the scene calls CActor::DrawActorSubset instead of CTriMesh::DrawSubset.

The DrawActorSubset method filters the rendering request down to each of its meshes. It does so by calling the CActor::DrawFrame method, passing in the subset number for which rendering has been requested. The DrawFrame method is another recursive function that visits every frame in the hierarchy searching for mesh containers. When a mesh container is found attached to a frame, the frame's world matrix (mtx_Combined) is set on the device, CTriMesh::DrawSubset is called for each mesh container attached to that frame, and traversal continues until every mesh has had a chance to render the requested subset.

As all of this traversal work is recursively performed inside the DrawFrame method, the DrawActorSubset method is a simple wrapper around the DrawFrame call. We will cover the DrawFrame method in a moment.

```
void CActor::DrawActorSubset( ULONG AttributeID )
{
    // Draw the frame heirarchy
    DrawFrame( m_pFrameRoot, (long)AttributeID );
}
```

CActor::DrawActor

If the CActor has not has the CALLBACK_ATTRIBUTEID function registered, but instead has had either CALLBACK_TEXTURE or CALLBACK_EFFECT registered, all meshes in the hierarchy will be created in managed mode. When this is the case, we can essentially describe the actor as being in managed mode.

In managed mode, each CTriMesh in the hierarchy will contain an attribute table containing the texture and material that should be set for each subset. This means each mesh in the hierarchy has the ability to render itself in a self-contained manner and does not require the scene to set the textures and materials

on the device prior to subset rendering. Just as CTriMesh has a function called CTriMesh::Draw which can be used render a managed mode CTriMesh in its entirety, so too does the actor.

The CActor::DrawActor function should only be used when the actor is in managed mode. Like the above function, it actually just wraps a call to the DrawFrame function. But unlike the DrawActorSubset call, no subset ID is passed into it. When the DrawFrame function has not been passed an attribute ID, it will render any CTriMeshes that exist in the hierarchy using the CTriMesh::Draw function. We know that this will cause the mesh to render all its subsets, taking care of state changing between each one by itself. Obviously, this can cause many redundant state changes, but managed mode is easy to use if you simply wish to view an asset that you have created or have not yet written the attribute callback function.

```
void CActor::DrawActor( )
{
    // Draw the frame heirarchy
    DrawFrame( m_pFrameRoot );
}
```

CActor::DrawFrame

It is in this function (called by both functions discussed previously) that the main rendering traversal is done. It is recursively called such that it processes every frame in the hierarchy.

For the current frame being processed (which is initially the root when called by the prior functions) its mesh container pointer will be non-NULL if a mesh container is attached. If multiple mesh containers have been assigned to this frame, then each mesh container will be arranged in a linked list via the D3DXMESHCONTAINER::pNextMeshContainer pointer.

If the mesh container pointer is not NULL, then a mesh exists and will need to be rendered. We set the frame world matrix, mtx_Combined (generated by a prior call to SetWorldMatrix or UpdateFrameMatrices), as the world matrix on the device. This matrix describes the world transform for all meshes in this frame.

We next initialize a for loop to step through all mesh containers assigned to this frame. For each one found, we call the CActor::DrawMeshContainer method to render the CTriMesh. How this function operates depends on the attribute ID passed into the function. If an attribute ID has been passed, then DrawMeshContainer will call CTriMesh::DrawSubset using this ID to render the requested subset stored in the mesh. If no attribute ID has been passed, as is the case when this function is called by the DrawActor method, the actor is assumed to be in managed mode and the DrawMeshContainer will render its mesh using CTriMesh::Draw to render all subsets at once.

```
void CActor::DrawFrame( LPD3DXFRAME pFrame, long AttributeID /* = -1 */ )
{
    LPD3DXMESHCONTAINER pMeshContainer;
    D3DXFRAME_MATRIX  * pMtxFrame  = (D3DXFRAME_MATRIX*)pFrame;

    // Set the frames combined matrix
    if (pMeshContainer) m_pD3DDevice->SetTransform( D3DTS_WORLD, &pMtxFrame->mtxCombined );
```

```
    // Loop through the frame's mesh container linked list
    for ( pMeshContainer = pFrame->pMeshContainer;
          pMeshContainer;
          pMeshContainer = pMeshContainer->pNextMeshContainer )
    {
        // Draw this container
        DrawMeshContainer( pMeshContainer, pFrame, AttributeID );

    } // Next Container

    // Move onto next sibling frame
    if ( pFrame->pFrameSibling ) DrawFrame( pFrame->pFrameSibling, AttributeID );

    // Move onto first child frame
    if ( pFrame->pFrameFirstChild ) DrawFrame( pFrame->pFrameFirstChild, AttributeID );
}
```

The familiar lines at the bottom of this function allow us to step through any sibling frames attached to the current frame, and the step down a level in the hierarchy to the child frames, if they exist. At the end of this function, all frames will have been visited. If an attribute ID was passed (non-managed mode), then all mesh subsets in the hierarchy with the requested ID will have been rendered. If no attribute ID is passed (-1 is the default) then the actor is in managed mode and all meshes in the hierarchy will have been entirely rendered.

CActor::DrawMeshContainer

The DrawMeshContainer function is called once by the previous function for each mesh container that exists in the tree. A mesh container linked to a frame contains a single CTriMesh, but there may be multiple mesh containers linked to a single frame. The job of this function, as we saw above, is to render the CTriMesh stored within each mesh container appropriately.

```
void CActor::DrawMeshContainer( LPD3DXMESHCONTAINER pMeshContainer,
                                LPD3DXFRAME pFrame, long AttributeID /* = -1 */ )
{
    D3DXFRAME_MATRIX          * pMtxFrame  = (D3DXFRAME_MATRIX*)pFrame;
    D3DXMESHCONTAINER_DERIVED * pContainer = (D3DXMESHCONTAINER_DERIVED*)pMeshContainer;
    CTriMesh                  * pMesh      = pContainer->pMesh;

    // Validate requirements
    if ( !pMesh ) return;

    // Render the mesh
    if ( AttributeID >= 0 )
    {
        // Set the FVF for the mesh
        m_pD3DDevice->SetFVF( pMesh->GetFVF() );
        pMesh->DrawSubset( (ULONG)AttributeID );

    } // End if attribute specified
    else
    {
        pMesh->Draw( );

    } // End if no attribute specified
}
```

This function is very simple thanks to the fact that we are using our CTriMesh class to represent mesh data. First it fetches a pointer to the CTriMesh object stored in the mesh container. Next, a check is done on the AttributeID passed in. If it is less than zero (-1) then this actor is in managed mode and the mesh can render itself (setting its own texture and material states before rendering each of its subsets). When this is the case, the function simply calls CTriMesh::Draw to instruct the mesh to render itself entirely.

If this is not the case, and the passed attribute ID is larger than –1, then the scene is rendering the individual mesh subsets, and all we wish to render is the requested subset of the mesh stored here. So we set the correct FVF flags for the mesh and use the CTriMesh::DrawSubset method to render only the requested subset. Notice that in this implementation of the function, the passed frame pointer is not used. We may very well need this later on though, and it is very useful for the rendering function to have access to its parent.

CActor Accessor Functions

The CActor class exposes several state accessor function so the application can performs tasks such as: retrieve a pointer to one of its registered callback functions, inquire about its mesh creation functions, or retrieve the name of the actor (i.e., the name of the X file).

```
CALLBACK_FUNC CActor::GetCallback( CALLBACK_TYPE Type ) const
{
    return m_CallBack[Type];
}
```

```
ULONG CActor::GetOptions( ) const
{
    return m_nOptions;
}
```

```
LPCTSTR CActor::GetActorName( ) const
{
    return m_strActorName;
}
```

CActor::GetFrameByName

This method is used to search an actor’s hierarchy for a frame with a matching name. The function will return a pointer to this frame if a name match is found. You will recall that in the X file, frames will often be assigned a name, and this is vital if we intend to animate them. We will see in our demo how the scene uses this function, after the automobile has been loaded, to retrieve pointers to the wheel and pivot frames. We then attach the relative matrices of these frames to CAnimation objects that can modify the matrices and allow us to spin the wheels.

The function is passed a string containing the name of the frame we wish to find, followed by a pointer to a frame from which you wish the search to begin. This will usually be the root frame so that the entire hierarchy is searched, but alternatively, we could limit our search to only a given sub-tree if desired.

```
LPD3DXFRAME CActor::GetFrameByName( LPCTSTR strName, LPD3DXFRAME pFrame /* = NULL */ ) const
{
    LPD3DXFRAME pRetFrame = NULL;

    // Any start frame passed in?
    if ( !pFrame ) pFrame = m_pFrameRoot;

    // Does this match ?
    if ( _tcsicmp( strName, pFrame->Name ) == 0 ) return pFrame;

    // Check sibling
    if ( pFrame->pFrameSibling )
    {
        pRetFrame = GetFrameByName( strName, pFrame->pFrameSibling );
        if ( pRetFrame ) return pRetFrame;

    } // End if has sibling

    // Check child
    if ( pFrame->pFrameFirstChild )
    {
        pRetFrame = GetFrameByName( strName, pFrame->pFrameFirstChild );
        if ( pRetFrame ) return pRetFrame;

    } // End if has sibling

    // Nothing found
    return NULL;
}
```

It should be obvious by now that this will be another recursive function because of its need to traverse the hierarchy. Starting at the frame passed in, we compare its name against the passed name. If the frame name matches the string name then we have found our match and return this frame immediately.

If it does not match then a check of the sibling pointer of the current frame is made and the function is recursively called if a sibling exists. We know this will, in turn, cause all siblings in the linked list to be visited and their names checked. When program flow returns back to the current instance, if pRetFrame is not NULL then it means that one of the sibling frames has a name that matched, so we return it. Otherwise, we recursively check the children in the same way.

If we get to the end of the function and there is no frame in the hierarchy with a matching name we return NULL. We will see this function being used to connect the CAnimation objects to the various frames in the hierarchy when we examine the modifications to the CScene class.

CActor::SaveActorToX

It is sometimes useful to be able to save the contents of an actor out to an X file. Perhaps you have altered the data in some way and would like the changes to be preserved. While it may not be an extremely useful option within your actual game, having this ability will certainly come in useful when you are writing your own tools (e.g., a hierarchy editor). In fact, in our next workbook we will build just such a tool (called Animation Splitter) that uses the CActor object to load an X file, split any animation data stored in that X file into multiple animations, and then save the re-organized actor and animation data back out to the X file as a hierarchy. You will understand why we build such a tool in the next

chapter when we discuss the D3DX animation system. For the time being, just know that there may be times when you will want your actor's frame hierarchy saved to an X file.

Before we look at the CActor::SaveActorToX method's source code which is a mere few lines in length, let us first take a look at the global D3DX helper function it uses to perform the task.

The D3DXSaveMeshHierarchyToFile Function

The D3DX library exposes a global function that an application can use to save an entire frame/mesh hierarchy out to an X file. It can be thought of as the opposing function to the D3DXLoadMeshHierarchyFromX function in that information flows from the hierarchy in memory out to a new X file, whereas in the case of the D3DXLoadMeshHierarchyFromX function, the information flow is in the other direction. The method is shown below along with a description of each of its parameters.

```
HRESULT WINAPI D3DXSaveMeshHierarchyToFile
(
    LPCSTR pFilename,
    DWORD XFormat,
    const D3DXFRAME *pFrameRoot,
    LPD3DXANIMATIONCONTROLLER pAnimController,
    LPD3DXSAVEUSERDATA pUserDataSaver
);
```

LPCSTR pFilename
This is a string containing the name of the new X file that will be created.

DWORD XFormat
This parameter is used to tell the function whether the application would like the X file to be created as a text or binary X file. We can pass one of the following D3DXF_FILEFORMAT flags:

#define	Value	Description
D3DXF_FILEFORMAT_BINARY	0	Legacy-format binary file.
D3DXF_FILEFORMAT_COMPRESSED	2	Compressed file. May be used in combination with other D3DXF_FILEFORMAT_ flags. This flag is not sufficient to completely specify the saved file format.
D3DXF_FILEFORMAT_TEXT	1	Text file.

const D3DXFRAME *pFrameRoot
All that is needed to gain access to the frame hierarchy for saving is the root frame. This function can use the root to traverse down through the tree and save off any frames, matrices, meshes, texture filenames and materials it finds. The result will be an X file containing all the information used by the hierarchy.

LPD3DXANIMATIONCONTROLLER *pAnimController*
We will see in the next chapter that when an X file that contains animation data is loaded, the D3DXLoadMeshHierachyFromX function will return a pointer an ID3DXAnimationController interface. We can think of the animation controller as being a manager object that contains all the animation data used by the hierarchy. It presents the application with a means to play back those animations via its exposed methods. For now, our actor will pass in NULL for this parameter as it does not yet support animation data. In the next workbook, we will upgrade our actor so that it also includes animation support. When this is the case, the save function must also be able to save off any animation data to the X file. Therefore, in the next chapter, when we upgrade our actor, this parameter will be passed a pointer to the actor's animation controller interface.

LPD3DXSAVEUSERDATA *pUserDataSaver*
When loading an X file using D3DXLoadMeshHierarchyFromX, we have the option of passing in a pointer to an ID3DXLOADUSERDATA derived object, whose methods would be called by D3DX when custom data objects are discovered in the X file. When saving the X file, D3DX will require the application to write out custom data chunks as well. Thus, the abstract ID3DXSAVEUSERDATA base class is the complementary interface for saving. Although we will not use this parameter in our demo, if you open up d3dxanim.h you will see that it is an interface with two methods that must be implemented in the derived class. We will simply pass in NULL as we have no custom chunks in our current application.

Finally, we will look at the code to the CActor::SaveActorToX method:

```
HRESULT CActor::SaveActorToX( LPCTSTR FileName, ULONG Format )
{
    HRESULT hRet;

    // Validate parameters
    if ( !FileName ) return D3DERR_INVALIDCALL;

    // If we are NOT managing our own attributes, fail
    if ( GetCallback( CActor::CALLBACK_ATTRIBUTEID ).pFunction != NULL )
        return D3DERR_INVALIDCALL;

    // Save the hierarchy back out to file
    hRet = D3DXSaveMeshHierarchyToFile( FileName, Format, m_pFrameRoot, NULL, NULL );

    if ( FAILED(hRet) ) return hRet;

    // Success!!
    return D3D_OK;
}
```

The application passes in the name of the X file and the format (binary vs. text) of the file. This request is passed straight into the D3DXSaveMeshHierarchyToFile function, along with the root frame of the actor. Notice that the function returns failure if the actor is in non-managed mode. The reason for this will be discussed in more detail later in this workbook when we cover the CAllocateHierarchy::CreateMeshContainer method. Ultimately, in non-managed mode, the application may have remapped all the subset IDs into a global pool of textures and materials. Because of this, the D3DXSaveMeshHierarchyToFile method will no longer have access to the materials and texture filenames used by each subset in a mesh. Therefore, saving a non-managed actor would result in meshes

being written out with incorrect texture and material data. As you are only likely to use the CActor::SaveActorToX in a situation where it is being used as part of a tool you are developing, it is a limitation we can work with. Unlike a real-time game situation, using managed mode actors in a tool is acceptable since performance is not necessarily the top priority.

Source Code Walkthrough – CAllocateHierarchy

The CAllocateHierarchy class is derived from the abstract interface ID3DXAllocateHierarchy. This interface exposes four virtual functions which must be overridden in the derived class. These four functions are used as callbacks during the creation and destruction of the frame hierarchy.

The CActor temporarily instantiates an object of this type in the CActor::LoadActorFromX function and passes it to D3DXLoadMeshHierarchyFromX. This function will use the object's CreateFrame and CreateMeshContainer functions to allow the application to allocate the frames and mesh containers that will be attached to the hierarchy. The CActor instantiates an object of this type a second time in the CActor::Release function and passes it to the D3DXFrameDestroy function to unload the hierarchy from memory. This function uses the interface's DestroyFrame and DestroyMeshContainer methods to allow the application to release the frames and meshes in the hierarchy and perform any other clean up.

The derived class definition (see CActor.h) is shown below. It implements the four base class virtual functions and exposes a constructor that accepts a pointer to a CActor. The CActor pointer is stored in its only member variable so that the CreateMeshContainer method can access the registered callbacks of the actor during material processing.

```
class CAllocateHierarchy: public ID3DXAllocateHierarchy
{
public:
    // Constructors & Destructors for This Class
    CAllocateHierarchy( CActor * pActor ) : m_pActor(pActor) {}

    // Public Functions for This Class
    STDMETHOD(CreateFrame)          ( THIS_ LPCTSTR Name, LPD3DXFRAME *ppNewFrame);
    STDMETHOD(CreateMeshContainer)  ( THIS_ LPCTSTR Name, CONST D3DXMESHDATA *pMeshData,
                                      CONST D3DXMATERIAL *pMaterials,
                                      CONST D3DXEFFECTINSTANCE *pEffectInstances,
                                      DWORD NumMaterials, CONST DWORD *pAdjacency,
                                     LPD3DXSKININFO pSkinInfo,
                                     LPD3DXMESHCONTAINER *ppNewMeshContainer);

    STDMETHOD(DestroyFrame)         (THIS_ LPD3DXFRAME pFrameToFree);
    STDMETHOD(DestroyMeshContainer) (THIS_ LPD3DXMESHCONTAINER pMeshContainerBase);

    // Public Variables for This Class
    CActor  * m_pActor;         // Actor we are allocating for

};
```

CAllocateHierarchy::CreateFrame

The CreateFrame function is called by D3DXLoadMeshHierarchyFromX when a new frame data object is encountered in the X file. The name of the frame will be passed to this function as its first parameter along with the address of a D3DXFRAME pointer.

CreateFrame must allocate the frame structure and perform any initialization of its data members before assigning the passed frame pointer to the newly allocated frame structure. When the function returns, D3DX will attach this frame to the hierarchy in its correct position.

It is very useful that D3DX provides us with a means for creating the frame structure and does not allocate a D3DXFRAME structure on our behalf. This allows us to allocate our D3DXFRAME derived structure type, which contains an extra matrix (mtx_Combined) to store the absolute world matrix of the frame when the hierarchy is updated (via CActor::UpdateFrameMatrices). Because our D3DXFRAME_MATRIX structure is derived from D3DXFRAME, the variables that D3DX cares about (basically just the matrix, sibling, and child pointers) are still in the correct position. So the structure can be safely cast. From the perspective of D3DX, it is passed back a D3DXFRAME structure and it can treat it as such.

```
HRESULT CAllocateHierarchy::CreateFrame( LPCTSTR Name, LPD3DXFRAME *ppNewFrame )
{
    D3DXFRAME_MATRIX * pNewFrame = NULL;

    // Clear out the passed frame (it may not be NULL)
    *ppNewFrame = NULL;

    // Allocate a new frame
    pNewFrame = new D3DXFRAME_MATRIX;
    if ( !pNewFrame ) return E_OUTOFMEMORY;

    // Clear out the frame
    ZeroMemory( pNewFrame, sizeof(D3DXFRAME_MATRIX) );

    // Copy over, and default other values
    if ( Name ) pNewFrame->Name = _tcsdup( Name );
    D3DXMatrixIdentity( &pNewFrame->TransformationMatrix );

    // Pass this new pointer back out
    *ppNewFrame = (D3DXFRAME*)pNewFrame;

    // Success!!
    return D3D_OK;
}
```

The function starts by allocating our derived D3DXFRAME_MATRIX structure, initializing it to zero for safety. It also sets the frame's relative matrix to identity. This is also for safety, since this matrix should be overwritten by D3DX with the actual matrix values for this frame stored in the X file when the function returns.

The next thing we do is store the name of the frame (passed as the first parameter) in the frame structure so that we can traverse the actor's hierarchy and search for frames by name. This is very important

because in our demo application we will need to search the actor's hierarchy for the wheel and pivot frames so that we can attach CAnimation objects to them.

Notice that we cannot simply copy the passed string into the frame structure Name member. This string memory is owned by D3DX and will be released as soon as the function returns. This would leave us with an invalid string pointer in our frame. Therefore we must copy the contents of the string into a new string that we allocate. The _tcsdup function does this job for us. We just pass in the string we wish to copy and it will allocate a new string of the correct size and copy over the contents of the source string. We can then store the returned string in our frame.

Finally, we assign the D3DXFRAME pointer passed by D3DX to point to our newly allocated D3DXFRAME_MATRIX (making sure we cast it). On function return, D3DX will now have access to our frame and can use its sibling and child pointers to attach it to the hierarchy.

CAllocateHierarchy::CreateMeshContainer

The CreateMeshContainer function is called by D3DXLoadMeshHierarchyFromX whenever a mesh data object is encountered in the X file. This method must use the passed information to construct a D3DXMESHCONTAINER (or derived) structure and return it to D3DX.

We are using our own derived mesh container type (called D3DXMESHCONTAINER_DERIVED) which includes an additional CTriMesh pointer. With D3DX providing this mesh creation callback mechanism, we are afforded complete freedom to manage the mesh data and materials for the mesh in whatever way our application sees fit. This will allow us to store the passed mesh data in a CTriMesh and send the material data to the scene callbacks for storage. This function also provides us with a chance to check the creation flags of the mesh and its vertex format and clone it into a new mesh using the format we desire.

Because this function actually has quite a lot of work to do, we will cover it a section at a time. Luckily, the resource management section is almost an exact duplicate of the material handling code we saw in the previous workbook for CTriMesh. This code should be very familiar to you.

```
HRESULT CAllocateHierarchy::CreateMeshContainer(LPCTSTR Name,
                                                CONST D3DXMESHDATA*pMeshData,
                                                CONST D3DXMATERIAL *pMaterials,
                                                CONST D3DXEFFECTINSTANCE *pEffectInstances,
                                                DWORD NumMaterials,
                                                CONST DWORD *pAdjacency,
                                                LPD3DXSKININFO pSkinInfo,
                                                LPD3DXMESHCONTAINER *ppNewMeshContainer)
{

    ULONG                       AttribID, i;
    HRESULT                     hRet;
    LPD3DXMESH                  pMesh          = NULL;
    D3DXMESHCONTAINER_DERIVED *pMeshContainer = NULL;
    LPDIRECT3DDEVICE9           pDevice        = NULL;
    CTriMesh                   *pNewMesh       = NULL;
    MESH_ATTRIB_DATA           *pAttribData    = NULL;
    ULONG                      *pAttribRemap   = NULL;
```

```
    bool                        ManageAttribs  = false;
    bool                        RemapAttribs   = false;
    CALLBACK_FUNC               Callback;

    // We only support standard meshes (i.e. no patch or progressive meshes in this demo)
    if ( pMeshData->Type != D3DXMESHTYPE_MESH ) return E_FAIL;
```

We can see immediately that the function accepts quite a lengthy parameter list. As the first parameter we are passed the name of the mesh. This is the name assigned to the mesh data object in the X file, if one exists. As the second parameter we are passed a D3DXMESHDATA structure. You will recall from the textbook that this structure contains either an ID3DXMesh interface pointer, an ID3DXPMesh interface pointer, or an ID3DXPatchMesh interface pointer. It also contains a Type member variable describing which mesh type it is. The D3DXMESHDATA member is shown below:

```
typedef struct D3DXMESHDATA
{
    D3DXMESHDATATYPE Type;
    union
    {
      LPD3DXMESH           pMesh;
      LPD3DXPMESH         pPMesh;
      LPD3DXPATCHMESH pPatchMesh;
    }
} D3DXMESHDATA, *LPD3DXMESHDATA
```

D3DXMESHDATATYPE is an enumeration which can contain one of three values: D3DXMESHTYPE_MESH, D3DXMESHTYPE_PMESH or D3DXMESHTYPE_PATCHMESH.

In our demo code, we will only support the common case where the structure contains an ID3DXMesh pointer. If you wish to add support for loading progressive meshes from an X file, then you should be able to modify this function to handle both cases without any problem given our discussions in the last chapter.

Returning to the above code, we can see that the third parameter to this function is an array of D3DXMATERIAL structures containing the texture filename and material information for each subset in the passed mesh. The fourth parameter contains an array of effect instances. We will ignore any reference to this at the moment until we cover effect files in Module III. The fifth parameter describes the number of elements in the previous two arrays (the number of subsets in the mesh). This is followed by a pointer to the mesh adjacency information. The penultimate parameter is a pointer to a D3DXSKININFO structure. We will see this being used in Chapter 11 when we cover skinned meshes and skeletal animation. For now we can ignore this member. The final parameter is the address of a pointer to a D3DXMESHCONTAINER structure which our function will assign to the mesh container structure that we allocate and populate within this function. When the function returns, D3DX will use this pointer to connect the mesh container to its correct frame in the hierarchy.

In the next code section we see that the first thing we do is assign the ID3DXMesh interface stored in the passed D3DXMESHDATA member to a local member variable (pMesh) for easier access. Notice that although we are copying a pointer to an interface here, we are not incrementing the reference count. This is because we may not actually want to keep this mesh. We have to first check its creation parameters and its vertex format.

Currently we only support FVF style mesh creation, so if this mesh's FVF flags are zero, then we return from the function.

```
    // Extract the standard mesh from the structure
    pMesh = pMeshData->pMesh;

    // We require FVF compatible meshes only
    if ( pMesh->GetFVF() == 0 ) return E_FAIL;

    // Allocate a mesh container structure
    pMeshContainer = new D3DXMESHCONTAINER_DERIVED;
    if ( !pMeshContainer ) return E_OUTOFMEMORY;

    // Clear out the structure to begin with
    ZeroMemory( pMeshContainer, sizeof(D3DXMESHCONTAINER_DERIVED) );

    // Copy over the name
    if ( Name ) pMeshContainer->Name = _tcsdup( Name );
```

You can see above that we allocate our new mesh container. It will be a D3DXMESHCONTAINER_DERIVED structure which has a CTriMesh pointer that we will need to use. We initialize the structure to zero and then copy over the name of the mesh into the mesh container's Name member. As described in the CAllocateHierarchy::CreateFrame method, the memory containing the string is owned by D3DX, so we must make a copy because we cannot rely on its persistence after the function returns.

At this point we have an empty mesh container, so it is time to start filling it up with the passed data. Before we do that however, we know that we want our data to be stored in a CTriMesh object, so we will allocate one. To avoid confusion, the point should be made that the local variable pNewMesh is a pointer to a CTriMesh object. The local variable pMesh is a pointer to an ID3DXMesh interface.

```
    // Allocate a new CTriMesh
    pNewMesh = new CTriMesh;
    if ( !pNewMesh ) { hRet = E_OUTOFMEMORY; goto ErrorOut; }
```

We now have an empty CTriMesh in hand. In the previous workbook, it is at this point that we would register our callback functions, but that would be pointless in this code because the CTriMesh::LoadMeshFromX function will never be used. That is why the same callback code will need to be implemented by hand in this function.

The ID3DXMesh data has already been loaded and passed to us by D3DX along with the materials that it uses. We will see in a moment that we will attach this ID3DXMesh to the CTriMesh using the CTriMesh::Attach function. But before we do that, we want to make sure that the ID3DXMesh that we have been passed is using a data format our application is happy with. If not, we will need to clone it into the appropriate format.

The next section of code tests to see whether the FVF flags of the ID3DXMesh that D3DX has passed us contains vertex normals. If it does not, then this mesh is no good to us and we will clone a new mesh and add the normals ourselves. We also clone the mesh if the mesh creation options are not what we requested. This may seem a strange test to do; after all, the application will pass the desired mesh

creation options into the CActor::LoadActorFromX function, which in turn passes the options on to the D3DXLoadMeshHierarchyFromX function. Therefore, the meshes should surely be created using the options we initially registered with the actor. Well, you would certainly think so. However, in our laboratory tests on various machines we found that the meshes created by D3DX did not always match the mesh creation options passed into D3DXLoadMeshHierarchyFromX. Sometimes it even placed the vertex or index buffer in system memory. So to be safe, we will retrieve the options from the passed mesh and compare them against the options registered with the actor (by the application), and if they are not a match, we will clone the mesh using the correct mesh creation flags.

```
    // If there are no normals, this demo requires them, so add them to the mesh's FVF
    if (!(pMesh->GetFVF()&D3DFVF_NORMAL) || (pMesh->GetOptions()!=m_pActor->GetOptions()) )
    {
        LPD3DXMESH pCloneMesh = NULL;

        // Retrieve the mesh's device (this adds a reference)
        pMesh->GetDevice( &pDevice );

        // Clone the mesh
        hRet = pMesh->CloneMeshFVF( m_pActor->GetOptions(),
                                    pMesh->GetFVF() | D3DFVF_NORMAL,
                                    pDevice,
                                    &pCloneMesh );

        if ( FAILED( hRet ) ) goto ErrorOut;

        // Note: we don't release the old mesh here, because we don't own it
        pMesh = pCloneMesh;

        // Compute the normals for the new mesh if there was no normal to begin with
        if ( !(pMesh->GetFVF() & D3DFVF_NORMAL) ) D3DXComputeNormals( pMesh, pAdjacency );

        // Release the device, we're done with it
        pDevice->Release();
        pDevice = NULL;

        // Attach our specified mesh to the new mesh (this addref's the chosen mesh)
        pNewMesh->Attach( pMesh );

    } // End if no vertex normal or wrong options
    else
    {
        // Simply attach our specified mesh to the new mesh (this addref's the chosen mesh)
        pNewMesh->Attach( pMesh );

    } // End if options ok
```

In the above code you can see that if the mesh creation options are incorrect or normals do not exist in the vertices then we clone a new mesh using the correct format. We never release the original mesh interface because we never incremented its reference count earlier. At this point, the original mesh (which we no longer need) has a reference count of 1 (i.e., D3DX's claim on the interface). When the function returns and D3DX decrements the reference count of the original mesh, it will be unloaded from memory. Notice that after the clone operation, we reassign the local pMesh pointer to point at the cloned mesh interface instead.

If normals did not previously exist then we just added room for them. Since the normal data is not yet initialized, we use the D3DXComputeNormals function, passing in the adjacency information that we were passed by D3DX, to calculate the normals.

Next, we release the device interface (retrieved from the mesh) which we no longer need, and we call the CTriMesh::Attach method to attach the tri-mesh to our ID3DXMesh. We looked at the CTriMesh::Attach function in the previous workbook -- it assigns the CTriMesh internal ID3DXMesh pointer to point to the passed interface. The final section of the above code demonstrates that when the passed mesh is already in the correct format, we can simply attach it to the CTriMesh. The Attach method will automatically increment the reference count of the passed interface.

At this point we have a CTriMesh with a valid ID3DXMesh containing the mesh data from the X file. We now have to decide what to do with the material data passed into the function. If the actor is in managed mode, then we will wish to register the texture filenames for each subset with the texture callback (pre-registered with the actor) and store the texture pointers and materials in the mesh itself. If this is a non-managed mode actor, then we will need to perform attribute buffer remapping.

The first line of the following code tests to see if the actor has had its CALLBACK_ATTRIBUTEID function registered. If so, then this actor is in non-managed mode and the meshes will contain their own attribute lists. If the function pointer is NULL, then ManageAttribs will be set to true and the actor is in managed mode. When this is the case, our first task is to allocate the CTriMesh's attribute data array to the correct size -- we need to it to be large enough to contain an entry for each subset. We allocate this array using the CTriMesh::AddAttributeData function and pass in the number of subsets in the mesh. Once it is allocated we use CTriMesh::GetAttributeData to retrieve a pointer to the first element in the array. This pointer will be used to populate the array with texture pointers and material information.

```
    // Are we managing our own attributes ?
    ManageAttribs = (m_pActor->GetCallback
                    ( CActor::CALLBACK_ATTRIBUTEID ).pFunction == NULL);

    // Allocate the attribute data if this is a manager mesh
    if ( ManageAttribs == true && NumMaterials > 0 )
    {
        if ( pNewMesh->AddAttributeData( NumMaterials ) < -1 )
                                                { hRet = E_OUTOFMEMORY; goto ErrorOut; }
        pAttribData = pNewMesh->GetAttributeData();

    } // End if managing attributes
    else
    {
        // Allocate attribute remap array
        pAttribRemap = new ULONG[ NumMaterials ];
        if ( !pAttribRemap ) { hRet = E_OUTOFMEMORY; goto ErrorOut; }

        // Default remap to their initial values.
        for ( i = 0; i < NumMaterials; ++i ) pAttribRemap[ i ] = i;

    } // End if not managing attributes
```

The above code also shows the case for a non-managed mode mesh. In this case we know we will need to re-map the attribute buffer, so we allocate an array large enough to be used as a temporary re-mapping buffer. This was all covered in the CTriMesh class in the previous workbook, so this should

not be new to you. We will use this temporary buffer to store the global attribute IDs for each subset returned by the scene's resource callback function.

We now loop through each material in the passed D3DXMATERIAL array and process them in accordance with the mode of the actor. The following code was described in its entirety in the previous chapter (only it was inside CTriMesh instead), so you should refer back if you need to refresh your memory. At the end of the loop, the attribute data array inside the CTriMesh will contain an element for each subset in the mesh. Each element will contain the texture, material and possible effect file used by the subset.

```
    // Loop through and process the attribute data
    for ( i = 0; i < NumMaterials; ++i )
    {
        if ( ManageAttribs == true )
        {
            // Store material
            pAttribData[i].Material = pMaterials[i].MatD3D;

            // Note : The X File specification contains no ambient material property
            pAttribData[i].Material.Ambient = D3DXCOLOR( 1.0f, 1.0f, 1.0f, 1.0f );

            // Request texture pointer via callback
            Callback = m_pActor->GetCallback( CActor::CALLBACK_TEXTURE );
            if ( Callback.pFunction )
            {
                COLLECTTEXTURE CollectTexture = (COLLECTTEXTURE)Callback.pFunction;
                pAttribData[i].Texture = CollectTexture( Callback.pContext,
                                                         pMaterials[i].pTextureFilename );

                // Add reference. We are now using this
                if ( pAttribData[i].Texture ) pAttribData[i].Texture->AddRef();

            } // End if callback available

            // Request effect pointer via callback
            Callback = m_pActor->GetCallback( CActor::CALLBACK_EFFECT );
            if ( Callback.pFunction )
            {
                COLLECTEFFECT CollectEffect = (COLLECTEFFECT)Callback.pFunction;
                pAttribData[i].Effect = CollectEffect( Callback.pContext,
                                                       pEffectInstances[i] );

                // Add reference. We are now using this
                if ( pAttribData[i].Effect ) pAttribData[i].Effect->AddRef();

            } // End if callback available

        } // End if attributes are managed
```

The next code block shows what happens when the actor is non-managed. Again, you can refer to the prior workbook for details about the operations encountered.

```
        else
        {
            // Request attribute ID via callback
            Callback = m_pActor->GetCallback( CActor::CALLBACK_ATTRIBUTEID );
            if ( Callback.pFunction )
```

```
            {
             COLLECTATTRIBUTEID CollectAttributeID =(COLLECTATTRIBUTEID)Callback.pFunction;
             AttribID = CollectAttributeID( Callback.pContext,
                                            pMaterials[i].pTextureFilename,
                                            &pMaterials[i].MatD3D, &pEffectInstances[i] );

                // Store this in our attribute remap table
                pAttribRemap[i] = AttribID;

                // Determine if any changes are required so far
                if ( AttribID != i ) RemapAttribs = true;

            } // End if callback available

        } // End if we don't manage attributes

    } // Next Material
```

At this point, a managed mesh will be completely set up, with its internal attribute information stored for self-contained rendering.

If the actor is in non-managed mode, then the current mesh still needs to have its attribute buffer re-mapped. So the next snippet of code will lock the attribute buffer of a non-managed mesh and use the temporary re-map array we just populated to change the attribute of each triangle to the new global attribute ID. This code is also not new to us -- the CTriMesh performs a very similar step when its CTriMesh::LoadMeshFromX function is used.

```
    // Remap attributes if required
    if ( pAttribRemap != NULL && RemapAttribs == true )
    {
        ULONG * pAttributes = NULL;

        // Lock the attribute buffer
        hRet = pMesh->LockAttributeBuffer( 0, &pAttributes );
        if ( FAILED(hRet) ) goto ErrorOut;

        // Loop through all faces
        for ( i = 0; i < pMesh->GetNumFaces(); ++i )
        {
            // Retrieve the current attribute ID for this face
            AttribID = pAttributes[i];

            // Replace it with the remap value
            pAttributes[i] = pAttribRemap[AttribID];

        } // Next Face

        // Finish up
        pMesh->UnlockAttributeBuffer( );

    } // End if remap attributes

    // Release remap data
    if ( pAttribRemap ) delete []pAttribRemap;
```

Our CTriMesh is now fully created, and the scene (or whatever object has registered the resource callbacks) has loaded and stored any textures and materials that the mesh uses.

We can now perform optimizations and cleaning using our CTriMesh methods. We will first perform a weld of the vertices to merge any duplicated vertices that may exist into a single vertex. This will allow us to reduce the vertex count in some cases. We then issue a call to CTriMesh::OptimizeInPlace to perform a compaction of the data (removing degenerate triangles for example), an attribute sort of the attribute buffer (for better subset rendering performance), and a vertex cache optimization to rearrange the mesh data for better vertex cache coherency.

```
    // Attempt to optimize the new mesh
    pNewMesh->WeldVertices( 0 );
    pNewMesh->OptimizeInPlace( D3DXMESHOPT_VERTEXCACHE );
```

With our mesh in top condition, we can now assign it to the mesh container that we allocated earlier in the function. Recall that we actually allocated an instance of our derived mesh container class, which contains a CTriMesh pointer in addition to the usual members of the base class. We store the CTriMesh pointer to our new mesh in the mesh container and store the CTriMesh's underlying ID3DXMesh interface in the mesh container's D3DXMESHDATA member. We do this final step so that D3DX helper functions (e.g., D3DXComputeBoundingSphere) will still be able to work with the mesh data stored in our hierarchy. Remember that any D3DX helper function that deals with meshes in a hierarchy will not be aware that the hierarchy now contains mesh data in the proprietary CTriMesh type added to the derived class. These functions expect the mesh data to be stored as an ID3DXMesh interface inside the D3DXMESHDATA member of the mesh container.

By fetching the CTriMesh's underlying ID3DXMesh interface and storing it in the D3DXMESHDATA member of the mesh container, we keep everybody happy. Our actor can access the methods of CTriMesh using the mesh container's CTriMesh pointer, and D3DX can traverse the hierarchy and access the raw mesh data via the ID3DXMesh interface stored in the expected place.

One such D3DX helper function that will need to access the mesh data is the D3DXSaveMeshHierarchyToFile method which we discussed earlier (see CActor::SaveActorToX). This function will traverse the hierarchy and write the frame hierarchy information and mesh container information out to the X file. But this function needs more than just access to the mesh data; it also needs to know about the materials and texture filenames used by the mesh so that they can be written to the file as well. This would seem to present a bit of a problem since the application manages the loading an storing of textures in data areas the actor might not have access to. The solution is actually quite simple -- it is in this function that we are first passed the D3DXMATERIAL array that contains the texture filenames and materials for each subset. We have seen how the scene callback functions are invoked by the actor to turn information in this array into real textures (instead of just filenames). Therefore, at this point, we already know the materials and texture filenames used by the mesh because D3DX passed them into this function to help us load the correct resources. So when this X file is saved, we simply need D3DX to get access to this array of D3DXMATERIAL's that it originally passed us during the loading process.

As we saw earlier, the D3DXMESHCONTAINER structure has members to store both a pointer to a D3DXMATERIAL array and the number of materials used by this array. This is exactly where the D3DXSaveMeshHierarchyToFile function expects the material and texture data for each mesh container to be stored. So all we have to do to make the save function work, is make a copy of the D3DXMATERIAL array that was passed into this function and store that in the mesh container too. We

must make a copy of the material array, and not just assign the mesh container members to point directly at it, because the material array is owned by D3DX and will be destroyed as soon as this method returns.

The next section of code shows how to do everything just discussed. It stores the CTriMesh's underlying ID3DXMesh interface in the mesh container's D3DXMESHDATA member, and copies the passed D3DXMATERIAL array into a new array. A pointer to this array and the number of elements in it are also stored in the mesh container's member variables, so that they can be accessed by D3DXSaveMeshHierarchyToFile.

```
    // Store our mesh in the container
    pMeshContainer->pMesh = pNewMesh;
    pMeshContainer->D3DXMESHDATA.pMesh=pNewMesh->GetMesh();
    pMeshContainer->NumMaterials   = NumMaterials;

    // Copy over material data only if in managed mode (i.e. we can save)
    if ( NumMaterials > 0 && ManageAttribs == true )
    {
        // Allocate material array
        pMeshContainer->pMaterials = new D3DXMATERIAL[ NumMaterials ];

        // Loop through and copy
        for ( i = 0; i < NumMaterials; ++i )
        {
            pMeshContainer->pMaterials[i].MatD3D = pMaterials[i].MatD3D;
            pMeshContainer->pMaterials[i].pTextureFilename =
                     _tcsdup( pMaterials[i].pTextureFilename );

        } // Next Material

    } // End if any materials to copy
```

Now the new mesh container contains all of the information we need it to store and it is ready to be attached to the hierarchy. As our final step, we assign the D3DXMESHCONTAINER pointer passed into this function by D3DX to point to the newly allocated container. On function return, D3DX will now have access to our mesh container and will attach it to the correct frame in the hierarchy.

```
    // Store this new mesh container pointer
    *ppNewMeshContainer = (D3DXMESHCONTAINER*)pMeshContainer;

    // Success!!
    return D3D_OK;

ErrorOut:
    // If we drop here, something failed
    DestroyMeshContainer( pMeshContainer );

    if ( pDevice      ) pDevice->Release();
    if ( pAttribRemap ) delete []pAttribRemap;
    if ( pNewMesh     ) delete pNewMesh;

    // Failed....
    return hRet;
}
```

The bottom section of the code performs cleanup if any errors happen. If anything goes wrong throughout this function, program flow is diverted to this section of code and everything is correctly cleaned up.

> **NOTE**: Notice that we only make a copy of the material array and store it in the mesh container if the mesh is in managed mode. In non-managed mode, the attribute IDs of each subset may have been remapped to different values. If we try to save an actor containing a non-managed mesh, the attribute IDs would be wrong and incorrect texture and material data would be output to the file for each subset. Because of this, the CActor::SaveActorToX function only works when the actor is in managed mode. This is not a major limitation, because you will generally want to save actor data when you are using the actor as a tool (not in your actual game). In this case, using the actor in managed mode is probably perfectly acceptable from a performance perspective.

CAllocateHierarchy::DestroyFrame

The CAllocateHierarchy::DestroyFrame function is called by the D3DXFrameDestroy function when it removes the hierarchy from memory. For each frame visited by that function, this function is passed the frame that needs to be deleted. D3DX cannot de-allocate the frame for us since it has no idea how we allocated the frame memory in the CAllocateHierarchy::CreateFrame method. It also has no means of knowing what other cleanup might have to be performed.

```
HRESULT CAllocateHierarchy::DestroyFrame( LPD3DXFRAME pFrameToFree )
{
    D3DXFRAME_MATRIX * pMtxFrame = (D3DXFRAME_MATRIX*)pFrameToFree;

    // Validate Parameters
    if ( !pMtxFrame ) return D3D_OK;

    // Release data
    if ( pMtxFrame->Name ) free( pMtxFrame->Name ); // '_tcsdup' allocated.
    delete pMtxFrame;                               // 'new' allocated.

    // Success!!
    return D3D_OK;
}
```

If the passed frame pointer is valid, the memory allocated for the frame name string is deleted. Notice that we use the C free function to delete this memory because _tcsdup was used to copy the string (_tcsdup uses the C memory allocation function alloc to allocate the memory). We must always make sure we match the memory allocation functions with their proper de-allocation functions if we are to avoid memory leaks.

Once the string has been deleted, we delete the frame structure itself. Notice how we use the delete operator for this because we allocated the frame memory in CreateFrame using the C++ new operator.

CAllocateHierarchy::DestroyMeshContainer

This is the final interface function that needs to be implemented, and it is responsible for releasing the memory for a mesh container. When our actor de-allocates its frame hierarchy (using D3DXFrameDestroy), this method will be called for every mesh container. A pointer to the mesh container to be deleted is the only parameter to this function.

We begin by releasing the D3DXMATERIAL array. Recall that this array was allocated in the CreateMeshContainer method to make a copy of the passed D3DXMATERIAL array so that the D3DXSaveMeshHierarchyToFile method will be able to access the materials and textures used by the mesh during the hierarchy saving procedure. If the mesh is in non-managed mode then this array should not exist, and the mesh container's pMaterials pointer should be NULL.

```
HRESULT CAllocateHierarchy::DestroyMeshContainer( LPD3DXMESHCONTAINER
                                                  pContainerToFree )
{
    D3DXMESHCONTAINER_DERIVED * pContainer = (D3DXMESHCONTAINER_DERIVED*)pContainerToFree;

    // Validate Parameters
    if ( !pContainer ) return D3D_OK;

    // Release material data ( used for saving X file )
    if ( pContainer->pMaterials )
    {
        for ( i = 0; i < pContainer->NumMaterials; ++i )
        {
            // Release the string data
            if ( pContainer->pMaterials[i].pTextureFilename )
                free( pContainer->pMaterials[i].pTextureFilename );

        } // Next Material

        // Destroy the array
        delete []pContainer->pMaterials;
        pContainer->pMaterials = NULL;

    } // End if any material data
```

Now we release the rest of the data allocated by the mesh container. First, you will recall that we stored a copy of the CTriMesh's underlying ID3DXMesh interface in the container's D3DXMESHDATA member. We must now release this interface. Second, we must also free the memory that was allocated to store the name of the mesh. Since this memory was allocated using _tcsdup in CreateMeshContainer, we must release it using the C free function. Finally, we delete the CTriMesh object stored in the mesh container's pMesh member.

```
    // Release data
    if ( pContainer->MeshData.pMesh ) pContainer->MeshData.pMesh->Release();
    if ( pContainer->Name ) free( pContainer->Name );   // '_tcsdup' allocated.
    if ( pContainer->pMesh ) delete pContainer->pMesh;
    delete pContainer;

    // Success!!
    return D3D_OK;
}
```

We have now discussed the CAllocateHierarchy class and the CActor class in their entirety. You should be fairly comfortable with your understanding of how they work together to construct the entire frame hierarchy from an X file, taking care of frame and mesh asset allocation in the process.

Source Code Walkthrough – CAnimation

The CAnimation class is implemented in this demo to demonstrate a simple means for animating frame hierarchies. This class is not one that we will find ourselves using moving forward, but understanding its operations and the way it interacts with an actor's hierarchy should prove helpful in preparing us for the following chapter on animation.

The CAnimation class is not used by the CActor or CAllocateHierarchy classes. Objects of this type are instantiated by the scene and attached to frames in an actor's hierarchy. The scene will then use an object of this type to apply rotations via the relative matrix of the frame.

The scene will use the CActor::FindFrameByName function to search for a frame that it wishes to animate (e.g., Wheel_FL) and that function will return a pointer to the matched frame. The scene will then store a pointer to that matrix in a CAnimation object (using CAnimation::Attach). During each iteration of the game loop, the scene can then call the CAnimation::Rotate family of functions to apply rotations to the attached frame.

In our application, the scene instantiates six CAnimation objects: four will be attached to the wheels of the cars and two will be attached to the pivot frames to perform the steering animation.

The class definition (see CAnimation.h) is shown below.

```
class CAnimation
{
public:
    // Constructors & Destructors for This Class
             CAnimation();
    virtual ~CAnimation();

    // Public Functions for This Class
    void            Attach      ( LPD3DXMATRIX pMatrix, LPCTSTR strName = NULL );
    LPCTSTR         GetName     ( ) const { return m_strName; }
    LPD3DXMATRIX    GetMatrix   ( ) const { return m_pMatrix; }

    void            RotationX   ( float fRadAngle, bool bLocalAxis = true );
    void            RotationY   ( float fRadAngle, bool bLocalAxis = true );
    void            RotationZ   ( float fRadAngle, bool bLocalAxis = true );

private:
    // Private Variables for This Class
    LPD3DXMATRIX    m_pMatrix;      // Attached interpolator matrix
    LPTSTR          m_strName;      // Name (if provided) of the frame
};
```

The class only has two member variables:

LPD3DXMATRIX m_pMatrix

This member is set via the CAnimation::Attach method. It will point to the relative matrix of a frame in the hierarchy. We could use this object type without frame hierarchies, since it can serve as a generic rotation matrix generator/updater. In our demo application however, any calls to RotationX, RotationY, or RotationZ functions will apply a rotation to a frame in our automobile hierarchy.

LPSTR m_strName

This member is also set via the CAnimation::Attach method. It is the name of the animation as well as the name of the frame in the hierarchy that will have its relative matrix updated by this object.

CAnimation::CAnimation()

The constructor simply initializes the member variables to NULL.

```
CAnimation::CAnimation()
{
    // Clear any required variables
    m_pMatrix   = NULL;
    m_strName   = NULL;
}
```

CAnimation::~CAnimation()

The destructor has to take care of releasing the string memory. This memory is allocated in the Attach method using _tcsdup, so a free call is required.

```
CAnimation::~CAnimation()
{
    // Release any memory
    if ( m_strName ) free( m_strName ); // '_tcsdup' allocated.

    // Clear Variables
    m_pMatrix   = NULL;
    m_strName   = NULL;
}
```

CAnimation::Attach

This function is called by the scene to attach a matrix and frame name to the object. The passed matrix pointer is copied into the member variable first. If the string containing the name is not NULL, then it already contains a name (perhaps the object was used previously to animate another frame), so we release its memory prior to copying the passed string.

```
void CAnimation::Attach( LPD3DXMATRIX pMatrix, LPCTSTR strName /* = NULL */ )
{
    // Attach us to the matrix specified
    m_pMatrix = pMatrix;

    // Release the old name
    if ( m_strName ) free( m_strName );
```

```
    m_strName = NULL;

    // Duplicate new name if provided
    if ( strName ) m_strName = _tcsdup( strName );
}
```

CAnimation::RotationX

The application animates the attached frame via its matrix using one of three rotation functions: RotationX, RotationY or RotationZ. As all three functions are identical (with the exception that they build a rotation around a different axis), we will only show the code to the RotationX function here. Check the sourse code if you would like to see implementations for the other two.

```
void CAnimation::RotationX( float fRadAngle, bool bLocalAxis /* = true */ )
{
    D3DXMATRIX mtxRotate;

    // Validate Prerequisites
    if ( !m_pMatrix ) return;

    // Generate rotation matrix
    D3DXMatrixRotationX( &mtxRotate, fRadAngle );

    // Concatenate the two matrices
    if ( bLocalAxis )
        D3DXMatrixMultiply( m_pMatrix, &mtxRotate, m_pMatrix );
    else
        D3DXMatrixMultiply( m_pMatrix, m_pMatrix, &mtxRotate );
}
```

This function is passed an angle (in radians) describing the angle we wish to rotate the frame by. The function also accepts a Boolean parameter called bLocalAxis which allows us to toggle whether we would like the frame to be rotated about its own coordinate system axis (usually the case) or whether we would like the rotation to apply around the parent frame's axis. As the frame is relative to its parent frame in the hierarchy, this is a simple case of switching the matrix multiplication order. We will apply local rotations to our wheel frames so that they rotate around their own origins and axes.

The function creates an X axis rotation matrix using the D3DXMatrixRotationX function and then multiplies the returned matrix with the attached frame matrix. The Boolean is checked to see if local or parent relative axis rotation should be applied and multiplication order is adjusted accordingly.

We have now covered all the new objects that have been introduced in this lab project. In the next section, we will look at how they are used collectively by the scene to load a multi-mesh X file and animate the desired frames.

Source Code Walkthrough – CScene Modifications

The changes to the scene class are quite small, but they are significant. For starters, any X files loaded via CScene::LoadSceneFromX or CScene::LoadSceneFromIWF will now be loaded into CActor objects instead of directly into CTriMesh objects. In the case of an IWF file, the external references in the IWF

file will be created as actors. Even if an X file contains only a single mesh and no frame hierarchy, the CActor class can still be used in the same way. The D3DXLoadMeshHierarchyFromX function will always create a root frame in such instances and the mesh will be attached as an immediate child.

The scene object will also have its Render function updated to handle actors instead of meshes. Of course, the scene will also need to create the CAnimation objects at load time and attach them to the relevant frames in the hierarchy. The CScene::AnimateObjects function will loop through its four wheel CAnimation objects and use their member functions to apply rotations to the wheels of the car.

The updated CScene class will include a pointer to an array of CActors. This array will contain all CActors that have been loaded. While this is the only new member we have to add, we will also list the member variables that were added in the previous workbook to get a better understanding of how everything fits together. The significant member variables of CScene are shown below:

```
    // Private Variables for This Class
    TEXTURE_ITEM       *m_pTextureList [MAX_TEXTURES];  // Array of texture pointers
    D3DMATERIAL9        m_pMaterialList[MAX_MATERIALS]; // Array of material structures
    CAnimation          m_pAnimList    [MAX_ANIMATIONS];// Array of animations

    ULONG               m_nTextureCount;                // Number of textures stored
    ULONG               m_nMaterialCount;               // Number of materials stored

    CObject           **m_pObject;                      // Array of objects storing meshes
    ULONG               m_nObjectCount;                 // Number of objects

    CTriMesh          **m_pMesh;                        // Array of loaded scene meshes
    ULONG               m_nMeshCount;                   // Number of meshes
    CActor            **m_pActor;                       // Array of loaded scene actors
    ULONG               m_nActorCount;                  // Number of actors
    ATTRIBUTE_ITEM      m_pAttribCombo[MAX_ATTRIBUTES]; // Table of attribute combinations
    ULONG               m_nAttribCount;                 // Number of attributes
};
```

Let us just briefly remind ourselves of the purpose of these member variables and the data they will contain when the scene is loaded:

TEXTURE_ITEM *m_pTextureList [MAX_TEXTURES]
ULONG m_nTextureCount
This array (added in the previous workbook) will contain all textures used by the scene. Each TEXTURE_ITEM structure contains a texture pointer and a texture filename. When X files are being loaded (either via CTriMesh::LoadMeshFromX or CActor::LoadActorFromX), all meshes will have a scene texture callback function registered. The texture data (filename) from the X file will be passed to the callback function and, if the texture does not already exist, it will be loaded and added to this array. If an IWF scene is being loaded, then this array will contain the textures used by the external references (X files) and the textures stored in the IWF file that are applied to the internal meshes (non X file meshes). So this array will contain all textures used by all CActors and CTriMeshes in the scene.

D3DMATERIAL9 m_pMaterialList [MAX_MATERIALS]
ULONG m_nMaterialCount
This array is analogous to the texture array and was also added in the previous workbook. It contains all the materials used by all meshes and actors in the scene. This includes all materials loaded from X files

as well as materials used by IWF internal meshes. This array will only contain the materials used by meshes and actors created in non-managed mode. As we know, meshes in managed mode will store the material information internally in their attribute data array. This is true whether they are standalone (in their own CObject) or part of an actor's hierarchy.

ATTRIBUTE_ITEM m_pAttribCombo[MAX_ATTRIBUTES]
ULONG m_nAttribCount
This array was also introduced in the previous chapter and describes an array of texture/material combinations used by all non-managed mode meshes. It is an index into this array that is returned from the scene attribute callback, used to re-map the attribute buffer of non-managed mode meshes. Each element in this array contains the texture and material for a single scene level subset.

CObject **m_pObject
ULONG m_nObjectCount
As with all previous implementations of the CScene class that we have implemented, this array contains all the objects that need to be rendered by the scene. Now a CObject may contain a pointer to a CActor instead of a CTriMesh. If the data is loaded from an IWF file for example, this array can contain a mixture of CObject types -- some may contain standalone CTriMeshes (i.e., the meshes stored internally in the IWF file) while others contain CActors that were specified in the IWF file as external references. Each object contains a world matrix that represents the position and orientation of the object in the scene. It is this object array that the scene will loop through and render during each cycle of the game loop.

CTriMesh **m_pMesh
ULONG m_nMeshCount
This array will contain any standalone CTriMeshes that have been loaded and stored in CObjects. If the scene is loaded from an X file then this array will be empty. If the scene has been loaded from an IWF file then it will contain CTriMeshes for the meshes in the file.

CActor **m_pActor
ULONG m_nActorCount
This array will contain pointers to all CActor objects that have been loaded by the scene and stored in CObjects. These members are the only new ones introduced in this demo application. A CActor will be created by each call to the CScene::LoadSceneFromX file. Multiple actors can be created and added to this array if the CScene::LoadSceneFromIWF file is used. An actor is created for each external mesh reference stored in the file.

Now that we know how the various member variables are connected, let us cover the CScene methods that are now or are significantly modified by the introduction of CActor. The discussion of each function below will have the label 'Modified' or 'New' indicating whether the method previously existed and has just been updated or whether it is a brand new addition to the CScene class. Some methods such as the constructors and destructors have also been modified to now initialize and destroy the new CActor array. We will not show the code to these functions as they contain routine steps that we have seen dozens of times before. Check the source code for more details.

CScene::LoadSceneFromX - Modified

As we have come to expect, this method is called by the CGameApp::BuildObjects function to load X files. This function is only called if we wish a single X file to be loaded. Sometimes we may want to load IWF scenes containing multiple meshes and external X file references, and on these occasions we will use the CScene::LoadSceneFromIWF call instead. In this lab project, we are loading a single X file containing an automobile, and as such, this function will be called to start the scene construction process.

This function is not very large and is mostly unchanged from the previous version. We will look at it in two sections.

```
bool CScene::LoadSceneFromX( TCHAR * strFileName )
{
    HRESULT hRet;

    // Validate Parameters
    if (!strFileName) return false;

    // Retrieve the data path
    if ( m_strDataPath ) free( m_strDataPath );
    m_strDataPath = _tcsdup( strFileName );

    // Strip off the filename
    TCHAR * LastSlash = _tcsrchr( m_strDataPath, _T('\\') );
    if (!LastSlash) LastSlash = _tcsrchr( m_strDataPath, _T('/') );
    if (LastSlash) LastSlash[1] = _T('\0'); else m_strDataPath[0] = _T('\0');

    CActor * pNewActor = new CActor;
    if (!pNewActor) return false;

    // Load in the specified X file
    pNewActor->RegisterCallback( CActor::CALLBACK_ATTRIBUTEID, CollectAttributeID, this );
    hRet = pNewActor->LoadActorFromX( strFileName, D3DXMESH_MANAGED, m_pD3DDevice );
    if ( FAILED(hRet) ) { delete pNewActor; return false; }
```

This function is passed the filename (complete with path) describing the name of the X file that is to be loaded. This is also the filename that will be passed and stored by the CActor that is ultimately created. The first thing the function does is make a copy of the complete filename and strip off the name of the file so that we are just left with the file path. It can often be useful for the scene object to know which folder houses its assets, so that it can be used to load any textures that the X file references.

After the path of the X file has been stored in the scene, we allocate a new CActor object. We know from our earlier discussion of CActor that it will initially contain no data and its root pointer will be set to NULL. The code then registers the CScene::CollectAttributeID static method as the CALLBACK_ATTRIBUTEID callback for the actor. This places the actor in non-managed mode, so all textures and materials contained in the X file we are about to load will be stored at the scene level. We know that this function will return global attribute IDs which are used to re-map the attribute buffers of all non-managed mode meshes.

With our non-managed mode callback registered with the actor, it is time to instruct the actor to load the X file. We call the CActor::LoadActorFromX function with the filename passed into the function and the D3DXMESH_MANAGED mesh option flag. This option flag will be stored in the actor and used to make sure that any CTriMeshes we create have their vertex and index buffers allocated in the managed resource pool. We also pass in a pointer to the Direct3D device that will own the mesh resources.

When this function returns, our CActor will have been populated with the frame/mesh hierarchy contained in the X file. Any textures and materials used by the meshes in the hierarchy will have been loaded and stored in the scene's texture, material and attribute arrays (by the callback).

Our CActor object is still a standalone object at this point, so we must add its pointer to the CScene's actor array. To do this we call a new CScene utility function called AddObject to resize the current CActor array and make room at the end for another pointer. (This function works identically to the AddMesh and AddObject utility functions from previous lessons). We then copy our new CActor pointer into the CActor array, at the end of the list. This is the list that the scene will traverse to destroy all currently loaded actors when the scene is cleaning itself up during its own destruction.

```
    // Store this new actor
    if ( AddActor( ) < 0 ) { delete pNewActor; return false; }
    m_pActor[ m_nActorCount - 1 ] = pNewActor;

    // Now build an object for this mesh (standard identity)
    CObject * pNewObject = new CObject( pNewActor );
    if ( !pNewObject ) return false;

    // Store this object
    if ( AddObject() < 0 ) { delete pNewObject; return false; }
    m_pObject[ m_nObjectCount - 1 ] = pNewObject;
```

As shown in the above code, we then allocate a new CObject. Our scene will work with CObjects so that both meshes and actors can be managed in a consistent manner. Most importantly, the CObject allows us to pair each CTriMesh or CActor with a world matrix. So when we create the CObject, we pass the CActor pointer into its constructor for storage. We then use the CScene::AddObject method to make room in the CScene's CObject array for another CObject pointer. Finally, the new CObject is added to the end of the array.

In this demo we do not use the light group mechanism from Chapter Five so that we can keep the code as focused as possible on the goals at hand. The X file will also contain no lighting information, so we will need to set up some default lights for viewing purposes. The next section of code handles this by creating four direction lights and storing them in the first four elements of the scene's D3DLIGHT9 array. These lights will be set on the device later and used by the pipeline to light our polygons. The remainder of the code is shown below:

```
    // Set up an arbitrary set of directional lights
    ZeroMemory( m_pLightList, 4 * sizeof(D3DLIGHT9));
    m_pLightList[0].Type = D3DLIGHT_DIRECTIONAL;
    m_pLightList[0].Diffuse = D3DXCOLOR( 1.0f, 0.92f, 0.82f, 0.0f );
    m_pLightList[0].Specular = D3DXCOLOR( 1.0f, 0.92f, 0.82f, 0.0f );
    m_pLightList[0].Direction = D3DXVECTOR3( 0.819f, -0.573f, 0.0f );

    m_pLightList[1].Type = D3DLIGHT_DIRECTIONAL;
```

```
    m_pLightList[1].Diffuse = D3DXCOLOR( 0.2f, 0.2f, 0.2f, 0.0f );
    m_pLightList[1].Specular = D3DXCOLOR( 0.3f, 0.3f, 0.3f, 0.0f );
    m_pLightList[1].Direction = D3DXVECTOR3( -0.819f, -0.573f, -0.0f );

    m_pLightList[2].Type = D3DLIGHT_DIRECTIONAL;
    m_pLightList[2].Diffuse = D3DXCOLOR( 0.2f, 0.2f, 0.2f, 0.0f );
    m_pLightList[2].Specular = D3DXCOLOR( 0.0f, 0.0f, 0.0f, 0.0f );
    m_pLightList[2].Direction = D3DXVECTOR3( 0.0f, 0.707107f, 0.707107f );

    m_pLightList[3].Type = D3DLIGHT_DIRECTIONAL;
    m_pLightList[3].Diffuse = D3DXCOLOR( 0.1f, 0.05f, 0.05f, 0.0f );
    m_pLightList[3].Specular = D3DXCOLOR( 0.6f, 0.6f, 0.6f, 0.0f );
    m_pLightList[3].Direction = D3DXVECTOR3( 0.0f, -0.707107f, 0.707107f );

    // We're now using 4 lights
    m_nLightCount = 4;

    // Build Animation 'Interpolators'
    BuildAnimations();

    // Success!
    return true;
}
```

Notice at the very bottom of the above function, we make a call to the new BuildAnimations method. This function is responsible for allocating six CAnimation objects and attaching them to the wheel and pivot frames in the hierarchy. We will look at that function in just a short while.

CScene::AddActor - New

This function is included here for completeness, but you have seen code like this many times before in our studies together. AddActor resizes the actor array when one or more CActors have to be added to the scene. The function takes a Count parameter (which defaults to 1) which can allow the function to add space for multiple CActor pointers at the end of the array.

Recall that the process of resizing is simply a case of allocating a large enough array and copying over the data from the old array to the new array. The old array can then be deleted and the original pointer can then be assigned to point at the new array. This function returns the index of the first newly allocated element in the array so that the caller can start adding the new information into the array from that point.

```
long CScene::AddActor( ULONG Count /* = 1 */ )
{
    CActor ** pActorBuffer = NULL;

    // Allocate new resized array
    if (!( pActorBuffer = new CActor*[ m_nActorCount + Count ] )) return -1;

    // Existing Data?
    if ( m_pActor )
    {
        // Copy old data into new buffer
        memcpy( pActorBuffer, m_pActor, m_nActorCount * sizeof(CActor*) );

        // Release old buffer
        delete []m_pActor;
```

```
    } // End if

    // Store pointer for new buffer
    m_pActor = pActorBuffer;

    // Clear the new items
    ZeroMemory( &m_pActor[m_nActorCount], Count * sizeof(CActor*) );

    // Increase Actor Count
    m_nActorCount += Count;

    // Return first Actor
    return m_nActorCount - Count;
}
```

CScene::BuildAnimations

The CScene::BuildAnimations function is called at the bottom of both the LoadSceneFromX and the LoadSceneFromIWF functions. Its purpose is to provide the scene class with an opportunity to attach CAnimation objects to various frames stored in the actors. In our demo, this function creates six CAnimations objects and attaches them to the four wheel frames and the two pivot frames.

At the start of the function, we declare an array with six string elements. Each string in this array contains the name of the frame we wish to animate. These are the names of the frame data objects in the X file and the thus, the names of the D3DXFRAME's in the hierarchy of actors we will be searching for.

> **NOTE:** This function will not be a permanent member of our CScene class. It has been added to this lab project only to introduce you to the concept of frame animation, before we cover it in proper detail in the next chapter. Therefore, this function is almost completely hard-coded for the model we are going to use and as such, will not be very useful to you outside of this single project.

In the outer loop, we loop six times. Each iteration of this loop is searching through all frames to find a frame with the given name. For example, in the first iteration of this loop, we are searching all objects in the scene which contain actors with a frame named 'Wheel_FL'. If we find one, we attach the frame's matrix to the CAnimation object (using the CAnimation::Attach function) and we are done with this frame name. Then we continue on to the next iteration of the outer loop.

```
void CScene::BuildAnimations( )
{
    ULONG   i, j;
    LPCTSTR FrameNames[] = { _T("Wheel_FL"), _T("Wheel_FR"),
                             _T("Wheel_BL"), _T("Wheel_BR"),
                             _T("Wheel_Pivot_FL"), _T("Wheel_Pivot_FR") };

    // Search for each of the four wheels
    for ( i = 0; i < 6; ++i )
    {
        // Loop through each object and search
        for ( j = 0; j < m_nObjectCount; ++j )
        {
            CObject * pObject = m_pObject[j];
            if ( !pObject ) continue;
```

```
            // Any actor ?
            CActor * pActor = pObject->m_pActor;
            if ( !pActor ) continue;

            // Any frame by this name ?
            LPD3DXFRAME pFrame = pActor->GetFrameByName( FrameNames[i] );
            if ( pFrame )
            {
                // Attach the animation to this object, and skip to the next wheel
                m_pAnimList[i].Attach( &pFrame->TransformationMatrix, FrameNames[i] );
                break;

            } // End if found frame
            else
            {
                // Clear this interpolator out
                m_pAnimList[i].Attach( NULL );

            } // End if no frame found

        } // Next Object

    } // Next Wheel

    // If wheel yaw has already been applied, set initial rotation to this
    m_pAnimList[ Wheel_Pivot_FL ].RotationY( D3DXToRadian( fWheelYaw ) );
    m_pAnimList[ Wheel_Pivot_FR ].RotationY( D3DXToRadian( fWheelYaw ) );
}
```

If a frame cannot be found, we set the corresponding CAnimation object in the scene's array such that it is not attached to any frame. We do this by passing NULL into the Attach method.

Finally, at the bottom of this function we set the initial steering angle that has been assigned to the wheels. Feel free to set the fWheelYaw variable to an initial angle other than zero if you want the automobile wheels rotated by some amount. Notice that, as discussed earlier, we apply a Y axis rotation to the pivot frames so that both of the car's front wheels are rotated around the car's up vector. Because the CAnimation objects are already attached to their frames at this point, we can simply use their RotationY methods (for the CAnimation objects attached to the pivots) to perform this task.

One thing of interest in the above function is that we are accessing to the two pivot animation objects using Wheel_Pivot_FL and Wheel_Pivot_FR as array indices. These values, as well as the indices for the other frames, are defined in the scene module's namespace, as shown below:

```
namespace
{
    const UCHAR AuthorID[5]       = { 'G', 'I', 'L', 'E', 'S' };
    const UCHAR Wheel_FL          = 0;
    const UCHAR Wheel_FR          = 1;
    const UCHAR Wheel_BL          = 2;
    const UCHAR Wheel_BR          = 3;
    const UCHAR Wheel_Pivot_FL    = 4;
    const UCHAR Wheel_Pivot_FR    = 5;
    float       fWheelYaw         = 0.0f;
    float       fWheelYawVelocity = 1000.0f;
};
```

Until now, only the AuthorID has existed in the namespace -- it was used by the IWF loading function to identify GILES™ custom chunks. Now we have added six Wheel_ members which describe the indices of the CAnimation objects in the scene that use the specified frames. We also have three new members at the bottom. The variable fWheelYaw will contain the current angle at which the pivot frames are rotated (i.e., the angle at which the front wheels are rotated). We saw this variable used in the previous code segment to set the rotation of the wheels. The variable fWheelYawVelocity contains the speed at which the front wheels will rotate left and right. We will see this variable used in a moment, when we examine the CScene::ProcessInput function.

CScene::AnimateObjects - Modified

This function is called by CGameApp::FrameAdvance for each cycle of the main game loop. This function has been a part of this class from the very start and provides the scene a chance to update its object during each frame.

In this version of the function, we rotate the four wheel frames via their matrices so that the car's wheels are continuously revolving around their local X axes. This function rotates the wheels at two revolutions per second (i.e., 720 degrees per second). We calculate the rotation angle for a given call by scaling 360 degrees by the number of revolutions (2) and then multiplying this by the elapsed time since the last frame. This will usually be fractions of a second, scaling the rotation angle for any particular update to only a few degrees. We pass the result of this calculation into the D3DXToRadian function so that we have the rotation angle in radians (required by the CAnimation::Rotation functions).

```
void CScene::AnimateObjects( CTimer & Timer )
{
    float fRevsPerSecond = 2.0f, fRadAngle;

    // Generate wheel frame rotation angle.
    fRadAngle = D3DXToRadian( (360.0f * fRevsPerSecond) * Timer.GetTimeElapsed() );

    // Rotate the wheels
    m_pAnimList[ Wheel_FL ].RotationX( fRadAngle );
    m_pAnimList[ Wheel_FR ].RotationX( fRadAngle );
    m_pAnimList[ Wheel_BL ].RotationX( fRadAngle );
    m_pAnimList[ Wheel_BR ].RotationX( fRadAngle );

}
```

Notice that because we have set up array index variables in the module namespace, we can quickly index into the CScene::m_pAnimList array and call the RotationX function for the correct CAnimation objects.

CScene::ProcessInput – Modified

CScene::ProcessInput is called by CGameApp::ProcessInput, which itself is called by CGameApp::FrameAdvance. The actual trapping of key data and subsequent camera updates are found in the CGameApp:ProcessInput function, as we saw in all previous lessons. When it calls this function,

it passes in an array of all the keys with their up/down state. In this function we are testing for the comma key and the period key, which allow the user to rotate the wheels left or right respectively.

The first thing this function does is check the VK_COMMA and VK_DOT indices of the key array. If either has its top four bits set, then they key is depressed and rotations need to be applied. To provide a smooth deceleration of the wheel when the user lets go of the key, we use the fWheelYawVelocity variable to store the turn velocity. We can think of this value as the number of degrees per second that we wish the wheels to turn left or right. Every time the key is down during this function call, another 400 degrees per second is added to the turn velocity. The velocity can be either positive or negative for left and right steering. If no keys are pressed, then 400 degrees per second is subtracted from the velocity each time the function is called. This allows the wheel rotations a more realistic ramping up/down when the keys are pressed and released.

```
void CScene::ProcessInput( UCHAR pKeyBuffer[], CTimer & Timer )
{
    float fAngle = 0.0f;

    // Apply rotations ?
    if ( pKeyBuffer[ VK_COMMA ] & 0xF0 )
        fWheelYawVelocity -= 400.0f * Timer.GetTimeElapsed();
    else if ( pKeyBuffer[ VK_DOT ] & 0xF0 )
        fWheelYawVelocity += 400.0f * Timer.GetTimeElapsed();
    else
    {
        // Decelerate the yaw
        if ( fWheelYawVelocity > 0 )
            fWheelYawVelocity -= min(fWheelYawVelocity, 400.0f * Timer.GetTimeElapsed() );
        else
            fWheelYawVelocity -= max(fWheelYawVelocity, -400.0f * Timer.GetTimeElapsed());
    } // End if declerate
```

At this point the yaw velocity is scaled by the elapsed time to give us the actual number of degrees we need to rotate the wheels in this frame. Remember, the rotations are being added incrementally. The fWheelYaw member contains the current turn angle of the wheels -- it has the incremental turn angles added to it each time the function is called. We clamp the turn angle to 45 degrees, so if the yaw angle exceeds this amount with the newly calculated incremental angle added to it, we set the yaw angle to –45 or +45 and recalculate the incremental angle to stay within these bounds.

Once the incremental angle has been calculated and clamped, we pass it into the CAnimation::RotationY method of the animation objects attached to both pivots. Since the pivots are defined in the root's frame of reference, a rotation around the pivot Y axis rotates the wheel about the automobile's up vector.

```
    // Get the angle increase for this frame
    fAngle = fWheelYawVelocity * Timer.GetTimeElapsed();

    // Anything applicable
    if ( fAngle != 0.0f )
    {
        // Apply to total yaw and clamp where appropriate
        fWheelYaw += fAngle;
        if ( fWheelYaw >  45.0f )
           { fAngle -= (fWheelYaw - 45.0f); fWheelYaw = 45.0f; fWheelYawVelocity = 0.0f; }
```

```
        if ( fWheelYaw < -45.0f )
           { fAngle -= (fWheelYaw + 45.0f); fWheelYaw = -45.0f; fWheelYawVelocity = 0.0f; }

        m_pAnimList[ Wheel_Pivot_FL ].RotationY( D3DXToRadian( fAngle ) );
        m_pAnimList[ Wheel_Pivot_FR ].RotationY( D3DXToRadian( fAngle ) );

    } // End if any rotation
}
```

If you are a little rusty with this kind of velocity scaling, refer back to Chapter Four where we used a similar technique for our camera movement system.

CScene::Render

The render function is responsible for setting the states and rendering the subsets of all CObjects in the scene. The CObjects can contain both actors and/or meshes, so we must make sure that we take this into account. The reason the scene is responsible for state setting in this application is that we created our actors/meshes in non-managed mode. Most of the following code should be familiar to:

```
void CScene::Render( CCamera & Camera )
{
    ULONG i, j;
    long  MaterialIndex, TextureIndex;

    if ( !m_pD3DDevice ) return;

    // Setup some states...
    m_pD3DDevice->SetRenderState( D3DRS_NORMALIZENORMALS, TRUE );

    // Render the skybox first !
    RenderSkyBox( Camera );

    // Enable lights
    for ( i = 0; i < m_nLightCount; ++i )
    {
        m_pD3DDevice->SetLight( i, &m_pLightList[i] );
        m_pD3DDevice->LightEnable( i, TRUE );

    } // Next Light
```

The function first checks that the device is valid and sets the D3DRS_NORMALIZENORMALS render state to true. This will make sure that even if a mesh or actor world matrix includes a scaling characteristic that would ordinarily scale the normals, no problems with the lighting pipeline will be encountered.

We then render call the RenderSkyBox function to render the skybox mesh (if one exists). This will only be the case if the scene has been loaded from an IWF file and the file contains a skybox entity.

The final section of the above code sets up the lights on the device and enables them. Unlike earlier demos where the light group system was employed, in this demo we are simply setting up the first N lights found in the IWF file. Alternatively, if we are loading the scene straight from an X file, four direction lights are hard-coded and set up as we saw earlier.

Why are we setting the same lights each time the render loop executes if they never change? The reasons are twofold. First, if you decide to integrate the light group system into this demo yourself, you will absolutely need to set and unset the lights belonging to each light group before rendering its assigned polygons. Second, this approach allows you to place code in the scene class that might dynamically change the light properties. By setting the light properties each time, we make sure that any dynamic changes to a light slot's properties will be reflected in the next render.

The next section of code contains the significant changes from previous implementation of CScene. We render our scene by looping through each CObject in the scene object array. For each object we check its CTriMesh pointer and its CActor pointer to see which are valid. This will tell us whether the object contains a single mesh or an actor encapsulating a complete mesh hierarchy. If the mesh pointer is valid then we set the object's world matrix and FVF flags on the device. If the actor pointer is valid then we pass the object's world matrix into the CActor::SetWorldMatrix function. Earlier we saw that by passing true for the second parameter (as in this case) the hierarchy will be traversed and the absolute world matrices for each frame in the hierarchy will be generated. At this point, either the mesh or the actor is ready to be rendered.

```
    // Process each object
    for ( i = 0; i < m_nObjectCount; ++i )
    {
        CActor    * pActor = m_pObject[i]->m_pActor;
        CTriMesh * pMesh  = m_pObject[i]->m_pMesh;
        if ( !pMesh && !pActor ) continue;

        // Set up transforms
        if ( pMesh )
        {
            // Setup the per-mesh / object details
            m_pD3DDevice->SetTransform( D3DTS_WORLD, &m_pObject[i]->m_mtxWorld );
            m_pD3DDevice->SetFVF( pMesh->GetFVF() );

        } // End if mesh
        else
        {
            // Set up actor / object details (Make sure we update the frame matices!)
            pActor->SetWorldMatrix( &m_pObject[i]->m_mtxWorld, true );

        } // End if actor
```

Because the scene is using its meshes and actors in non-managed mode, we must now loop through every global subset in the scene's ATTRIBUTE_ITEM array, fetch the texture and material for that subset, and set them on the device. If a subset contains no material, then a default material of bright white is used. If a subset has no texture, then the texture stage is set to NULL and the subset will be rendered in shaded mode only.

With the states set, we call either CTriMesh::DrawSubset or CActor::DrawSubset to render the given subset depending on which type of object we are processing.

```
        // Loop through each scene owned attribute
        for ( j = 0; j < m_nAttribCount; j++ )
        {
            // Retrieve indices
```

```
            MaterialIndex = m_pAttribCombo[j].MaterialIndex;
            TextureIndex  = m_pAttribCombo[j].TextureIndex;

            // Set the states
            if ( MaterialIndex >= 0 )
                m_pD3DDevice->SetMaterial( &m_pMaterialList[ MaterialIndex ] );
            else
                m_pD3DDevice->SetMaterial( &m_DefaultMaterial );

            if ( TextureIndex >= 0 )
                m_pD3DDevice->SetTexture( 0, m_pTextureList[ TextureIndex ]->Texture );
            else
                m_pD3DDevice->SetTexture( 0, NULL );

            // Render all faces with this attribute ID
            if ( pMesh )
                pMesh->DrawSubset( j );
            else
                pActor->DrawActorSubset( j );

        } // Next Attribute

    } // Next Object

    // Disable lights again (to prevent problems later)
    for ( i = 0; i < m_nLightCount; ++i ) m_pD3DDevice->LightEnable( i, FALSE );

}
```

As we know, CTriMesh::DrawSubset simply wraps a call to the ID3DXMesh::DrawSubset function, instructing the underlying mesh to render its subsets. If the object contains an actor then CActor::DrawSubset is called and this function does a lot more work. We examined this function earlier and saw how it traverses every frame in the hierarchy and searches for frames that have mesh containers attached. For each one found, the frame's world matrix is set as the device world matrix and then CTriMesh::DrawSubset is called for each mesh attached to that frame. This will cause all matching subsets in all meshes contained in the hierarchy to be rendered.

Finally, we disable all of the lights at the end of the function. While this is not strictly necessary in our current demo, it does allow us to safely animate or even delete lights from the scene's light array if we wanted to. This step makes sure that if a scene's light is deleted, that its properties will not continue to be used by the light slot is was previously assigned to.

CScene::ProcessReference

Before wrapping up this workbook, we will examine the modified CScene::ProcessReference function, which now handles creating actors from IWF file external X file references.

As usual, the scene uses the IWF SDK classes to load data from IWF files and then calls various functions (ProcessMeshes, ProcessMaterials, ProcessVertices, etc.) to extract the data from the IWF SDK objects and copy it into its own arrays. Recall that the ProcessEntities function is called to process any entities stored in the IWF file and this function in turn called the ProcessReference function if an entity being processed was a GILES™ reference entity. The ProcessReference function was

implemented in the previous workbook to extract the filename of an external reference and use it to load a CTriMesh and add it to the scene. Now, this function (while mostly unchanged) creates a CActor from the reference filename instead.

We will not dwell long on this function since much of the actor creation and setup is the same as the CScene::LoadSceneFromX function which we have already covered.

The first section of the function checks that this is an external reference before continuing. It then builds the filename string used to create the absolute filename (with path) for the X file being loaded. The IWF ReferenceEntity object only contains the name of the X file and does not include path information (for obvious reasons). We do this by adding the entity name to the path name stored in the scene's m_strDataPath string. This data path was stored in this string in the LoadSceneFromIWF function by truncating the absolute filename passed in.

```
bool CScene::ProcessReference( const ReferenceEntity& Reference,
                               const D3DXMATRIX & mtxWorld )
{
    HRESULT   hRet;
    CActor  * pReferenceActor = NULL;

    // Skip if this is anything other than an external reference.
    // Internal references are not supported in this demo.
    if (Reference.ReferenceType != 1) return true;

    // Build filename string
    TCHAR Buffer[MAX_PATH];
    _tcscpy( Buffer, m_strDataPath );
    _tcscat( Buffer, Reference.ReferenceName );
```

We will not immediately load the actor (like we do in the LoadSceneFromX function) because the IWF file might contain multiple instances of the same actor in the scene. So, first a search is done through the scene's CActor array to see if an actor exists with a matching name. If one is found then we will use this pointer, otherwise, we will need to create a new CActor, register the scene callbacks and load the file:

```
    // Search to see if this X file has already been loaded
    for ( ULONG i = 0; i < m_nActorCount; ++i )
    {
        if (!m_pActor[i]) continue;
        if ( _tcsicmp( Buffer, m_pActor[i]->GetActorName() ) == 0 ) break;

    } // Next Actor

    // If we didn't reach then end, this Actor already exists
    if ( i != m_nActorCount )
    {
        // Store reference Actor.
        pReferenceActor = m_pActor[i];
    }   // End if Actor already exists
    else
    {
        // Allocate a new Actor for this reference
        CActor * pNewActor = new CActor;
        if (!pNewActor) return false;

        // Load in the externally referenced X File
```

```
        pNewActor->RegisterCallback(CActor::CALLBACK_ATTRIBUTEID,CollectAttributeID,this );
        hRet = pNewActor->LoadActorFromX( Buffer, D3DXMESH_MANAGED, m_pD3DDevice );
        if ( FAILED(hRet) ) { delete pNewActor; return false; }

        // Store this new Actor
        if ( AddActor( ) < 0 ) { delete pNewActor; return false; }
        m_pActor[ m_nActorCount - 1 ] = pNewActor;

        // Store as object reference Actor
        pReferenceActor = pNewActor;

    } // End if Actor doesn't exist.
```

At this point, the local variable pReferenceActor is pointing to the actor we need. This will either be a new actor we have just loaded or a pointer to an actor that already existed in the scene's CActor array.

Our final task is to add a new CObject to the scene's object array and store this actor pointer in it. As it happens, IWF references also contain a world matrix describing where the reference is situated in the scene, so we can copy this matrix from the reference object into the CObject as well.

```
    // Now build an object for this Actor (standard identity)
    CObject * pNewObject = new CObject( pReferenceActor );
    if ( !pNewObject ) return false;

    // Copy over the specified matrix
    pNewObject->m_mtxWorld = mtxWorld;

    // Store this object
    if ( AddObject() < 0 ) { delete pNewObject; return false; }
    m_pObject[ m_nObjectCount - 1 ] = pNewObject;

    // Success!!
    return true;
}
```

Conclusion

In this lab project we put in place the foundations of a very useful class called CActor, which we will see used repeatedly throughout the rest of this course. This will be true in next chapter when we cover hierarchical animation and in the following chapters when we cover skinning and skeletal animation. The CActor class is a very welcome addition to our toolkit and it will make our job a lot simpler from here on in.

While we lightly touched on hierarchical animation in this chapter, the next chapter will be devoted entirely to this subject. We will learn how to use the D3DX animation controller to load complex keyframed animations that can be blended with other animations and applied to our hierarchy. These techniques will then be carried into later lessons where the animation controller will be used to animate the skeletal system of game characters and other dynamic entity types. Be sure that you understand how our hierarchy (and CActor) system works before moving on, since it is the core of just about everything we will do in the next few lessons.

Chapter Ten

Animation

Introduction

To date our coursework has focused primarily on the three dimensions of physical space. We looked at how to build, position, and orient models in a 3D world so that we can take a snapshot of the scene and present it to our player. But there is also a fourth important dimension that we have looked at only briefly: time. Time is the dimension introduced when animation becomes a part of our game design.

To animate something means literally to "give life" to it. This is clearly an important concept in computer games. Of course, most of our lab projects have included animation in one form or another. From the spinning cubes back in Chapter One to the movement of our player/camera through the world as the result of user input, we have had a degree of animation in almost all of our demos. In this lesson we will look at some of the more traditional animation concepts that one thinks about when working with 3D computer graphics.

In today's 3D computer games, being able to animate 3D models and scenes in a controlled or pre-recorded way is absolutely essential. We will see later in the course how animated characters in computer games will have many pre-recorded animations that our application can select and playback at runtime in response to some game event. For example, a character might include pre-recorded animations for walking and running so that as it travels from point A to point B in the world, it looks correct while doing so. There may also exist pre-recorded animations of several death sequences for the character that can be played back by our application in response to the character's health falling below zero. We would also need animations to play when character itself is firing its weapon, etc.

Most of the difficult work of building and capturing animation data is the domain of the project artist, modeller, and animator. Most popular 3D modelling packages include tools to animate 3D models and export that data. As programmers, our job will focus on integrating the results of their efforts into our game engine. Our only real requirement is that the data be delivered in a format supported by the engine we have designed. In this particular lesson, that format will be the X file format. Fortunately, most commercial modelling programs support the export of animated scenes to the X format, either natively or through the use of a plug-in. Those of you who are fortunate to own or have access to high-end programs like 3D Studio Max™ and Maya™ will indeed have a great opportunity to design and export complex animations. There are also excellent packages like Milkshape3D™ that are a more cost-effective solution for the hobbyist, that still offer a wealth of animation and export options.

> **Note:** Our focus in this lesson will be on working with pre-recorded animation sequences that are created offline by our project artist. However, it should be noted that there are also animation techniques that can be calculated procedurally at runtime to produce certain interesting behaviours. These techniques (such as inverse kinematics to cite just one example) will be explored later in this course series.

Real-time animation is such an integral part of today's videogame experience. Not so many years ago, video games would typically play pre-recorded movie clips called 'cut-scenes' at key points in the game to help move the storyline forward. While the quality of those cut-scenes generally exceeded the in-game graphics quality, there were a number of criticisms that followed from their use. First, they would often be associated with large load times which would destroy the sense of immersion and game flow.

Perhaps more importantly, the player was transformed from being a participant in a 3D world where they had total freedom of movement, to passively watching non-interactive slide shows or movies.

In modern games, given that the hardware they run on has more dedicated processing power for graphics and animation, cut-scenes are commonly played out using the actual game engine. This allows them to become an integral part of the game experience, where in-game story events can happen on the fly without the need to cut away and make the player idly watch. Player immersion is preserved and the world feels much more real. Players can often continue to move about the world even while these scripted events are playing out. If you load in Lab Project 10.1 you will see a very simple pre-scripted animation of a spaceship taking off and flying into the distance. While this is the simplest of examples as far as such things go (normally such events are triggered as part of an evolving storyline), the point is that you are still allowed to move freely around the world while the sequence plays out around you. Imagine that just prior to the ship taking off, your squad mate informed you that he would commandeer the ship and meet you at the rendezvous point. Then you watched him jog off into the distance under heavy fire, board the ship, and take off for deep space. All the while, you were laying down covering fire for him as he made his way across the dangerous killing field. While our demo is not nearly as exciting, you can certainly imagine such a sequence taking place in a commercial game. Modern 3D game titles are littered with these small but often critical sets of scripts and animations and they are vital to making the 3D world feel more realistic. But even when this is not the case and a game actually cuts away and the player must simply passively watch the sequence, using the in-game graphics engine provides a sense of consistency that keeps the player immersed in the world.

Finally, it is worth noting that it is much more efficient to store scripts and animations for the game engine (the animations are generally built from simple translation and rotation instructions that can be interpolated -- more on this shortly) than it is to store full motion video sequences at 30 frames per second. Such videos can consume significant disk space, and require important processor time especially if used frequently.

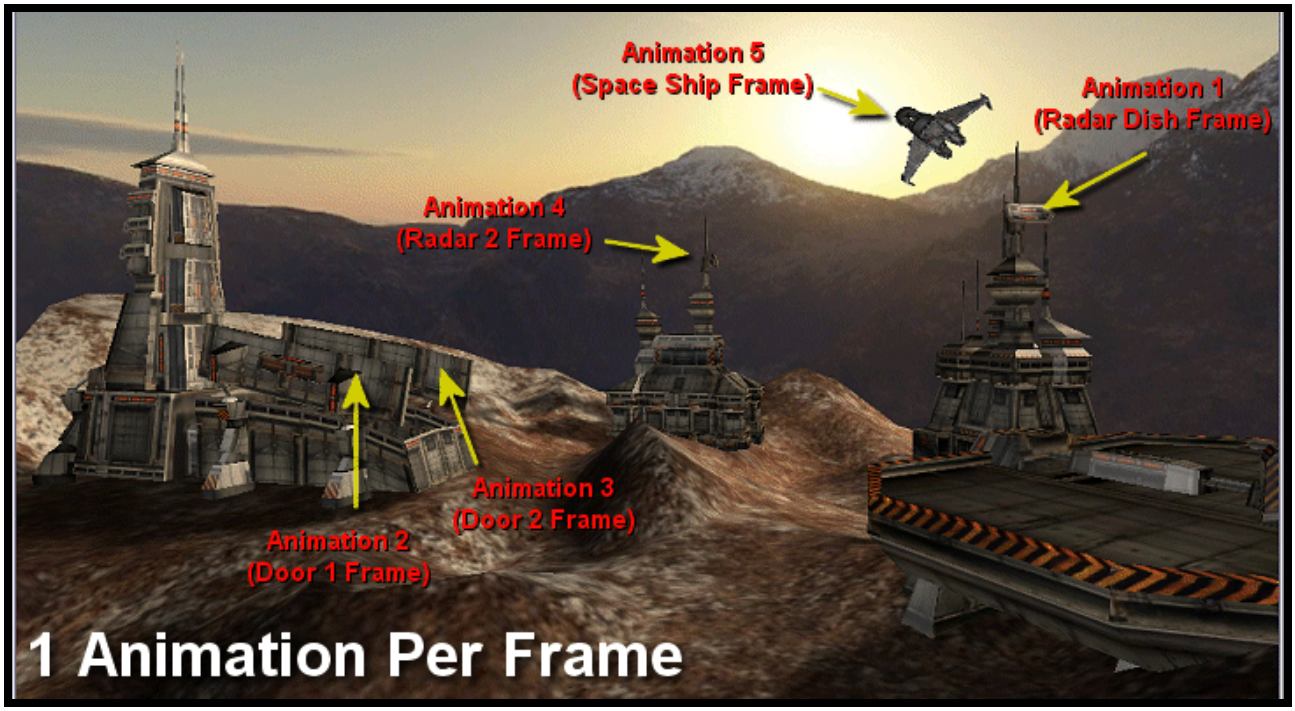
10.1 Basic Animation

Before we examine the underlying mechanisms of the DirectX animation system, it will be encouraging to take a quick look at how easy it is to load a hierarchical X file that includes animation data and then play that animation in our game engine. D3DXLoadMeshHierarchyFromX allows us to load hierarchical X files that include animation, so we are already on the right track. The final parameter we pass to the function is the address of a pointer to an ID3DXAnimationController. If the file contains animation data, then this pointer will ultimately be used to access, manipulate, and play those stored sequences. If the file contains no animation data, then this pointer will be set to NULL on function return. With this in mind, let us see how we would load an animated X file. In many ways this next code snippet brings together everything that we have learned so far:

```
CAllocator Allocator;
D3DXFRAME * pRootFrame = NULL;
ID3DXAnimationController * pAnimController = NULL;
D3DXLoadMeshHierarchyFromX( “MyScene.x”, D3DXMESH_MANAGED, pD3DDevice, &Allocator,
                            NULL, &pFrameRoot, &pAnimController );
```

The animation data stored in the X file will be used to manipulate the values stored in the hierarchy frame matrices. When loaded by D3DX, each frame in the hierarchy that the artist decides to animate will have attached an **Animation Data Set** that contains a set of animation information for a single frame in the hierarchy. You should recall our earlier theoretical discussion about frame animation in the Chapter Nine -- our CAnimation object simply applied a rotation to the frame to which it was attached. But we are already familiar with the concept of these objects being attached to frames in the hierarchy and being responsible for managing their animation. While D3DX does not create a separate object to contain the animation data for a single frame in the hierarchy, we can think of the animation data for each frame as being a packet of animation data that is assigned to an animation set and registered with the animation controller. For example, if the file contains a single animation set that animated 10 frames in the hierarchy, D3DX would create an animation set object that contained 10 packets of animation data, one for each frame. Each packet is also assigned a name that matches the name of the frame to which it is assigned and to which its animation data applies. This name is also referred to as the name of the Animation. Therefore, in DirectX terminology, when we discuss an 'Animation' we are referring to a set of animation information linked to a single frame in the hierarchy and contained inside an animation set.

Lab Project 10.1 provides a basic demonstration of animating a scene hierarchy. It includes a small animated spacecraft, a pair of hanger doors that open and close, and rotating radar domes on two of the buildings. The entire scene is stored as a single hierarchy, but only certain frames include attached animations. There are in fact, five animations in total: one for each animated frame in the scene. Static frames do not have animations created for them. The five animations in this scene were all created by D3DXLoadMeshHierarchyFromX automatically when we loaded the X file. An animation set was created and the five animations were added to it. The animation set was then registered with the animation controller so that on function return, our application can start playing the animation(s) immediately.



At a high level, the animation controller returned from the D3DXLoadMeshHierarchyFromX function is like an **Animation Set Manager**; it stores all of the animations found in the X file (in one or more animation sets) and manages communication between them and the application. When the application wants to advance the global timeline of the animated scene, we instruct the animation controller via its AdvanceTime method. The animation controller in turn relays this timeline update to each of its currently active animation sets. Each animation set is a collection of frame animations. Each frame animation stored in the animation set is used to generate the new matrix for the frame to which it is attached for that position in the timeline. In short, with a single call to the ID3DXAnimationController::AdvanceTime function, all active animation sets update the frame matrices for which they have animations defined.

> **Note:** While the first part of this lesson will focus on populating the D3DX animation system with animation data stored in X files, we will see later that D3DX provides the ability to construct all the frame interpolators, animation sets and the animation controller manually. This would allow an application to import data from any file format into the D3DX animation system. This would be done by manually attaching animations to the various frames in the hierarchy and registering them with animation sets on the animation controller. We will discuss how to manually build the components of the D3DX animation system later.

While the techniques for creating simple animated scenes vary from application to application, one concept remains universal: **the animation timeline**. Every animation package includes a timeline where transformations or other types of events can be placed in chronological order. These events are called *keyframes* and they represent the most important transitions that must take place at particular moments in time. Time itself can be measured in seconds or milliseconds or by the more arbitrary timing method of 'ticks'. When D3DX loads animation sets from an X file, every animation set will include its own animation timeline. Therefore, while our application will be advancing a single global time via the ID3DXAnimationController::AdvanceTime method, each animation set has its own local timeline which the animation controller takes care of updating. The length of an animation set's timeline (also referred to as its *period*) is equal to the length of its largest defined **animation**. Remember that an **animation** is a set of animation data for a single frame in the hierarchy.

> **Note:** As the D3DX loading functions load their animation data from the X file format, it is important that you install the appropriate 'X file Exporter Plug-in' for your chosen 3D modelling application. 3D Studio Max™ is a very popular choice for artists and modellers, so if this is your chosen application then you are in luck since there are a couple to choose from. While the DirectX9 SDK ships with an 'X File Exporter' plug-in for 3D Studio Max™, you are provided with only the source code. This means you must compile the plug-in yourself, which comes with its own set of problems as discussed in Chapter 8. Luckily, there are some very good 3rd party X file exporters for MAX (one called 'Panda X File Exporter' which is freely available is worth investigating). There are also exporter plug-ins available for other popular programs, such as Maya™ and Milkshape™ for example.

Each animation set will have been defined by the artist using its own local time. As several animation sets may be playing at once, each of which may have different durations (periods), the ID3DXAnimationController::AdvanceTime is used to calculate and mix the local animation timelines using a single global time. For example, Animation Set 1 may have a duration of 10 seconds, while Animation Set 2 may have a duration of 30 seconds. If both of the animation sets were created to be looping animations (more on this in a moment), then their timelines will wrap back around again to the beginning when the global time of the animation controller exceeds their local time. If the global time of the animation controller was at 35 seconds, at which periodic position on their local timelines would

each of the above animation sets be? Animation Set 1 would be 5 seconds into its local timeline and Animation Set 2 would also be 4 seconds in. Why? Consider the wrapping property of the animation sets. At 35 seconds, Animation Set 1 (which only lasts of 10 seconds) would have wrapped around three times and would now be on the fifth second of its fourth payback. Animation Set 2 which lasts for 30 seconds reached the end of its timeline 5 seconds ago, so now has a local periodic position of 5 seconds into its second playback.

Updating the animation sets and instructing them to rebuild their associated frame matrices is actually quite simple. The ID3DXAnimationController interface includes a method called AdvanceTime which serves as the main update function for the animation controller and all its underlying animation sets. The application will pass in a value in seconds that represents the *elapsed* time (i.e., the time since the last call to AdvanceTime) that we would like to use to progress the animation controller's global timeline. This value is passed on to each animation set in the scene so that their local timelines are updated, and wrapped if necessary. After an animation set timeline update, the animation set will loop through each of its stored animations and use their data to re-build the frame matrices assigned to them from the hierarchy.

The following code shows a simple game loop that cycles the animation:

```
void GameLoop( float ElapsedTime )
{
      pAnimController->AdvanceTime( ElapsedTime );
      RenderFrame( pRootFrame, NULL );
}
```

The GameLoop function would be called every frame and is passed the amount of time (in seconds or fractions of a second) that has passed since the last render. The call to ID3DXAnimationController::AdvanceTime updates the controller's global time and also passes the elapsed time along to each of its animation sets so that their local timelines are also advanced. Each animation set will use this new local time to perform a look up in its list of stored animations. Each animation (which stores animation keyframes for a single frame in the hierarchy) will be used to calculate what the matrix for the assigned frame should look like at the specified time. When the function returns, all of the animations stored in the animation set will have updated the matrices of their attached frames in the hierarchy.

> **Note:** It is important to emphasize that time drives the animation loop. This is critical to maintaining smooth animation independent of frame rate. While it might seem easier to simply increment a frame counter for controlling animation, it is much more risky given the different speeds your game will run on different hardware. Locking the frame rate can minimize the problems, but that is not usually a desirable method as it imposes a limitation you probably do not want. Nor can you count on all hardware even meeting your minimums. Since the animation sequences in modelling packages are based on time, the engine should be as well. This is certainly easy enough to accommodate, so do not try to cut corners here.

Now all we have to do is render the hierarchy. As we saw earlier, this involves stepping through the hierarchy, combining the relative matrices as we go. Any of these relative frame matrices that have had animations assigned (in an active animation set) will have been updated at this point, so the changes will automatically affect all child frames and meshes. For example, if we were to apply a rotation animation

to the root frame, although there would be only a single animation in the animation set currently being played, and the AdvanceTime method would only affect one matrix directly (the root matrix), the entire frame hierarchy will rotate because all child matrices are relative transformations. When we build the world matrices for each frame during the traversal and matrix concatenation process (i.e., the update pass), these changes would be reflected down through all children. So essentially, by advancing the global animation time via the animation controller, we are simply instructing all contained animations to update their attached frame matrices to reflect what the position and orientation of the frame should be at this time. Remember, it is the relative frame matrices that are updated -- the ones that were loaded from the X file. We still have to generate the world matrices for each frame using the standard traversal and concatenation technique, after these relative matrices have been updated.

As discussed earlier, it is often preferable to separate our rendering logic into an update pass and a drawing pass. Recall that this involved maintaining a local copy of the world matrix for each frame that is updated as the hierarchy is traversed. We can modify our previous GameLoop function to accommodate this strategy very quickly:

```
void GameLoop( float ElapsedTime )
{
      pAnimController->AdvanceTime( ElapsedTime );
      UpdateHierarchy( pRootFrame, NULL );
      RenderHierarchy( pRootFrame, pCamera );
}
```

It is worth noting that the example GameLoop function above does not bother wrapping around the global animation time value but simply continues to advance it. As it happens, if the animation sets have been created such that they should loop, it will automatically take any value that is out of bounds and turn it into a time within its animation set's timeline based on the length of the animation set. For example, if we have an animation set that runs for 15 seconds (i.e., its longest animation runs for 15 seconds) and the global time of the animation was currently at 18 seconds, it would be treated as 3 seconds into the second animation loop. A value of 31 would be treated as 1 second into the third loop of the animation, and so on. If your animation sets are not configured to loop then you might not want to continue increasing the global time of the animation controller. Instead you might want to reset it back to zero when it gets too large. This will allow the non-looping animations to play again when the global time restarts at zero.

The DirectX animation system underwent significant change in the 2003 summer update of the SDK. Previously, individual animations (formerly called Interpolators) within an animation set also had their own local timelines. This third time layer was extremely useful as it meant that you could have several animations within an animation set, all with different durations and independent looping capability. This was arguably more convenient, but perhaps this third layer of individual animation independence was slowing down the entire system. This could potentially justify its demise. However, because individual animations within an animation set are now just 'dumb' animation data containers for frames in the hierarchy, the artist will often have to make sure that all animations assigned to a given animation set last for the same duration. This is because the animation set's local timeline only wraps around when the end of its period is reached (its period is the duration of its longest running animation). When the 2003 summer update was released, the assets for Lab Project 10.1 had to be completely rebuilt. Initially, the five animations in our space ship scene were all part of the same animation set. The radar dish

animations only lasted a short period of time compared to the length of time it took the spaceship to take off and fly away into the distance. We can see from watching the scene that the radar dishes will rotate many times during this sequence. Previously, it did not matter that the radar dish animation did not last as long as the space ship animation because although they belonged to the same animation set, the animations themselves had their own loop-capable timelines. Once the radar dish had finished one complete cycle, it would just wrap around and do it again. This support has now been removed from DirectX 9 and there is no per-animation timeline concept anymore. To upgrade our assets, we had to insert extra animation data for the radar dishes (adding extra rotations implicitly) so that the duration of every animation lasted as long as the flying ship. All animations now have the same duration, which is equal to the duration of the animation set to which the animations belong. One might argue that this was not exactly a change for the better, but so it goes.

So at its simplest, rendering an animated X file scene involves only one additional function call (ID3DXAnimationController::AdvanceTime). Very often, this may be all your application needs to do. Of course, the D3DX animation subsystem is much more sophisticated than this and includes many additional interfaces and function calls. But we can see now that including pre-generated animations in our existing game engine is actually quite an easy thing to do.

The remainder of our chapter will cover the D3DX animation interfaces and the functionality they expose. We will soon see that the ID3DXAnimationController has much more depth than we saw in this section. While it can be used in the very simple way we just learned, where the entire scene was animated using just one function call, it can also be used to produce animation techniques of great complexity.

10.2 Keyframe Interpolation

Animation is a time-driven concept. We know that each frame in our hierarchy can be assigned its own animation which maintains a timeline of animation information for that frame. Along the timeline at specified intervals are keyframes which store transformation information such as position, rotation, and scale. This is a very efficient way to store animation. By interpolating the transformation data stored in the keyframes at runtime, we are able to dynamically generate our animation data (a frame matrix) for any given moment in the game. This means that we will not need to store a copy of the scene data in every possible position/orientation along the timeline; we simply need a handful of stored keyframes that represent the important ‘poses’ along the timeline. This saves a lot of storage space, and certainly makes the artist’s life much easier. Animation data is stored in an X file (and in most modelling files) as keyframes.

> **Note:** Understanding how keyframe animation works is simpler if you know how to create the data in a modelling package. A small tutorial on how to create animation data in a 3D modelling package can be found in Appendix A. It would be helpful if you read this short tutorial before continuing.

Let us now spend a little time discussing keyframes in more detail and how the D3DX animation controller will use them to generate animation data at runtime.

One of the earliest forms of animation was the flipbook. A flipbook contains a collection of pages, each with a drawing that is slightly altered from the previous page, such that when we rapidly flip the pages from front to back or vice versa, the drawing appears to animate.

Let us imagine a 100 page flipbook containing an animation of a ball rolling along the ground from left to right. On page 1 the ball is at its furthest point left, and on page 100 the ball has been drawn at its far right position. For all pages in between, the ball is drawn such that it moves further to the right as the page number increases.

If someone were to ask you to guess the position of the ball on an arbitrary page in the book, your guess would probably be reasonably correct. On page 50, you would know that it should be equidistant from its start and end positions. On page 25, it would be about 25% of the way from its start position with about 75% of the path left to traverse. We can make these assumptions because we know in advance that the animation is designed to represent a linear translation between two known locations over a known number of pages (assuming a constant speed of course).

Now imagine that we rip out all of the pages except the first and last pages. Do you think that you could fill in the images on the 98 missing pages by hand? Of course you could. This is because you know where the ball needs to be on any given page.

Keyframes are essentially like the first and last pages in the flipbook. They tell us the state of an object at a given point in an animation sequence. Once we know the starting state and ending state, it just becomes a case of filling in the gaps.

Let us think of this example in the context of our animation controller. Our hierarchy will contain a single frame (call it BallFrame) with an attached animation. The animation would store two keyframes. The first keyframe would describe the starting position of the ball frame and the time at which the ball should be placed at this position. Since this is the start keyframe, the time will be zero. The second keyframe would contain the end position for the ball and the time at which the ball should reach this position. Let us say for example that animation will last 20 seconds. So keyframe 2 will have a timestamp of 20.

> **Note:** This is a simple example for the purposes of explaining the concept. A keyframe's timestamp is not normally stored explicitly as seconds, but is usually stored using a measurement of time with a higher granularity. This can actually be an arbitrary time unit as we will see in a moment. Either way, D3DX will take care of loading this data in so that we can specify our time in seconds in the 'AdvanceTime' method of the ID3DXAnimationController interface.

Now, let us say we were to call ID3DXAnimationController::AdvanceTime with a value that would advance the global timeline of the controller to 15 seconds. Let us also assume that the animation set's local timeline is also set at 15 seconds. For each animation contained within an animation set, we can locate the two keyframes that most closely bound the passed time (i.e. the closest keyframes to the left and right of the current time on the timeline). In this simple example, we will say there are only two keyframes describing a position at 0 seconds and a position at 20 seconds. These are the start and end positions of our 'rolling ball' flipbook analogy. We know that in this case the two keyframes that are closest to either side of the passed time (15 secs) will be the start keyframe (0 secs) and the end keyframe (20 secs).

With the bounding frames located, the animation set will now use the passed time to linearly interpolate between the translation values stored in the keyframes. This will determine exactly where the ball should be at 15 seconds. Next we see a very simple example of what the animation set might do to calculate the position of an animation called 'Ball_Animation' at 15 seconds. For reasons of clarity we are referencing the animation data for 'Ball_Animation' as if it is a C++ object. In reality, it would just be an array of keyframes stored in the animation set assigned the name 'Ball_Frame'.

```
PassedTime = 15.0;

D3DXVECTOR3 StartPos = Ball_Animation.KeyFrame[0].Position;  // Position at 0 seconds
D3DXVECTOR3 EndPos   = Ball_Animation.KeyFrame[1].Position;  // Position at 20 seconds

float s  =  PassedTime – Ball_Animation.KeyFrame[0].Time;
      s /= ( Ball_Animation.KeyFrame[1].Time – Ball_Animation.KeyFrame[0]Time);

CurrentPosition = StartPos + (s * (EndPos - StartPos));
```

In reality, when the current position is calculated, it would be placed inside the frame matrix that the ball animation is attached to. We do not have to implement any of this code, as it is all handled by the D3DXAnimationSet object contained inside the animation controller. We are currently just trying to get a better feel for how the whole system works.

What if we wanted the ball in our example to jump up in the air somewhere around the middle of the animation? Not a problem. More complex animations simply require more key-frames, every subsequent pair of which describes a single transition between events. To create the jump effect, we could use the keyframes seen in Fig 9.6.

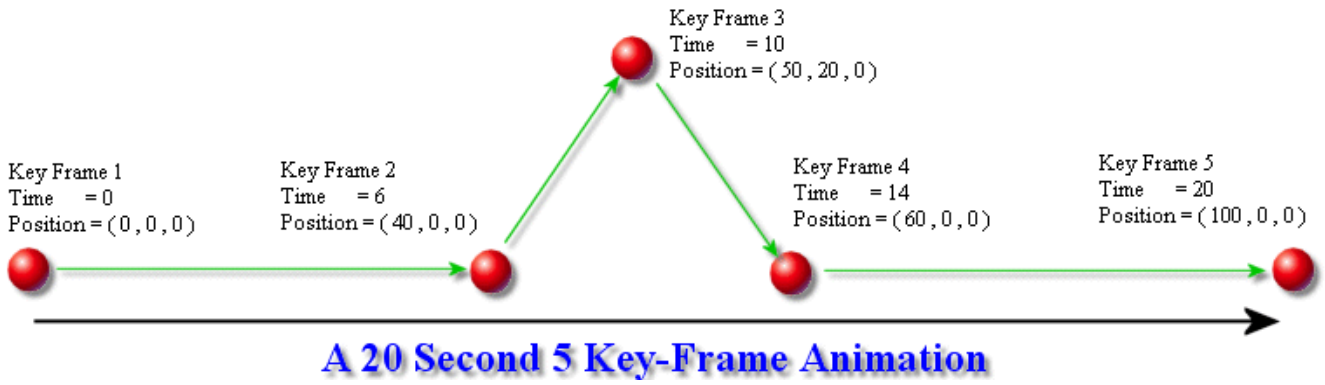


Figure 9.6

Using the example in Fig 9.6, let us think about what will happen if we passed in an elapsed time of 8 seconds.

First the animation set would find the two bounding keyframes for this time. Since we passed in a time of 8 seconds, the two bounding keyframes would be keyframe 2 and keyframe 3 at 6 and 10 seconds respectively. We would then use the passed time to linearly interpolate between the two positions.

```
D3DXVECTOR3 KeyFrameAPos  = ( 40 , 0 , 0 );   // Low Closest Key Frame '2'
float       KeyFrameATime = 6;

D3DXVECTOR3 KeyFrameBPos  = ( 50 , 20 , 0 );  // Higher Closest Key Frame '3'
float       KeyFrameBTime = 10;

float       PassedTime  = 8 ;       // The time out application requested

float s =  PassedTime – KeyFrameATime;       // = 2
      s /= (KeyFrameBTime – KeyFrameATime);  // = 2 / ( 10-6 ) = 0.5

Current Position  = KeyFrameAPos + ( s    *  (KeyFrameBPos – KeyFrameAPos );

            // = ( 40 , 0 , 0 )  + ( 0.5  *  ( 10 , 20 , 0 ) );
            // = ( 40 , 0 , 0 )  + ( 5 , 10 , 0 );
            // = ( 45, 10 ,0 )
```

The final position calculated would place our ball exactly half way along the green direction vector between keyframes 2 and 3 in the diagram.

So far we have looked only at translation-based animation examples, but often, animations will contain rotation and scaling sequences as well. The concepts are identical in these cases -- scaling will also use a linear interpolation approach (just like we saw with translation key frames) while rotations (stored as quaternion keyframes) will use a spherical linear interpolation (i.e. slerp) to accomplish the same objective. While these are the only keyframe types that D3DX supports in its animation controller, you could certainly use keyframes to manage other types of events in your engine. In Module III of this course series for example, we will process a set of keyframes that store color and transparency events for animating particles.

D3DXAnimationSets can store their keyframe data for a given animation in two storage styles. The first style uses separate lists for the individual transformation types (translation, rotation, or scaling). This is referred to as the SRT storage model (**S**cale**R**otate**T**ranslate). There is a list of scale vectors, a separate list of translation vectors and a list of rotation quaternions describing all the scale, translation and rotation keys assigned to that single animation respectively (the SRT for a single hierarchy frame). Every instruction in each list is assigned the time at which the instruction should be applied to the attached frame. Keyframe interpolation has to be done for each list in isolation (for times in between keyframes) to generate a final scale, position and orientation which are used to update the attached frame matrix. This is referred to as *SRT interpolation*. In the animation controller, an animation is really just a list of keyframes (usually in SRT format) and a frame name describing the name of the frame to which the keyframes are applied.

The second storage style uses a single list of 4x4 matrices that represent the combination of all three transform types. In this format, each animation is stored as a single list of matrix keys along with their assigned times. When this time is reached in the animation set's local timeline, the corresponding matrix will become the frame matrix to which it is attached. For times in between keyframes, the two matrices that most closely bound the desired time will be used to interpolate a new matrix that will be used instead.

While it may seem more convenient to store animations as a single list of matrix keys, there are times when storing matrix keyframes is less than ideal (we will discuss this later). As programmers, the choice of whether each animation's keyframes are stored as matrix keys or as separate scale, rotation and translation keys (SRT Keys) is usually out of our hands. We have to adapt our approach according to how that data is stored in the X file. The modeler or artist who created the X file may well have a choice when exporting their data to X file format as to which keyframe data format they prefer, so if you have preference for your engine, it is best to let them know in advance.

Once we know how the keyframe animation data is stored in an X file, things will start to make a lot more sense. Let us explore that concept in the next section.

10.3 X Files and Animation

Animation data is stored in an X file using three standard templates. We will look at each in turn.

The first template we will study is the **Animation** template, which manages the keyframe data for a single frame in the hierarchy. When the D3DX loading function encounters an Animation data object, it will create and add a new animation to the animation set currently being constructed. The animation itself (which is just an array of keyframes) will be populated by the keyframes specified in the Animation data object in the X file. Therefore, the Animation data object in an X file is analogous to an 'Animation' in the D3DX animation system. The X file Animation data object will contain one or more **AnimationKey** child data objects that store the actual keyframe data. There will also be a child data reference object which is the name of the frame in the hierarchy for which this keyframe data applies.

Using our automobile example from the last chapter, let us assume that our artist has applied rotation data to the wheels. In this case there would be four Animation data objects in the file -- one for each wheel frame in the hierarchy. D3DX would create an animation set with four animations. Each animation would be attached to a wheel frame.

The Animation template is an open template defined in DirectX as follows:

```
template Animation
{
      <3D82AB4F-62DA-11cf-AB39-0020AF71E433>
      [...]
}
```

The first thing an object of this type will need is the name of the frame in the hierarchy that it animates. For example, in our bouncing ball example we might give the frame that stores the ball the name 'Ball_Frame'. We would embed this name in the Animation object in the X file as follows:

```
Animation BallAnimation
{
      { Ball_Frame }
}
```

Now that the Animation object is linked to a frame in our hierarchy, we will need to add some keyframe data. If the animation has been saved in SRT format (scale, rotation, translation) then there could potentially be three AnimationKey data objects that exist as children of the Animation object.

Each AnimationKey data object will contain a list of one or more keyframes for a specific key type. For example, the first AnimationKey object may contain a list of Scale keyframes, where each keyframe describes the scale for the attached frame matrix at a particular point in the timeline. The second AnimationKey object might contain a list of Rotation keyframes where each keyframe in this list describes the orientation of the attached frame at a given point along the timeline. Finally, the third AnimationKey object might contain a list of Translation keyframes describing the position of the attached frame at key points in the animation timeline. In the SRT format we can see that all three transformation types are stored separately, although this is not necessarily a one-to-one mapping. For example, we may have 10 scale keyframes, 150 rotation keyframes, and 0 translation keyframes. In this example the Animation object would contain only two child AnimationKey objects because there is no translation data to be stored. If the animation data is stored in matrix format instead of SRT format, the Animation data object will always contain only a single child AnimationKey data object that acts as a container for the animation matrix keys.

The AnimationKey template is a standard X file template and is defined as follows:

```
template AnimationKey
{
      <10DD46A8-775B-11cf-8F52-0040333594A3>
      DWORD keyType;
      DWORD nKeys;
      array TimedFloatKeys keys[nKeys];
}
```

DWORD KeyType

The AnimationKey object can store individual transformation components or a combined matrix. This first member identifies the type of keyframe data contained in the object. The possible values are shown in the table below.

KeyType	Description
0	The AnimationKey object will contain a list of rotation keyframes. Each key frame stores a rotation quaternion in a 4D vector representing the parent relative orientation of the frame.
1	The AnimationKey object will contain a list of scale keyframes. Each keyframe will store a 3D vector describing how to scale the frame along its X, Y, and Z axes respectively.
2	The AnimationKey object will contain a list of translation vectors. Each keyframe in the list will be represented as a 3D vector describing the position of the frame relative to its parent frame.
4	The AnimationKey object will contain a list of matrix keyframes. Each keyframe will be a 4x4 matrix containing the relative scale, rotation, and translation information for the frame at the assigned time

> **Note:** The SDK 9.0 documentation states that a value of '3' denotes the AnimationKey as containing matrices. This is incorrect and the correct value to identify an AnimationKey as a matrix keyframe container is '4' as shown in the above table.

DWORD nKeys

The second member of the AnimationKey template describes the number of keyframes in the list that follows. For example, if the KeyType member was set to 2 and the nKeys member was set to 22, this would indicate that the animation key contains 22 translation keyframes.

array TimedFloatKeys keys[nKeys]

The final member of the AnimationKey template is an array of TimedFloatKeys, which are the keyframe data. Each element in this array is a single keyframe and the array will be large enough to hold as many keyframes as are described in the nKeys member.

The TimedFloatKey type is another standard template and is defined as follows:

```
template TimedFloatKeys
{
    < F406B180-7B3B-11cf-8F52-0040333594A3 >
    DWORD time;
    FloatKeys tfkeys;
}
```

An object of this type will exist for each keyframe in the array. The first member contains the time where this keyframe can be found on the timeline. We will discuss time units (seconds, milliseconds, etc.) shortly. The FloatKeys child object is another standard template object:

```
template FloatKeys
{
   < 10DD46A9-775B-11cf-8F52-0040333594A3 >
   DWORD nValues;
   array float values[nValues];
 }
```

The FloatKeys object allows us to store arbitrary length vectors. Rotation keyframes are represented as 4 floats (a quaternion), while scaling and translation keyframes require only 3 floats. We can also store matrix keyframes as a 4x4 matrix (16 floats). The nValues member will tell us how many floats are stored in the array.

TimedFloatKeys data objects are really just wrappers around FloatKeys data objects with an additional time component.

With all of this in mind, let us examine a simple X file with two animated frames. The first frame (MyFrame1) will include rotation and translation animations, but no scaling. This means the Animation object for this frame will have two AnimationKey child objects -- one containing a list of rotation keyframes, the other a list of translation keyframes.

The second frame (MyFrame2) will use a list of matrix keyframes instead of separate scale, rotation and translation lists. As a result, the Animation object for this frame will contain a single AnimationKey child data object with a list of matrix keyframes.

We will look only at the relevant part of the X file so you can just assume that the frame hierarchy and meshes are stored elsewhere.

```
Animation   Anim1     // Animation Data for 1st animated frame
{
      { MyFrame1 }

      AnimationKey
      {
            0;    // Rotation Key Frames
            4;    // Four rotation key frames in list

            //    Time  NumFloats   Quaternion Data
            0;    4;    1.00000 ;  0.00000 ; 0.00000 ; 0.70000;;;  // Key Frame 1
            5;    4;    0.22222 ;  0.00000 ; 0.03333 ; 0.20000;;;  // Key Frame 2
            10;   4;    0.02000 ;  0.00000 ; 1.00000 ; 0.70000;;;  // Key Frame 3
            20;   4;    0.22222 ;  1.00000 ; 0.03333 ; 0.20000;;;  // Key Frame 4
      }

      AnimationKey
      {
            2;    // Translation Key Frames
            3;    // 3 Translation key frames in list

            //    Time  NumFloats   3D Translation Vectors
            0;    3;     0.00000 ; 0.00000 ; 0.70000;;; // Key Frame 1
            2;    3;     0.00000 ; 4.03333 ; 0.20000;;; // Key Frame 2
            4;    3;     0.00000 ; 1.00000 ; 3.70000;;; // Key Frame 3
      }
}

Animation Anim2    // Animation data for 2nd animated frame
{
      {MyFrame2}

       AnimationKey
       {
            4;    // This Animation Key holds Matrix Key Frame Data
            3;    // Three Key Frames

            //    Time  NumFloats   Matrix Data
            0;    16;   1.00000;    0.00000;    0.00000;    0.00000; // Key 1
                        0.00000;    1.00000;    0.00000;    0.00000;
                        0.00000;    0.00000;    1.00000;    0.00000;
                        0.00000;    0.00000;    0.00000;    1.00000;;;
            20;   16;   1.00000;    0.00000;    0.00000;    0.00000; // Key 2
                        0.00000;    1.00000;    0.00000;    0.00000;
                        0.00000;    0.00000;    1.00000;    0.00000;
                        10.00000;   0.00000;    0.00000;    1.00000;;;
            30;   16;   1.00000;    0.00000;    0.00000;    0.00000; // Key 3
                        0.00000;    1.00000;    0.00000;    0.00000;
```

```
                        0.00000;    0.00000;    1.00000;    0.00000;
                        20.00000;   30.00000;   0.00000;    1.00000;;;
      }
}
```

Notice that there are three semi-colons at the end of each keyframe. This is because, in addition to ending the float (one semi-colon), we are also closing the FloatKey object (another semi-colon) and the outer TimedFloatKey object (the third semi-colon). For more information on why these semi-colons appear, please read the section in the DX9 SDK docs entitled "Use of Commas and Semicolons".

> **Note:** Quaternions are stored inside X files with their components in WXYZ order, not the more typical XYZW format of 4D vectors.

It is important to emphasize that D3DXLoadMeshHierarchyFromX will automatically load the keyframe data (regardless of the format it is in) and internally store the data for each of its animations inside an animation set in **SRT format**.

The next template we will look at is called AnimationOptions. This is another potential child object of the Animation data object (the X file version of a 'frame animation') and is part of the standard template collection. This object will tell us whether this frame animation is a looping animation or not as well as whether interpolation between keys should be linear or spline based (splines are curves and will be discussed later in the series). The template used to describe the animation options is:

```
template AnimationOptions
{
  < E2BF56C0-840F-11cf-8F52-0040333594A3 >
    DWORD openclosed;
    DWORD positionquality;
}
```

The first DWORD indicates whether the animation is open or closed. If we set this value to '0' then the animation is described as a 'closed' animation and it will not loop. If we set this value to '1' then the animation is 'open' and should loop.
The second member describes whether linear interpolation or spline-based interpolation should be performed between keyframes. A value of 0 requests cheaper but lower quality linear position interpolations, while a value of one requests smoother but more expensive spline-based position interpolations.

> **Note:** Based on some internal testing results, it would appear that for the moment at least, this template type is not properly recognized by the D3DX animation controller (DX 9.0b). Please keep this in mind if you choose to use this template in your own X files.

The next animation related X file template that we will examine is the AnimationSet:

```
template AnimationSet
{
      <3D82AB50-62DA-11cf-AB39-0020AF71E433>
      [Animation]
}
```

The AnimationSet data object is a container for Animation objects (note that it is a restricted template). All Animation objects will be contained within a parent AnimationSet. In the previous chapter on hierarchies, you will remember that we actually wrote our own CAnimationSet class that was basically a container for CAnimation objects. The relationship between the X file AnimationSet data object and the X file Animation data object is analogous to the relationship between our proprietary CAnimationSet class and the CAnimation class. However, as mentioned, the data for a single frame animation is not stored in its own objects but stored directly inside the animation set to which it is assigned (likely in a large array of animations). The animation set is also more than just a container; it also provides the logic to interpolate between the SRT keyframes stored in each of its animations to generate the frame matrix for each animation at a specific periodic position in its timeline. The animation set also has its own local timeline, although that is managed at the animation controller level by the animation mixer (more on this later).

We will see later in this chapter that we can actually have multiple AnimationSets assigned to the same hierarchy. This is especially useful when animating a character hierarchy, where one animation set would contain all of the Animations (i.e., frame animations) to make the character walk while a second animation set would contain the Animations to make the character fire a weapon. Both animation sets would reference the same hierarchy, and indeed the Animations in two different animation sets will often animate the same hierarchy frame. Since the D3DX animation controller allows us to mix multiple animation sets together, we can even simultaneously blend the walking animation with the weapon firing animation so that a character can fire while on the move. We will return to explore this concept in great detail later in the lesson.

Next we see how animation data might look in a stripped-down X file using the animation set concept just discussed.

```
AnimationSet Walk // Walking Animation
{
      Animation   // Animation data for 1st animated frame
      {
            {MyFrame1}
            AnimationKey
            {
                  4;    // This Animation Key holds Matrix Key Frame Data
                  3;    // Three Key Frames
                  Key-Frame Matrix Data Goes here
            }
      }

      Animation   // Animation data for 2nd animated frame
      {
            {MyFrame2}
            AnimationKey
            {
                  4;    // This Animation Key holds Matrix Key Frame Data
                  3;    // Three Key Frames
                  Key-Frame Matrix Data Goes here
            }
      }
}  // end Walk animation set
```

```
AnimationSet Shoot     // Shooting animation
{
      Animation   // Animation data for 1st  animated frame
      {
            {MyFrame1}
             AnimationKey
             {
                  4;    // This Animation Key holds Matrix Key Frame Data
                  3;    // Three Key Frames
                  Key-Frame Matrix Data Goes here
             }
      }

      Animation   // Animation data for 3rd animated frame
      {
            {MyFrame3}
             AnimationKey
             {
                  4;    // This Animation Key holds Matrix Key Frame Data
                  3;    // Three Key Frames
                  Key-Frame Matrix Data Goes here
             }
      }
}  // end 'Shoot' animation set
```

Note that you do not have to give an animation set a name since they can be referenced by index once they have been loaded by D3DX. However, giving them a name is always a good idea if given the choice in your X file exporter. The D3DXLoadMeshHierarchyFromX would load the sample X file and would create two animation sets that would then be registered with the animation controller. Each animation set in this example would have two animations.

In the walk animation set above, Frame1 and Frame2 of the hierarchy are manipulated. For the shoot animation, Frame1 and Frame3 are manipulated. If these animation sets were blended together, then Frame1, Frame2, and Frame3 would be animated simultaneously. Frame1 would be influenced by both animation sets because there would be an animation in both animation sets attached to it and updating its matrix.

Unfortunately, at least at the time of this writing, many X file exporters are able to save only a single animation set in the X file. This is true regardless of how many logical types of animations are created for the scene (walk, run, jump, etc.). To be clear, the frames for these logical animations are all saved; they just happen to be stored in the same animation set in many cases. While you can usually configure the modeller to export only a specific range of keyframes, often the entire hierarchy will need to be saved as well. However even if you can avoid this, or code around it, or simply do not care about the extra space, it is still much easier to manage your animation data if it is not all stored in a single set.

On the bright side, in Lab Project 10.2 we will create a small tool to circumvent this problem. Our GUI tool will allow the user to load an X file that contains all of its animations in a single animation set and then use the D3DX animation interfaces to break those animations into separate named animation sets before resaving the file. Apart from being a very handy tool, it will also get us acquainted with using the D3DX animation interfaces to build an ID3DXAnimationController and ID3DXAnimationSet objects

from scratch. This is something you will definitely want to learn how to do if your animation data is stored in a file format other than X.

10.3.1 Timing and X Files

As it turns out, the timing values stored within the keyframes of an X file are not specified in seconds; time is instead specified using *ticks*. By itself, this timestamp format is fairly useless, for it is largely arbitrary, and depends on factors such as how fast we want the animation to run and how many of these ticks the exporting application (the 3D modelling program) was processing per second. For D3DX to process these keyframe timestamps in a meaningful way and convert them into seconds, there is an additional X file template, called `AnimTicksPerSecond`, which can be placed anywhere in the file. It contains a single DWORD which tells us (and D3DXLoadMeshHierarchyFromX) how many of these ticks equal one second in application time. The D3DX loading function uses this data to convert keyframe timestamp values stored in the X file into seconds for storage within its interpolator objects.

```
template AnimTicksPerSecond
{
      DWORD NumberOfTicks;
}
```

As it turns out, this data is omitted from most X files. If it is not included, D3DX assumes a default of 4800 ticks per second. This is the default also assumed by most 3D modelling applications which export to the X file format. This means that if the last keyframe in any given animation has a timestamp of 67200, the animation will have a length of 14 seconds. Although this may seem to be an unnecessary middle level of interpretation introduced at load time, it does allow for the easy alteration of an animation's speed and length by simply changing the number of ticks per second value stored in the X file. Perhaps we might find that the animation data exported from a certain application runs too fast and we would like to slow it down. Without this Ticks Per Second concept, we would have to manually adjust the timestamps of every keyframe in the X file (a laborious process indeed).

There are a few traditional `AnimTicksPerSecond` values that many developers/modellers use beyond the default of 4800. Values like 30, 60, 24, and 25 are often used as well. These values generally correspond to 'frames per second' standards that are used across the industry. If we were to use the 30 ticks per second case as an example, this would mean that for a keyframe to be triggered ten seconds into the animation, its timestamp should be 300. Again, this is all handled on our behalf by the D3DX animation controller and its animation sets, so it may not seem relevant. However, it certainly helps to understand how the timing is interpreted when building animations manually, or when writing your own exporter.

Before moving on to the next section, let us quickly sum up what we know so far. First, we now have a good understanding of how animation data is represented in an X file. We know that there will usually be a single animation set, and it will contain one or more animation data objects. Each animation data object is connected to a single frame (by reference) in the frame hierarchy (contained elsewhere in the X file) and stores the keyframe data for that frame, essentially describing that single animation's timeline. We know that inside the animation object, the keyframe data can be stored in SRT format, where there

will be three separate keyframe lists (three AnimationKey objects) for scale, rotation, and translation data. Alternatively, the data can be stored as a single AnimationKey using a keyframe list of matrices storing the combined scale, rotation, and translation information. We also know that regardless of how the data is stored in the X file, once loaded, the animation data will be stored inside the animation set as SRT lists for each animation defined. We learned that the timestamp of each keyframe in an animation is defined in the X file using an arbitrary unit of measurement called a tick, which is given meaning by the exporter by either inserting an AnimTicksPerSecond data object somewhere in the file or by using the D3DX default (4800 ticks/sec). Finally, we know that more often than not, we will let D3DX do all of the hard work for us. We will simply call ID3DXAnimationController::AdvanceTime to generate/update the relative matrices for each frame to correspond to the elapsed time for the currently active animation(s).

10.4 The D3DX Animation Interfaces (Overview)

Now that we know how our animation data is stored at the file level, let us examine how it is arranged in memory once D3DX has loaded it using D3DXLoadMeshHierarchyFromX. As it turns out, there is not much difference between the two cases.

When D3DXLoadMeshHierarchyFromX loads in animation data, that data is stored and managed by a D3DX animation subsystem consisting of two different COM object types. This exposes two main animation interfaces to our application (there are others used for intermediate tasks). We will look at each of them very briefly here first, and then in more detail as the chapter progresses.

10.4.1. The Animation Controller

The top level of the animation subsystem is the ID3DXAnimationController interface. An interface to this object is returned to our application by the D3DXLoadMeshHierarchyFromX function. It is this interface that our application will work with most frequently. We can think of it as being an animation set manager -- when animation sets are loaded from the X file, each animation set is registered with the newly created animation controller and an interface to this controller is returned to the application.

The animation controller also provides a very powerful *animation mixer* that can be used to assign animation sets to different ‘tracks’ and blend them together when the animations are played. The animation mixer can be thought of as being somewhat like a multiple-track audio mixing desk, where we would feed in individual pieces of audio data (drums, guitar, vocals, etc.) on different ‘tracks’ or ‘channels’ and blend them together based on the properties that we have set for each track (ex. volume, bass, treble, etc.). What comes out of the mixing desk output jack is all of the audio data, from all of the tracks, combined together into a final product that can be saved to CD and played back.

If we needed to play only a single animation set and did not require blending, the animations sets would all still be loaded and registered with the animation controller by the D3DXLoadMeshHierarchyFromX function; we would just assign the animation set we wish to play to track 1 and play it back by itself.

Note: Even if an X file contains multiple animation sets, by default D3DXLoadMeshHierarchyFromX will assign the only last animation set defined in the file to track 1 of the mixer. No other mixer tracks or animation sets will be set up for you, so if you wish to play them, you will have to assign these animation sets to the mixer tracks manually. This is why you will not see us setting up the animation mixer or doing any kind of animation set initialisation in Lab Project 10.1. The X file only contains a single animation set and it is assigned to track 1 by default. When the loading function returns, we are ready to start playing the animation set immediately.

10.4.2. The Animation Set

The ID3DXAnimationSet interface and its underlying COM object mirrors the X file AnimationSet template almost exactly. This is the base class interface and it is actually the ID3DXKeyframedAnimationSet that we will be using most of the time. There is also an ID3DXCompressedAnimationSet which is an animation set containing compressed keyframe data. Once keyframe animation data has been loaded by D3DX into an ID3DXKeyframedAnimationSet, we can use the methods of this interface to create a compressed animation set if we wish.

The base interface (ID3DXAnimationSet) is pure abstract, thus allowing you to derive your own animation set classes which interpolate between the keyframes of each of its animations in a customized manner. As long as the derived class exposes the functions of the base interface, the animation controller will happily work with it to generate the frame matrices without caring how that matrix data was generated.

For each AnimationSet data object contained in the X file, D3DXLoadMeshHierarchyFromX will create a new D3DXKeyframedAnimationSet object and register it with the animation controller. On function return, we can use the methods of the ID3DXAnimationController interface to assign these animation sets to tracks on the mixer so that they are ready for playback. Each animation set will contain the SRT data of each animation data object stored in the file. It will also contain a mapping describing which keyframe animation data sets are assigned to which frame(s) in the hierarchy. This is a simple name match. In other words, the name of an animation within an animation set matches the name of its assigned frame in the hierarchy.

Recall that an X file animation object is essentially a container of AnimationKey data objects for a single frame in the hierarchy. This same relationship is maintained in D3DX. In this case however, each Animation Set will contain the array of SRT keyframes along with a frame name. It is the SRT keyframe set for a single frame in the hierarchy which is referred to as being a ***frame animation***, or an ‘Animation’ for short. The contents of each Animation inside of an animation set are equivalent to the X file AnimationKey data object contents. For each frame that is animated in the hierarchy, a matching animation will be created and attached to that frame and managed by D3DX via its parent animation set. The Animation stores all the keyframe data for that frame for the animation set to which it is assigned.

For example, if an X file contains an animation set that animates five frames in the hierarchy, a D3DXKeyframedAnimationSet object will be created and registered with the animation controller, and five Animations will be created and stored inside it. They will contain the individual keyframes for each

of the animated hierarchy frames. These animations are owned by the animation set and the animation set will be owned by the animation controller.

We will hardly ever need to work with the ID3DXAnimationSet interface or the ID3DXKeyframedAnimationSet interface when playing back an animation. Often, our application's only exposure to these interfaces will occur when we wish to use the animation mixer to blend animation sets, or assign animation sets to mixer tracks. For example, ID3DXAnimationController has a function called SetTrackAnimationSet which takes two parameters: a track number and an ID3DXAnimationSet interface. Calling this method will assign the passed animation set to the specified track on the animation controller's mixer. When using the animation controller in this simple way, we will often have no need to actually call any of the animation set's methods. The methods of the animation set are usually called by the animation controller to generate the SRT data for each animated frame in the hierarchy (in response to a call to AdvanceTime from the application).

Keyframe animation sets are much more than simple animation containers. In fact, when our application calls ID3DXAnimationController::AdvanceTime, the animation sets manage much of the total animation process. They select the appropriate keyframes for a given moment in time for each animation and then use them to generate dynamic animation data that transforms the frames to which the animations are attached.

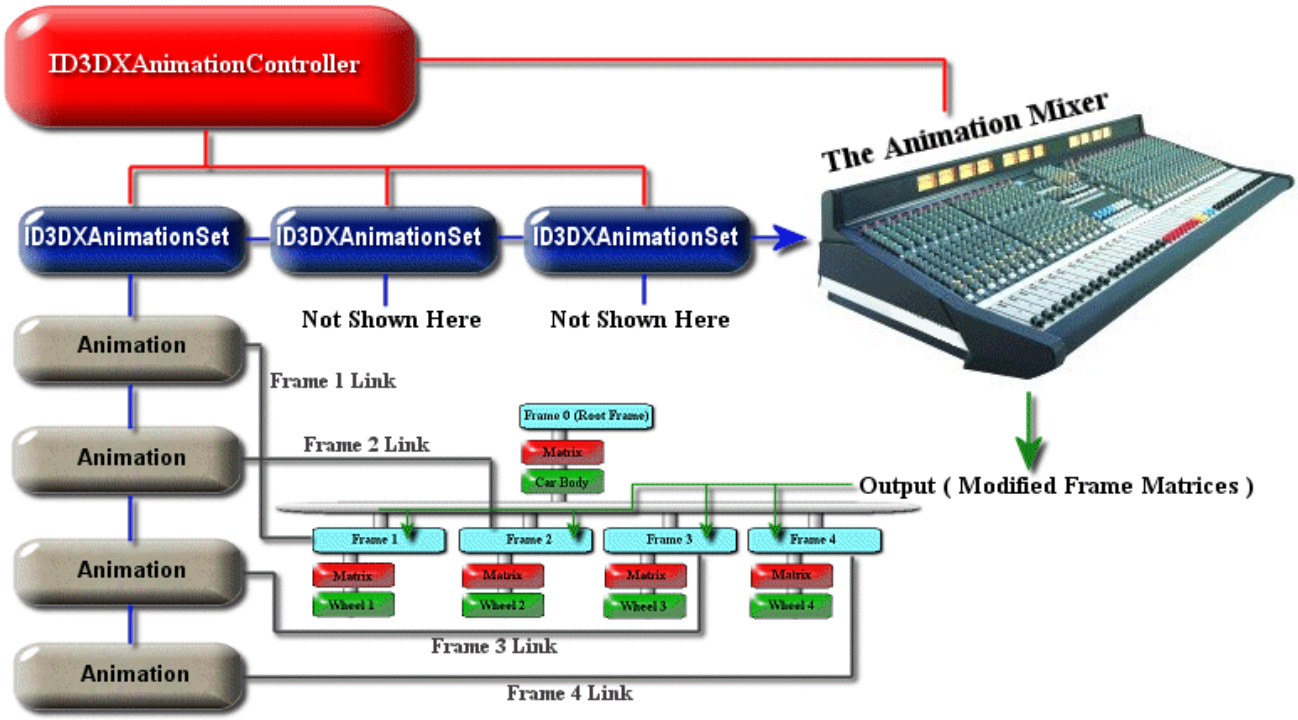
When ID3DXAnimationController::AdvanceTime is called, the animation controller will begin by looping through each of its currently active AnimationSets (an *active* set is one that has been assigned to a track on the animation mixer). For each animation set, it will use the ID3DXAnimatonSet interface to fetch each of its underlying animations. For each animation, the controller will call the ID3DXAnimationSet::GetSRT function. GetSRT will use the current animation local time (i.e., periodic position) of the animation set to search for its two bounding keyframes and then interpolate a new value somewhere in between. The output is a new position, scale and rotation for the frame to which it is attached. The animation controller will do this for each animation contained in each animation set. At the end of this process, the animation controller will contain the new matrix information for each animated frame in the hierarchy. These may be placed directly into the frame matrices or, depending on how the mixer is configured, this matrix data might be blended together to create the final matrix data for the assigned frame in the hierarchy. So, in the case of the ID3DXKeyframedAnimationSet interface, the animation set is responsible for performing the actual keyframe interpolation and handing the results back up to the animation controller for mixing.

The animation controller will typically cache the new frame position, scale, and rotation information generated by the ID3DXAnimationSet::GetSRT function call (for each animation) until all active animation sets have been processed. Then the new frame data for each animation set will be scaled by the weight assigned to its track. If two animation sets have keyframe animations defined for the same frame in the hierarchy, then the results of each animation will be blended together taking the track weights into account. The results are then stored in the parent-relative frame matrix for the appropriate owner frame in the hierarchy.

> **Note:** We can also use the ID3DXKeyFrameAnimationSet interface to directly work with the keyframe data. This can be useful if you are designing your own animation tool and need the ability to create, edit, or destroy keyframe data values. For example, we can use the ID3DXKeyframedAnimationSet::RegisterAnimationSRTKeys method to place our own keyframes directly

into an animation set that we manually create. This allows us to register animations manually with the animation set. This would be useful if you wish to use the D3DX animation system but intend to load the animation data from a custom file format. You could programmatically build the animation controller, create and register animation sets with the controller, and then add you own animations to the animation set. The keyframe data for each animation you add could be the data imported from your custom file format.

Fig 9.7 depicts an animation controller that owns three animation sets. You will notice that we are reusing our automobile hierarchy once again and that for the first animation set, there is an animation for each wheel frame (the grey lines show the frame that each animation is connected to). When we call ID3DXAnimationController::AdvanceTime, the clocks for each track on the mixer are incremented by this value. Once the timers for each track have been updated, the current time of the track is mapped to the local time of the animation set assigned to it (to account for looping, etc). Each animation set uses this time to calculate a new position, rotation, and scale for each animation by interpolating its stored keyframes (via its GetSRT function). It passes the results back up to the animation controller where they are fed into the animation mixer. The result of the mixing process is a new frame matrix generated using any or all of the animation sets results. This data is stored in the frame matrices so that the next time we update and render the hierarchy, the matrices have been adjusted and the children (meshes, other frames) appear in their new position or orientation.



The D3DX Animation System

Figure 9.7

So we actually have several timers at work here. The global time of the animation controller is the time that is updated every time our application calls the ID3DXAnimationController::AdvanceTime method.

We pass in an elapsed time value that is used to update the controller's timer variable. This same elapsed time is also added to the timers of each active track on the mixer (a track that has an animation set assigned to it). We can think of these as being global times for a given track. By keeping a global time for each track, we have the ability to advance the time of a single track without affecting any of the others. If we only had a single global time shared by all tracks, altering the position of the global time would cause all tracks to be updated.

Finally, while we might think that the track time is the time used by the animation set to fetch its keyframes, this is not the case. The track time is still a global time value that has no consideration for the duration of the animation or whether it is used to play in a looping or ping-pong fashion. Therefore, once the timer of a given track has been updated, the controller will use the ID3DXAnimationSet::GetPeriodicPosition method to map the track time into a local time for the animation. This local time is referred to as the *periodic position* of the animation and it is this periodic position that is passed into the ID3DXAnimationSet::GetSRT method by the controller to fetch the SRT data for a given animation. We will discuss the periodic position of an animation set and the mapping of track time into local animation time more a bit later in the chapter. Just know for now, that this is all handled on our behalf by the animation controller.

10.5 SRT vs. Matrix Keyframes

Earlier we discussed the fact that X file keyframe data can be stored in one of two ways: SRT transforms can be maintained in separate lists or they can be combined into a single list of 4x4 matrices. Regardless of the file keyframe format, the ID3DXKeyframedAnimationSet always stores keyframe data in SRT format. Internally, the D3DXKeyframedAnimationSet maintains a list of private arrays for **each** animation, similar to what we see below:

```
LPCSTR                  AnimationName;
LPD3DXKEY_VECTOR3       pTranslationKeys;
LPD3DXKEY_QUATERNION    pRotationKeys;
LPD3DXKEY_VECTOR3       pScaleKeys;
ULONG                   NumTranslationKeys;
ULONG                   NumRotationKeys;
ULONG                   NumScaleKeys;
```

Each animation maintains three separate lists of keyframe data and stores an animation name so that it knows which frame in the hierarchy these keyframe lists affect. The name of the animation will be the name of the frame to which it is attached. Translation and scaling keyframes are both stored in D3DXKEY_VECTOR3 arrays. This structure contains a time value and a 3D vector:

```
typedef struct _D3DKEY_VECTOR3
{
      FLOAT       Time;
      D3DXVECTOR3 Value;
} D3DKEY_VECTOR3, *LPD3DXKEY_VECTOR3;
```

When used to store translation keyframes, the 3D vector contains the position of the frame relative to its parent frame. When this structure is used to store scale keyframes, the 3D vector stores scaling amounts for the frame matrix along the X, Y, and Z axes.

Rotation keyframes are stored as an array of D3DXKEY_QUATERNION structures. This structure includes a timestamp in addition to a standard quaternion.

```
typedef struct _D3DKEY_QUATERNION
{
      FLOAT             Time;
      D3DXQUATERNION    Value;

} D3DXKEY_QUATERNION, *LPD3DXKEY_QUATERNION;
```

The D3DXQUATERNION structure is a 4 float structure (X,Y,Z,W) that will store the frame orientation relative to the parent. D3DXLoadMeshHierarchyFromX takes care of converting quaternions stored in the X file in WXYZ format to XYZW format before storing them in the interpolator quaternion array.

> **Note:** 3D Studio Max™, Milkshape™ and other animation editors also store their keyframe data in SRT format, not as a single array of matrices. If you are familiar with 3D Studio Max™ you will notice that on the timeline bar, when a keyframe is registered, there are three different colored blocks which denote the type of 'event' is tracked at that time (scale, rotation, or translation). If only a translation occurred, there will only be one colored block there. The animation information layout in the .3DS file format also stores its keyframe animation in an almost identical manner to that discussed above.

It is worth noting that even if your original keyframe data was stored as a matrix list, those matrices would be split into SRT components before they are stored in the animation's SRT arrays by D3DX. Why do this? After all, matrix keyframes seem like a nice idea since we only have to maintain a single array of keyframe data.

As it turns out, there are actually a few good reasons why SRT lists are preferred over matrices. One of the more obvious is memory footprint. There are 16 floats in a matrix keyframe and a maximum of 10 in an SRT keyframe (and perhaps fewer depending on which components are active).

But more importantly, accurate interpolation between matrices is essentially not possible under certain circumstances. This is a direct result of the fact that scaling data and rotation data become intermixed, and are ultimately indistinguishable in the upper 3x3 portion of the matrix.

Consider the following example animation data. In our editing package, we create two cubes side by side. One of these we wish to **scale** by a factor of (`X:-1, Y:1, Z:-1`) over the course of the animation ('the animation' being a simple two keyframe animation) and the other is **rotated** 180 degrees around the Y axis. So in SRT keyframe format, we would end up with two keyframes for each cube:

```
Animation {

  { Cube01 }

  AnimationKey {
```

```
    1;      // 1 = Scale
    2;      // 2 Key frames
    0;     3;  1.000000, 1.000000,  1.000000;;,
    67200; 3; -1.000000, 1.000000, -1.000000;;;
  }
}

Animation {

  { Cube02 }

  AnimationKey {
    0;      // 0 = Rotation
    2;      // 2 Key frames
    0;     4; 0.000000, 0.000000, 0.000000, 1.000000;;.
    67200; 4; 0.000000, 1.000000, 0.000000, 0.000000;;;
  }
}
```

This works fine and we can see that when we run the animation, each cube acts as we would expect it to when the animation is played out. Interpolation of each cube's animation data will produce expected results for any time within the timeline. In the case of the first cube, two scale keyframes are being interpolated, causing the cube to slowly invert itself over the duration of the timeline. In the case of the second cube, two rotation keys will be used for interpolation, causing the cube to turn 180 degrees over the duration of the timeline. If we were to switch over to matrix keys however, let us take a look at the matrix keyframe values that would now be stored in the X file:

```
Animation {
  { Cube01 }
  AnimationKey {
    4;      // 4 = Matrix Key
    2;      // 2 Key frames
    0;     16; {MatrixA};;,
    67200; 16; {MatrixB};;;
  }
}

Animation {
  { Cube02 }
  AnimationKey {
    4;      // 4 = Matrix Key
    2;      // 2 Key frames
    0;     16; {MatrixA};;,
    67200; 16; {MatrixC};;;
  }
}
```

The matrices listed above are just placeholders, so let us have a look at the actual values. MatrixA and MatrixB describe the two matrix keyframes of the first frame (which is to be scaled) and MatrixA and MatrixC describe the two matrix keyframes for the second animated frame (which is to be rotated).

```
{MatrixA}    1.000000, 0.000000, 0.000000, 0.000000,
             0.000000, 1.000000, 0.000000, 0.000000,
             0.000000, 0.000000, 1.000000, 0.000000,
             0.000000, 0.000000, 0.000000, 1.000000

{MatrixB}   -1.000000, 0.000000,  0.000000, 0.000000,
             0.000000, 1.000000,  0.000000, 0.000000,
             0.000000, 0.000000, -1.000000, 0.000000,
             0.000000, 0.000000,  0.000000, 1.000000

{MatrixC}   -1.000000, 0.000000,  0.000000, 0.000000,
             0.000000, 1.000000,  0.000000, 0.000000,
             0.000000, 0.000000, -1.000000, 0.000000,
             0.000000, 0.000000,  0.000000, 1.000000
```

We can see that the first cube (the cube we are attempting to scale by -1 on both the X and Z axes) uses both MatrixA and MatrixB as its keyframes. MatrixA is an identity matrix (for both frames) so the cube meshes attached to those frames will start off aligned with the world X, Y, and Z axes facing down +Z. We can see that MatrixB is a scaling matrix. At 67200 ticks, the first cube will scale itself such that it will then be inverted and facing down -Z. So far, this is all essentially fine.

However, have a close look at MatrixC which is used for the second cube's final keyframe. This defines our 180 degree Y rotation keyframe. You will notice that MatrixB and MatrixC contain the exact same values. In fact, a two axis negative scaling matrix is identical to a 180 degree rotation matrix on the third (unused) axis. At first you might think that this is not a problem. After all, the final result you want in both cases is identical, and thus the matrices should be identical too, right? Certainly, in both cases, at timestamp 67200, both cubes would be facing down the -Z axis and would look identical.

The problem occurs when the animation set for which the animation is defined is trying to interpolate between the two keyframes (A/ B and A/C) to generate the frame matrix for a time that falls between their timestamps. How would the interpolation process know whether it should gradually scale the object from one keyframe to the next or whether it should rotate it between keyframes? Take a look at the following two matrices which show how the matrices in between the keyframes in our example might look, depending on whether the two keyframes are supposed to represent a scale or a rotation:

The first matrix is 50% through a 180 degree rotation about the Y axis. This is the frame matrix we would expect the interpolation process to generate for our rotating cube frame exactly halfway through its timeline:

```
0.000000, 0.000000, -1.000000, 0.000000,
0.000000, 1.000000,  0.000000, 0.000000,
1.000000, 0.000000,  0.000000, 0.000000,
0.000000, 0.000000,  0.000000, 1.000000
```

The second matrix is 50% through a -1.0 scaling along the X and Z axes. This is the frame matrix we would expect the interpolation process to generate for our scaling cube frame exactly halfway through its timeline.

```
0.000000, 0.000000, 0.000000, 0.000000,
0.000000, 1.000000, 0.000000, 0.000000,
0.000000, 0.000000, 0.000000, 0.000000,
0.000000, 0.000000, 0.000000, 1.000000
```

These two matrices are clearly quite different, even though carrying on interpolating all the way to the end of the animation (100%) would result in identical matrices, as we have seen. This shows that while the keyframe matrices of both a 180 degree Y axis rotation and a –1.0 XZ axis scale are identical, the matrices generated by the interpolation at times that fall between the two keyframes can be very different.

So how exactly does D3DX address this problem when converting matrix keyframes stored in an X file to separate SRT lists for the animation stored inside the animation set? How does it look at two keyframe matrices (such as those in our example) and determine whether these two keyframes represent a scale or a rotation? The answer is: it does not know. There is no way to distinguish between our scale and rotation examples because in both cases the two keyframes for each animation are identical, even though we would desire different intermediate matrices during animation.

At load time, D3DX will extract what rotation, translation, and scale data it can from the matrix keyframes and store them in SRT format and hope they are correct. It will simply assume, in a case like we see above, that rotation is the correct animation and store the data in the animation's rotation keyframe list. This is generally fairly safe to assume as rotation animations are typically more common than scaling animations.

This matrix keyframe ambiguity is precisely why most modeling applications export keyframes in SRT format. Matrix keys are not completely useless however. Certain animations that require transforms that cannot easily be represented with the SRT approach (skew matrices, projection matrices, etc.) can benefit from a matrix keyframe list. In fact, this is why keyframe matrices were added to DirectX 8.0 (they did not exist in DirectX prior to that point).

There is a way around some of these matrix keyframe problems. If we were to use three key-frames for these cases instead of two, inserting our '50%' matrices outlined above into the animation, we would end up with a more accurate representation of the desired animation type. It would still have significant issues, but the more keys we add, the more accurate the animation will become. There are other cases, other than the one outlined above, where the use of matrix keys can cause problems, but generally, by sampling more keyframes during the export of the animation data, these problems can be reduced.

The bottom line is, it is probably best to favor SRT format if you have a choice when exporting your X files. Only choose a matrix format if you are sure that they will not present a problem.

10.6 The D3DX Animation Interfaces

In this next section we will examine the D3DX animation interfaces that our application will need to work with in order to animate frame hierarchies. Rather than starting at the top level of the system and covering the ID3DXAnimationController interface first (which is often the only interface our application will need to work with extensively), we will take the reverse approach and study the ID3DXKeyframedAnimationSet first. This will give us a better idea about how the animation controller uses the interface of its registered animation sets to generate the new matrices for our frame hierarchy. This discussion is not superfluous. If we understand how the system works internally, we will be better informed to use it wisely.

When we load an X file that contains keyframe animation data, one or more of these animation sets will be created for us by D3DXLoadMeshHierarchyFromX and will be registered with the animation controller. Each animation set contains a collection of one or more animations. Each animation is really just a named set of keyframes that apply to a frame in the hierarchy with a matching name when the animation set is played.

Our application will rarely need to work with the methods of the ID3DXKeyframedAnimationSet interface directly. Often, our only exposure comes when using the interface to bind animation to a track on the animation controller's internal mixer. For example, we will frequently use the ID3DXAnimationContoller interface to return one of its registered animation sets, by name or index. We will get back an ID3DXAnimationSet interface (the base class interface) which we can pass into ID3DXAnimationController::SetTrackAnimationSet to bind that animation set to a track on the mixer. Regardless of how many animation sets are registered with the animation controller, only animation sets assigned to active tracks on the animation mixer will influence the hierarchy on the next call to ID3DXAnimationController::AdvanceTime.

10.6.1 The ID3DXKeyframedAnimationSet Interface

In DirectX terminology, an *animation* is a set of keyframe lists for a single frame in the hierarchy. The *animation set* stores and manages a set of animations. Animation sets are in turn managed by the *animation controller*, which itself is the top level interface in the D3DX animation system. You may recall that this was the case based on our earlier discussions about the way the data was stored inside the X file. In our X file we saw that an AnimationSet data object contained a number of Animation data objects. These Animation data objects are the file-bound cousins of an animation in an animation set, containing keyframe data for a given frame in the hierarchy.

> **Note:** Many currently available X file exporters for 3D Studio Max™ and Milkshape™ save their data into a single animation set. This means that, without modification, these files will cause D3DXLoadMeshHierarchyFromX to create an animation controller with a single animation set containing all of the keyframe interpolators in the file. In Lab Project 10.2 we will develop a tool that allows us to modify X files so that they can contain multiple animation sets.

The ID3DXKeyframedAnimationSet mirrors the AnimationSet data object in the X file -- storing one or more animations. When D3DX loads an X file that contains animation data, it will automatically create all of the animations and incorporate them into their appropriate animation sets.

ID3DXAnimationSet exposes many methods, most of which we are not likely to need very often. This is because, when playing back animations, the animation controller will interact with the animation sets (and their underlying animations) on our behalf. All we have to do is call the controller's AdvanceTime function and all of this happens automatically. However, the interface also exposes methods to retrieve the underlying keyframe data for each of its animations so that one can directly examine the keyframes assigned to a given frame in the hierarchy. While this is not something you are likely to do on a frequent basis, it might come in handy during debugging. Studying this interface will also teach us how the entire D3DX animation system works at a low level and will provide us the knowledge to build and populate our own animation sets programmatically if we wish.

The collection of animations stored in an animation set defines the purpose of the set. Sometimes a single animation set will animate every frame in the hierarchy and under other circumstances only select frames may be affected. The latter is useful when we only wish to update portions of an articulated structure. A character is a good example; we could separate the character into logical areas (legs, torso, arms, head, etc.) and apply particular animation sets to individual parts. Consider the following animation set types for an example game avatar:

Animation Set: 1
Name: Walk
Description: This animation set contains animations which animate the leg frames of the character hierarchy to emulate the act of walking. No other animations are included for any other portion of the character.

Animation Set: 2
Name: Run
Description: Identical to the Walk animation set in that it only contains animations which animate the legs of the character. In this case, the legs are animated to give the impression that the character is running.

AnimationSet: 3
Name: Attack
Description: This animation set contains animations which animate the characters arms and torso to swing his sword.

While many more possible animation sets can exist, and some of these may even be too restrictive, the key point here is the isolation of important areas in the hierarchy. The more we can do this, the more effective will be our use of the animation mixer. As we will see later, we will be able to mix multiple animation sets together on the fly, which means that we can have our character run and attack simultaneously, without the artist having to create a specific 'Run+Attack' animation set.

You are reminded that each animation owned by an animation set may have its own unique animation length and that each animation runs concurrently. If you would prefer that all animations in a given set

finish execution simultaneously, you can do this quickly in your editing package by adding a final keyframe (at the same point in the timeline) for all frames that are animated. Remember that the duration of the animation set is the length of its longest animation (i.e., it is determined by the keyframe with the largest time stamp). If the animation set is configured to play continuously, then the animation will only loop (or ping-pong) around once this keyframe has been executed. If other animations in the set have reached their final keyframe some time before, they will remain inert until the animation set timeline restarts. The length of an animation set is referred to by DirectX as its *period* and the current position within the local timeline of an animation set is referred to as its *periodic position*.

This ID3DXKeyframedAnimationSet interface is derived from the ID3DXAnimationSet interface, which is essentially an abstract base class derived from `IUnknown`. ID3DXAnimationSet does not implement any functionality itself, but serves as the base for `ID3DXKeyframedAnimationSet` and `ID3DXCompressedAnimationSet`. It can also be inherited in order to implement your own custom SRT interpolation system if desired. Generically speaking, an animation set must generate the scale, rotation, and translation keyframe values for one of its animations based on a specified time value passed into its GetSRT member function. It returns that information via the base class functions to the animation controller.

The animation controller is only concerned with the methods exposed in the base interface, and as such, any interfaces must implement all of these methods. The ID3DXKeyframedAnimationSet interface would be useless to the controller if it did not implement the GetSRT method of the base interface. However, the ID3DXKeyframedAnimationSet interface exposes many other functions that our application can use to examine or set the keyframe data. When D3DXLoadMeshHierarchyFromX loads in animation data of the type discussed above, it will automatically create keyframed animation sets for us and register them with the returned controller. The exception to the rule is if the animation is stored in the X file in compressed format. In this case, a compressed animation set will be created instead. The controller works with both interfaces in exactly the same way, since they both expose the base class functionality that the controller desires. It is currently very rare to find X files that contain compressed animation data, so we will usually be dealing with the ID3DXKeyframedAnimationSet interface.

The base animation set interface, ID3DXAnimationSet, exposes eight methods. Each is implemented by the ID3DXKeyframedAnimationSet. While the animation controller will work with these on our behalf most of the time, if you intend to plug your own animation set interpolation system into the D3DX animation system, your derived class will need to implement these functions. This means knowing what the animation controller will expect in return when it calls them.

Base Methods

```
LPCSTR GetName(VOID);
```

This function takes no parameters and it returns a string containing the name of the AnimationSet. D3DXLoadMeshHierarchyFromX will create D3DXAnimationSet object(s) and properly assign them names based on the matching AnimationSet data object name in the X file.

The following example is the beginning of an AnimationSet data object in an X file which has been assigned the name ‘Climb’. The D3DXAnimationSet for this object will be assigned the same name, and calling ID3DXAnimationSet::GetName would thus return the string ‘Climb’.

```
AnimationSet Climb
{
      child ‘Animation’ objects defined here
}
```

You may recall from our earlier examination of X files that we are not required to assign names to data objects. Therefore it is possible that D3DX will load animation sets that have not been explicitly named in the X file. In this case, the corresponding D3DXAnimationSet will have an empty name string. If you have the choice (in your editing package or X file exporter) to assign animation sets meaningful names, it is helpful to do so. It allows you to reference the different animation sets through the animation controller using the actual name of the animation set (such as ‘Walk’ or ‘Climb’) instead of relying on a numeric index.

`DOUBLE GetPeriod (VOID);`

This function returns the total amount of time (in seconds) of the longest running animation in the animation set. The duration of an animation set is referred to as its period. If animation 1 runs for 14 seconds, but animation 2 runs for 18 seconds, this function will return 18. Indeed the first animation will have finished 4 seconds previously during playback. Only when the period value is reached in an animation set’s local timeline, will its timeline be reset back to zero and both animations would being animating again (assuming the animation set is configured to loop or ping-pong). The period of the animation set is equal to the scale, rotate, or translation key with the highest timestamp among all animations in the set. If we have a scale key, a rotation key and a translation key with timestamps of 50 ticks, 150 ticks and 20 ticks, the period of the animation set would be 150/TicksPerSecond.

`DOUBLE GetPeriodicPosition ( DOUBLE Position );`

This function is used by the animation controller to get the current position within an animation set’s local timeline, given a global track time (as discussed previously). Every time we pass an elapsed time value into the ID3DXAnimationController::AdvanceTime function, the animation controller adds this input time to the timer of each mixer track. Thus, the mixer track timers continue to increment with each call to AdvanceTime. When the animation controller needs to fetch the SRT data for an animation from a given animation set, it will use this method to map the track time of the animation controller into the animation set’s local timeline. This is because the track time is always incremented when we call AdvanceTime and therefore it may be well outside the period of the animation set.

If the animation set is set to loop or ping-pong, then the animation set must not simply stop when the track time exceeds its period. Rather, the track time should be mapped into a local time (a periodic position) that is within the range of its keyframe data. It is this time that should be returned to the controller so that it can be used to fetch SRT data. Therefore, studying the above function, we can see that the Position parameter would contain a track time that would be passed in by the controller. This

track time needs mapping into an animation set's local time. Again, this local time is referred to as the periodic position.

This function essentially provides a mechanism for the animation set to use the track position to map into its own time (or not) however it sees fit. As the controller has no idea what data is contained in the animation set or whether or not it is set to loop, this function allows the animation set to control that process without involving the controller in the specifics. All the controller cares about is getting back a time value that it can use to fetch SRT values. How this time value is generated from the track position is entirely up to the animation set. For a non-looping animation, this function might simply test to see if the track time is larger than its highest keyframe timestamp. If so, it can pass back the timestamp of the last keyframe in the animation. This would mean that once the track time had exceeded the period of the animation set, it would appear to stop or freeze in its final position, because in every call to AdvanceTime thereafter, the period of the animation set would be returned. This would always generate the same SRT data, with the animation set in its final position.

How the return value of this function is generated depends on whether the animation set is configured to loop or ping pong. For example, imagine that we have called AdvanceTime many times and that the animation controller's track time (the timer of the track the animation set is assigned too) is now set to 155 seconds. Also imagine that the animation set which we are using is configured to loop each time its end is reached. Also, let us assume that this animation has a period of 50 seconds. The animation controller will pass this function the track time (155) and will get returned a value of 5 seconds. This is because at 155 global seconds, the animation set has looped three times and is now on the 5th second of its 4th iteration. Of course, the value returned would be different if the animation set was configured to ping-pong. Ping-Ponging is like looping except, when the animation set reaches the end, the timeline is traversed backwards to the beginning. When the beginning is reached, it starts moving forward again, and so on. Therefore, for every even loop the timeline is moving forward and for every odd loop it is moving backwards (assuming 0 based loop indexing). If we were to call this method on a ping-pong animation, we would get back a periodic position of 45 seconds. This is because it is beginning its fourth cycle and would be moving backwards (5 seconds from its total period of 50 seconds).

The following code might be used by the animation controller when it needed to fetch the SRT data for the first animation in an animation set during a call to AdvanceTime. TrackTime is the current time of the track (accumulated during AdvanceTime calls) which, in our example, is currently at 155 seconds. Do not worry about how the GetSRT function works for the time being; we will cover it in a moment. Just know that it fills the passed scale and translation vectors and the rotation quaternion with the correct interpolated keyframe data given the input local animation set time.

```
D3DXVECTOR3      Scale , Translate; // Used to store animations scale and position
D3DXQUATERNION   Rotate;            // Used to store animations new orientation

AnimationIndex    = 0;   // Get SRT data for first animation in set
TrackTime         = 155; // Accumulated global time of the track.

AnimSetLocalTime  = pAnimSet->GetPeriodicPosition ( TrackTime )
pAnimSet->GetSRT( AnimSetLocalTime, AnimationIndex, &Scale, &Rotate, &Translate );
```

The above code should give you a pretty good idea of the interaction between the animation controller and its animation sets. The important point here is that the animation set's GetSRT function expects to

be given a local time value which is fully contained within the range of time specified by its keyframe data. GetPeriodicPosition performs this mapping from a global time value, giving the animation controller the correct local time value to pass into the GetSRT function.

`UINT GetNumAnimations(VOID);`

This function accepts no parameters and returns an unsigned integer containing the number of animations being managed by this animation set. This tells the animation controller (or any caller for that matter) how many frames in the hierarchy are being manipulated by this animation set. Each animation in the animation set contains a frame name and SRT keyframe lists for that frame.

This function will be called by the animation controller during the call to AdvanceTime. The controller can then loop through these animations and call ID3DXAnimationSet::GetSRT for each one. This will generate the new SRT data for each frame in the hierarchy animated by this animation set. This SRT data is then used to build the matrix for each of these frames.

`HRESULT GetAnimationIndexByName( LPCSTR pName, UINT*pIndex )`

There may be times when your application wants to fetch the keyframe data for an individual animation within an animation set. You will see in a moment that there are methods of the ID3DXKeyframedAnimationSet interface that allow us to do this, but they must be passed the index of the animation. Often, your application might not know the index but will know the name of the animation/frame. Using this function we can pass in the name of the animation we wish to retrieve an index for and also pass the address of an unsigned integer. On function return, if an animation exists that animates the frame name, the index of this animation will be returned in the pIndex parameter. It is the index of the animation that the animation controller passes to the ID3DXAnimationSet::GetSRT function.

`HRESULT GetAnimationNameByIndex( UINT Index, LPCSTR *ppName );`

This function is the converse for the above one. If you know the index of an animation within an animation set, you can use this function to retrieve its name. As the first parameter you pass in the index of the animation whose name you wish to know, and in the second parameter you pass in the address of a string pointer. On function return, the string will contain the name of the animation. As this is also the name of the frame in the hierarchy to which the animation is attached, we can imagine how this could be very useful.

The animation controller itself might well use this function inside its AdvanceTime method. As mentioned previously, the AdvanceTime method will loop through each animation stored in the animation set and call GetSRT for it. Once this SRT data has been combined into a new matrix, that matrix should replace the parent-relative matrix data currently existing in the assigned frame. At this point, the animation controller has the new matrix and the index of the animation it was generated for, but does not yet have its name.

The following code snippet shows how the animation controller might use this function to get the name of the animation which it then uses to find the matching name in the hierarchy. Much of the detail is left out (such as the call to GetSRT for each animation and the construction of the new matrix) but hopefully you will get the overall idea.

```
for ( UINT i = 0 ; i < pAnimSet->GetNumAnimations(); i++ )
{
     …
     …
     // GetSRT would be called here and the new matrix (mtxFrame )
     // for this animation would be  generated
     …
     …
     LPCSTR pName = NULL;
     pAnimSet->GetAnimationNameByIndex( i, &pName );
     pFrame = D3DXFrameFind(m_pFrameRoot, pName );

     // Store the new matrix in the frame hierarchy
     pFrame->TransformationMatrix = mtxFrame;
}
```

The next function, GetSRT, is really the core of the interpolation system.

```
HRESULT GetSRT
(
    DOUBLE           PeriodicPosition,
    UINT              Animation,
    D3DXVECTOR3      *pScale,
    D3DXQUATERNION   *pRotate,
    D3DXVECTOR3      *pTranslate
);
```

This method is usually called by the animation controller to fetch the SRT data for a specified frame in the hierarchy. If no other animation set is being used which has an animation assigned to the same frame in the hierarchy, then this SRT data will be placed directly into the hierarchy frame matrix. Therefore we might say that this method generates the new matrix data for a specified frame in the hierarchy for a specified local time. If multiple animation sets are assigned to the animation mixer which animate the same frame in the hierarchy, then the resulting SRT data for that frame from **each** animation set will be blended together (by the animation controller) based on the current mixer track settings. The resulting blended data will then be placed into the frame matrix.

This function is passed the time (in seconds) in the local timeline of the animation that we would like to have the SRT data returned for. In other words, this function expects to be passed the periodic position in the animation set for which SRT data will be generated for the specified animation. We also pass in an integer as the second parameter describing the animation we would like the SRT data returned for. Remember, an animation is just a named container of keyframe data that is assigned to a frame in the hierarchy. Therefore, if the animation controller (or our application) would like to get the SRT data for a frame in the hierarchy called ‘Wheel_Frame’ for a global time of 406 seconds, we could do something like we see in the following code:

```
UINT              Animation ;
D3DXVECTOR3       Scale , Translate;
D3DXQUATERNION    Rotate;

// Get the index of the frames animation in the animation set
pAnimSet->GetAnimationIndexByName("Wheel_Frame" , &Animation );

// Map ever increasing track time to local time taking into account
// looping or ping-ponging
PeriodicPosition = pAnimSet->GetPeriodicPosition( 405 );

// Get the SRT data for that animation at 405 global seconds
pAnimSet->GetSRT( PeriodicPosition , Animation , &Scale , &Rotate , &Translate);

// Here the animation controller would use Scale, Rotate and Translate to
// build a new frame matrix
```

As the above code demonstrates, if you do not know the index of the animation within the animation set then you can use the GetAnimationIndexByName method to retrieve the index of the animation/frame with the specified name. We can then pass this index into the GetSRT Method. The code above is very similar to the call made by the animation controller to an animation set to fetch the SRT data for each of its animations.

Notice how we also pass in the address of a scale vector, a rotation quaternion and a translation vector. On function return, these three variables will be filled with the SRT data that can then be used to rebuild the matrix.

> **Note** : Our application will not need to call the GetSRT method directly to generate the SRT data for each animation. The animation controller will handle these calls on our behalf when we call ID3DXAnimationController::AdvanceTime. However, you do have access to the interface for each animation set, so your application could use an animation set object as a simple keyframe interpolator even if your application was not using the D3DX animation controller. For example, if you have your own animation system in place, you could manually create a D3DXKeyframedAnimationSet object, fill it with keyframe data and use it to interpolate SRT data for your own proprietary system.

In summary, when we call ID3DXAnimationController::AdvanceTime, the animation controller will loop through each of its active animation sets. For each animation set it will loop through each stored animation. For each animation it will call ID3DXAnimationSet::GetSRT. This function will return the scale, rotation and position that the assigned frame in the hierarchy should have based on the current time. When this process is finished and the SRT data for all animations in all active animations sets is handed back to the controller, it will then check to see if multiple SRT data exists for the same frame in the hierarchy. This can happen when two animation sets have an animation that animate the same frame in the hierarchy. When this is the case, the multiple SRT data sets for that frame are blended together and used to construct the final frame matrix. When only one set of SRT data exists (because a hierarchy frame is being animated by only a single animation set) the SRT data is used to build the frame matrix directly. However, the SRT data will still have the properties of the mixer track to which it is assigned applied to it. Therefore, if the mixer track to which the animation set was assigned was configured to scale the SRT data by 0.5 for example, that scaling process will still occur regardless of whether multiple animations are used or not. We will cover the animation mixer later when we examine the ID3DXAnimationController interface.

So we now know how the ID3DXAnimationSet::GetSRT function is used, but how does it return the SRT data for the requested animation? Although we do not have access to the original DirectX source code, we can, for the purpose of understanding the methodology, write our own version of the function. We will do this at the end of this section. This will demonstrate not only how the GetSRT function works (in case you need to derive your own animation set interfaces for use with the D3DX animation system), but also how it fits into grand scheme of things.

Keyframe Retrieval Functions

The ID3DXKeyframedAnimationSet interface also has several functions that allow an external process to query its underlying keyframe arrays. We can query the number of scale, rotate and translation keys that might exist for a given animation in the set or even retrieve those keyframes for examination. Usually, our application will not need to do this, but these functions can be useful for debugging purposes or for applications that need to manipulate keyframe data directly (like the animation set splitter application we will create in lab project 10.2).

```
UINT GetNumScaleKeys( UINT Animation );
```

This function takes a single parameter, which is the index of the animation we are querying. It returns an unsigned integer describing the number of scale keyframes stored in the animation set for the specified animation. We can use this function to determine how big an array of D3DXKEY_VECTOR3s we need to allocate if we need to retrieve the data (via a call to GetScaleKeys which will be covered in a moment).

```
UINT GetNumRotationKeys( UINT Animation );
```

This function takes a single parameter, which is the index of the animation we are querying. It returns an unsigned integer describing the number of rotation keyframes stored in the animation set for the specified animation. We can use this function to determine how big an array of D3DXKEY_QUATERNIONs to allocate if we need to retrieve the data (via a call to GetRotationKeys which will be covered in a moment).

```
UINT GetNumTranslationKeys( UINT Animation );
```

This function takes a single parameter, which is the index of the animation we are querying. It returns an unsigned integer describing the number of translation keyframes stored in the animation set for the specified animation. We can use this function to determine how big an array of D3DXKEY_VECTOR3s we need to allocate if we need to retrieve the data (via a call to GetTranslationKeys which will be covered in a moment).

HRESULT GetScaleKeys(UINT Animation, LPD3DXKEY_VECTOR3 pKeys);

This function is called to retrieve all scale keyframes stored within the animation set for the specified animation. We must pass the index of the animation we wish to enquire about and pointer to a pre-allocated array of D3DXKEY_VECTOR3 structures large enough to store every scale keyframe. The scale keys are then copied into this array by the function. The following code demonstrates this concept:

```
D3DXKEY_VECTOR3 *pSKeys = NULL;
pSKeys = new D3DXKEY_VECTOR3 [ pAnimSet->GetNumScaleKeys() ];
pAnimSet->GetScaleKeys( pSKeys );

… //Do something with key data here such as read it or copy it….

delete [] pSKeys;
```

Keep in mind that you are getting back a *copy* of the keyframe data, so modifying the data will not affect the behavior of the interpolator.

HRESULT GetScaleKey(UINT Animation, UINT Key,
LPD3DXKEY_VECTOR3 pScaleKeys);

This function is similar to the previous function except it allows us to retrieve only a single specified scale keyframe. We pass in the index of the animation we wish to retrieve the keyframe for, the index of the keyframe in the animation's keyframe array we wish to retrieve, and the address of a D3DXKEY_VECTOR3 structure. If the animation index and the key index parameters are valid, on function return the input structure in the third parameter will contain the scale keyframe at the specified index (UINT Key) in the specified animation (UINT Animation).

HRESULT GetRotationKeys (UINT Animation, LPD3DXKEY_QUATERNION pKeys);

This function is called to retrieve all rotation keyframes stored within the specified animation within the animation set. We must pass in the index of the animation we wish to retrieve the rotation keyframes for, and a pointer to a pre-allocated array of D3DXKEY_ QUATERNION structures large enough to store every rotation keyframe. The rotation keys are then copied into this array by the function.

HRESULT GetRotationKey(UINT Animation, UINT Key,
D3DXKEY_QUATERNION pRotationKeys) ;

This function is the single key version of the previous function. We pass in the animation index, the index of the rotation keyframe we wish to retrieve, and the address of a D3DXKEY_QUATERNION to fill. Remember that this is a copy of the keyframe you are being returned, so modifying it will not alter the behavior of the animation.

```
HRESULT GetTranslationKeys ( UINT Animation, LPD3DXKEY_VECTOR3 pKeys );
```

This function is called to retrieve all translation keyframes stored within the animation set for the specified animation. We pass the index of the animation we wish to retrieve the position keyframes for and a pointer to a pre-allocated array of D3DXKEY_VECTOR3 structures large enough to store every translation keyframe. The translation keys are then copied into this array by the function

```
HRESULT GetTranslationKey( UINT Animation, UINT Key,
                           LPD3DXKEY_VECTOR3 pTranslationKey );
```

This is the single key version of the function previously described. We pass in the index of the animation we wish to retrieve the keyframe for, the index of the translation keyframe we wish to retrieve, and the address of a D3DXKEY_VECTOR3. On successful function return, the vector will contain a copy of the requested key.

Changing Key Properties

The ID3DXKeyframedAnimationSet interface also exposes three methods (one for each keyframe type) that allow the changing of keyframe values on the fly. Each function takes three parameters. The first parameter is the index of the animation you wish to alter the key value for. The second parameter is the index of the key in the animation's S, R, or T lists that you wish to modify. The final parameter is the new key itself. This final parameter should be the address of a D3DXKEY_VECTOR3 structure if you are modifying a scale or translation key, or the address of a D3DXKEY_QUATERNION structure if you are updating a rotation key. These methods are listed next:

```
HRESULT SetRotationKey( UINT Animation, UINT Key,
                        LPD3DXKEY_QUATERNION pRotationKeys );

HRESULT SetScaleKey( UINT Animation, UINT Key,
                     LPD3DXKEY_VECTOR3 pScaleKeys );

HRESULT SetTranslationKey( UINT Animation, UINT Key,
                           LPD3DXKEY_VECTOR3 pTranslationKey );
```

The animation and the key must already exist in the animation set. That is to say, you can not add keys to an animation with these functions; you can only change the values of existing keys.

Removing Keys

Just as we have the ability to change the property of an already defined keyframe, methods are also available that allow for the removal of keyframes from the animation set. Three methods are exposed through which we can unregister scale keys, rotation keys and translation keys respectively. Each of these methods takes two parameters. The first is the index of the animation we wish to unregister a key for, and the second is the index of the key we wish to remove. These methods are shown below.

```
HRESULT UnregisterRotationKey( UINT Animation, UINT Key );

HRESULT UnregisterScaleKey( UINT Animation, UINT Key );

HRESULT UnregisterTranslationKey( UINT Animation, UINT Key );
```

It should be noted that you should not be unregistering keys during the main game loop or in any time critical section of your code. These functions are very slow because they require the animation set to resize the S, R, and T arrays (depending on which key you are unregistering). For example, if you use the UnregisterRotationKey function and specify a key index somewhere in the middle of the array, the array will need to be resized. This involves dynamically allocating a smaller array and copying the data from the old array into the new array (minus the key you just unregistered) before releasing the old key array from memory. Typically you might do something like this just after you have loaded an animated X file and wish to remove certain keyframes that are not needed.

Removing Animations

The ID3DXKeyframedAnimationSet interface also exposes a method that allows for the removal of an entire animation and all of its SRT data from the animation set. This might be useful if you loaded an animated X file that animated a frame in your hierarchy that you did not want animated.

```
HRESULT UnregisterAnimation( UINT Index );
```

This function takes a single parameter; the index of the animation you wish to unregister.

As an example, let us imagine that we loaded an animated X file and found that when playing its animation, one of the frames in the hierarchy that it animated was called ‘MyFrame1’. Let us also assume that for some reason we do not wish this frame to be animated by the animation set. After loading the X file, we could use the following code to unregister the animation that animates this frame. The code assumes pAnimSet is a pointer to a valid ID3DXKeyframedAnimationSet interface that has been previously fetched from the animation controller. We will cover how to retrieve interfaces for animation sets when we cover the ID3DXAnimationController method shortly.

```
UINT AnimationIndex;
pAnimSet->GetAnimationIndexByName(“MyFrame1”, &AnimationIndex );
pAnimSet->UnregisterAnimation ( AnimationIndex );
```

Retrieving the Ticks per Second Ratio

As previously discussed, keyframe timestamps in an animation set are defined internally using arbitrary units known as ticks. How many of these ticks are considered to equal one second in real time is largely dependant on the application which exported the animation data and the resolution the artist used on the timeline. A function is exposed by the animation set which allows the application to query the TicksPerSecond ratio in which its keyframe timestamps are defined.

DOUBLE GetSourceTicksPerSecond(VOID);

While our application will rarely need to call this method, the animation set object absolutely must know this value. After all, when the animation controller requires the SRT data for a given frame in the hierarchy, it calls the animation set's GetSRT method. This method accepts a time in seconds (not ticks), so the GetSRT function must covert the passed time in seconds into ticks to find the two bounding keyframes to interpolate between.

10.6.2 A Closer Look at GetSRT

In this section we will discuss how we could write our own GetSRT function for an animation set. This will be helpful if you need to derive your own version of an animation set that you will plug into the D3DX animation system. It will also allow us to better understand what the animation controller and its underlying animation sets are doing when we call ID3DXAnimationController::AdvanceTime.

While this source code is not the exact implementation of ID3DXKeyframedAnimationSet::GetSRT, it will return the same data. In fact, we have tested this code as a drop-in replacement and it works very well. This code is for teaching purposes only. Our goal is to look at and understand the interpolation process for SRT keyframes. You will not need to write a function like this in order to use the D3DX Animation System as it is already implemented in ID3DXKeyframedAnimationSet::GetSRT. Note as well that the application will never even have to call this function, because the animation controller will call it for each frame that is animated by each currently active animation set.

As our example function will not be a method of the ID3DXAnimationSet interface, we will add an extra parameter on the end. This will be a pointer to an ID3DXKeyframedAnimationSet interface. We will use this so that our function can fetch the keyframe data from the animation set. In the real method, this pointer is not needed and neither are the methods to fetch the keyframe data from the animation set since the keyframes are owned by the animation set and are directly accessible.

Remember when looking at the following code that this function has one job: to return the SRT data for a single frame/animation for a specified periodic position in the animation set's timeline. We will look at the code a section at a time. As with the function we are emulating, this function should be passed the periodic position and animation index we wish to retrieve the SRT data for, and should also be passed addresses for a scale vector, a rotation quaternion and a translation vector. On function return we will fill these with the interpolated scale, rotation and position information for the specified time. This function will demonstrate what happens behind the scenes when the animation controller calls ID3DXKeyframedAnimationSet::GetSRT for one of its animation sets for a given animation.

```
HRESULT GetSRT( double Time, ULONG Index, D3DXVECTOR3 * pScale,
                D3DXQUATERNION * pRotate, D3DXVECTOR3 * pTranslate,
                ID3DXKeyframedAnimationSet * pSet )
{
    ULONG i;
    double fInterpVal;
    LPD3DXKEY_VECTOR3 pKeyVec1, pKeyVec2;
    LPD3DXKEY_QUATERNION pKeyQuat1, pKeyQuat2;
```

```
    D3DXVECTOR3 v1, v2;
    D3DXQUATERNION q1, q2;

    // Validate parameters
    if ( !pScale || !pRotate || !pTranslate ) return D3DERR_INVALIDCALL;

    // Clear them out as D3D does for us :)
    *pScale     = D3DXVECTOR3( 0.0f, 0.0f, 0.0f );
    *pTranslate = D3DXVECTOR3( 0.0f, 0.0f, 0.0f );
    D3DXQuaternionIdentity( pRotate );

    ULONG ScaleKeyCount       = pSet->GetNumScaleKeys( Index );
    ULONG RotationKeyCount    = pSet->GetNumRotationKeys( Index );
    ULONG TranslationKeyCount = pSet->GetNumTranslationKeys( Index );
```

The first section simply initialises the passed scale and translation vectors to zero and sets the passed quaternion to identity. We then use the passed animation set interface to fetch the total number of scale, rotation, and translation keyframes. As discussed earlier, these three methods take, as their only parameter, the index of the animation we are interested in and return the count values. In the actual ID3DXKeyframedAnimationSet::GetSRT function there would be no need for this call because the keyframe data is stored in the animation set. But our mock function will need to access them in order to simulate the interpolation step.

In the next section we have to convert the passed periodic position into ticks. You will recall from our earlier discussion how each animation set has its keyframe timestamps specified in ticks. As the periodic position passed into the function is in seconds, we must multiply the periodic position by the TicksPerSecond value stored in the X file. You will also recall that there may be an AnimTicksPerSecond data object in the X file describing the timing granularity for the timestamps exported by the modelling application. If none is specified, then a default value of 4800 ticks per second is used. The animation set internally stores this ticks per second value. We can use another ID3DXKeyFramesAnimationSet interface method called ‘GetSourceTicksPerSecond’ to retrieve the number of ticks per second. By multiplying the periodic position (in seconds) by the ticks per second, we get the periodic position in ticks. This is the timing value used to define the keyframe timestamps.

```
    double TicksPerSecond     = pSet->GetSourceTicksPerSecond( );
    double CurrentTick        = Time * TicksPerSecond
```

Notice how in the above code we store the period position converted into ticks in the CurrentTick local variable.

As our function is not a method of ID3DXKeyframedAnimationSet and therefore does not have direct access to its keyframe arrays, the following code will need to fetch the keyframes from the animation set. We therefore allocate the (possible) three keyframe arrays (scale, rotation and translation) using the count values previously fetched, and then pass these arrays into the GetScaleKeys, GetTranslationKeys and GetRotationKeys to fetch copies of the keyframe arrays for the specified animation. Remember, the index of the animation we wish to fetch was passed in as the ‘index’ parameter.

```
    D3DXKEY_VECTOR3 * ScaleKeys = NULL;
    D3DXKEY_VECTOR3 * TranslateKeys = NULL;
    D3DXKEY_QUATERNION * RotateKeys = NULL;
```

```
    if(ScaleKeyCount )
       ScaleKeys = new D3DXKEY_VECTOR3[ ScaleKeyCount ];

    if(TranslationKeyCount)
      TranslateKeys= new D3DXKEY_VECTOR3[ TranslationKeyCount ];

    if( RotationKeyCount )
      RotateKeys = new D3DXKEY_QUATERNION[ RotationKeyCount ];

    if ( ScaleKeyCount )      pSet->GetScaleKeys( Index, ScaleKeys );
    if ( TranslationKeyCount )pSet->GetTranslationKeys( Index, TranslateKeys );
    if ( RotationKeyCount )   pSet->GetRotationKeys( Index, RotateKeys );
```

At this point, we have the keyframe data for the animation we wish to generate interpolated SRT data for. Now it is time to examine each array in turn and perform the interpolation. We will start by looking at the generation of the interpolated scale data.

In order to perform keyframe interpolation, we must find the two keyframes that bound the current tick time. Therefore, we loop through each scale key searching for the correct pair. If we find two consecutive keyframes where the current tick is larger or equal to the first and smaller or equal to the second, then we have found our bounding keyframes. When this is the case, we store these two keyframes in pKeyVec1 and pKeyVec2 and break from the loop.

```
    // Calculate an interpolated scale by finding the
    // two key-frames which bound this timestamp value.
    pKeyVec1 = pKeyVec2 = NULL;
    for ( i = 0; i < ScaleKeyCount - 1; ++i )
    {
        LPD3DXKEY_VECTOR3 pKey     = &ScaleKeys[i];
        LPD3DXKEY_VECTOR3 pNextKey = &ScaleKeys[i + 1];

        // Do these keys  bound the requested time ?
        if ( CurrentTicks >= pKey->Time && CurrentTick <= pNextKey->Time )
        {
            // Store the two bounding keys
            pKeyVec1 = pKey;
            pKeyVec2 = pNextKey;
            break;

        } // End if found keys
    } // Next Scale Key
```

At this point, we have the two scale keyframes which must be interpolated. Next we copy the 3D scale vectors from each keyframe (stored in D3DXKEY_VECTOR3::Value) into 3D vectors v1 and v2. We have discussed interpolation several times in prior lessons and this interpolation is no different. We calulate the time delta between the current tick and the first keyframe's timestamp, and then we divide that by the time delta between both timestamps. This returns a value in the range of 0.0 to 1.0 which can be used to linearly interpolate between the two 3D vectors. The result of the linear interpolation is stored in 'pScale' so that it is accessible to the caller on function return.

```
    // Make sure we found keys
    if ( pKeyVec1 && pKeyVec2 )
```

```
    {
        // Interpolate the values
        v1 = pKeyVec1->Value;
        v2 = pKeyVec2->Value;
        fInterpVal  = CurrentTick - pKeyVec1->Time;
        fInterpVal /= (pKeyVec2->Time - pKeyVec1->Time);
        D3DXVec3Lerp( pScale, &v1, &v2, (float)fInterpVal );
    } // End if keys were found
```

Notice in the above code that we use the 3D vector interpolation function provided by D3DX. D3DXVec3Lerp performs the interpolation between 3D vectors v1 and v2 using the passed interpolation percentage value. This function simply does the following:

V1 + fInterpVal * (V2 – V1)

As fInterpVal is a value between 0.0 and 1.0, we can see how the resulting vector will be a vector positioned somewhere between these two keyframes. We have now successfully generated the S component of the SRT data that the function needs to return.

Our next task is to interpolate the rotation component of the SRT data. We do this is very much the same way. We first loop through every keyframe in the rotation keyframe array (remember that these are stored as quaternions) and search for the two keyframes the bound the current tick.

```
    // calculate an interpolated rotation by finding the
    // two key-frames which bound this timestamp value.
    pKeyQuat1 = pKeyQuat2 = NULL;
    for ( i = 0; i < RotationKeyCount - 1; ++i )
    {
        LPD3DXKEY_QUATERNION pKey     = &RotateKeys[i];
        LPD3DXKEY_QUATERNION pNextKey = &RotateKeys[i + 1];

        // Do these keys bound the requested time ?
        if ( CurrentTick >= pKey->Time && CurrentTick <= pNextKey->Time )
        {
            // Store the two bounding keys
            pKeyQuat1 = pKey;
            pKeyQuat2 = pNextKey;
            break;
        } // End if found keys
    } // Next Rotation Key
```

Now that we have found the two quaternions that describe the rotation to interpolate, we will interpolate between the two quaternions using the D3DXQuaternionSlerp method. Performing a spherical linear interpolation (SLERP) is one of the main reasons quaternions are used to represent rotations. Rather than linearly interpolate between the rotation angles which would cut a straight line from one to the other, a spherical linear interpolation allows us to interpolate along an arc between the rotations. This provides much smoother and more consistent movement from one rotation to the next. If we imagine that the two rotation vectors describe two points on a sphere, slerping between them will follow the path from one point to the next over the surface of the sphere. A linear interpolation would cut a straight line through the sphere from one point to the other.

```
    // Make sure we found keys
    if ( pKeyQuat1 && pKeyQuat2 )
    {
        // Interpolate the values
        D3DXQuaternionConjugate( &q1, &pKeyQuat1->Value );
        D3DXQuaternionConjugate( &q2, &pKeyQuat2->Value );
        fInterpVal  = CurrentTick - pKeyVec1->Time;
        fInterpVal /= (pKeyVec2->Time - pKeyVec1->Time);
        D3DXQuaternionSlerp( pRotate, &q1, &q2, (float)fInterpVal );
    } // End if keys were found
```

Notice how the above code converts the quaternions for compliance with a left-handed coordinate system by using the D3DXQuaternionConjugate function. This function negates the sign of the *x*,*y*,*z* components of the quaternion (the rotation axis), essentially flipping it to point in the opposite direction. The reason we do not need to negate the *w* component (the rotation angle) also is that the D3DX functions expect the *w* component of the quaternion to represent a counter-clockwise rotation about the axis. This is the opposite direction that rotations are interpreted in a matrix. Therefore, by flipping the axis and not changing the sign of *w*, we essentially end up with the rotation axis flipped so that it now represents the same axis in a left-handed coordinate system with a *w* component giving us a clockwise rotation about this axis. Note as well how the result of the slerp is stored in the quaternion structure passed into the function so that it is accessible the caller on function return.

Finally, we interpolate the translation vector using the two bounding keyframes. This code is almost identical to the code that interpolates the scale vectors, so it is shown in its entirety below.

```
    // Calculate an interpolated translation by finding the
    // two key-frames which bound this timestamp value.
    pKeyVec1 = pKeyVec2 = NULL;
    for ( i = 0; i < TranslationKeyCount - 1; ++i )
    {
        LPD3DXKEY_VECTOR3 pKey     = &TranslateKeys[i];
        LPD3DXKEY_VECTOR3 pNextKey = &TranslateKeys[i + 1];

        // Do these keys bound the requested time ?
        if ( CurrentTick >= pKey->Time && CurrentTick <= pNextKey->Time )
        {
            // Store the two bounding keys
            pKeyVec1 = pKey;
            pKeyVec2 = pNextKey;
            break;
        } // End if found keys
    } // Next Translation Key

    // Make sure we found keys
    if ( pKeyVec1 && pKeyVec2 )
    {
        // Interpolate the values
        v1 = pKeyVec1->Value;
        v2 = pKeyVec2->Value;
        fInterpVal  = CurrentTick - pKeyVec1->Time;
        fInterpVal /= (pKeyVec2->Time - pKeyVec1->Time);
        D3DXVec3Lerp( pTranslate, &v1, &v2, (float)fInterpVal );
    } // End if keys were found
```

Finally, with the SRT data correctly interpolated and stored correctly, this version of the function must delete the key arrays that were temporarily allocated to retrieve the keyframe data from the animation set. Obviously, the ID3DXKeyframedAnimationSet::GetSRT method would not need to allocate or deallocate these arrays as it would have direct access to the keys.

```
    if ( ScaleKeys ) delete []ScaleKeys;
    if ( RotateKeys ) delete []RotateKeys;
    if ( TranslateKeys ) delete []TranslateKeys;

    // Success !!
    return D3D_OK;
}
```

There are still a few methods of the ID3DXKeyframedAnimationSet that we have not yet covered. Primarily, the ones we are most interested in for this chapter are those we will use to register callback functions that are triggered by keyframes. We will look at these methods later when we cover the D3DX animation callback system.

10.6.3 D3DXCreateKeyFramedAnimationSet

There will be times when you will be unable to use D3DXLoadMeshHierarchyFromX to load animation data. For example, you may be creating runtime animation data for the animation controller or perhaps loading a custom animation file. In these cases you will need to know how to manually build D3DXAnimationSet objects so that you can register them with the animation controller yourself. D3DX exposes a global function for this purpose called D3DXCreateKeyFramedAnimationSet. The function is shown below with its parameter list followed by a description of each parameter.

```
HRESULT WINAPI D3DXCreateKeyframedAnimationSet
(
    LPCSTR pName, DOUBLE TicksPerSecond,
    D3DXPLAYBACK_TYPE Playback,
    UINT NumAnimations, UINT NumCallbackKeys,
    CONST LPD3DXKEY_CALLBACK *pCallKeys,
    LPD3DXKEYFRAMEDANIMATIONSET *ppAnimationSet
);
```

Let us discuss the parameters to this function one at a time:

LPCSTR *pName*

This function allows you to assign the animation set a name. While not required it is often more intuitive to work with named animation sets. You will see when we cover the ID3DXAnimationController interface shortly, that one of the things we will often want to do is have it return us a pointer to one of its animation sets. While we can fetch animation sets by index, it is often preferable to use ID3DXAnimationController::GetAnimationSetByName function (covered shortly). It is certainly more intuitive when looking at animation code to see references to animation sets such as ‘Walk’ or ‘Run’ instead of indices like 2 or 4. This parameter is analogous to the name that may be assigned to an AnimationSet data object in an X file.

DOUBLE *TicksPerSecond*

When creating an animation set manually, we will be responsible for filling its SRT keyframe arrays. Therefore, the units of measurement used for keyframe timestamps (ticks) are completely up to us. We must inform the animation set, at creation time, the number of ticks per second that we will be using in our keyframe timestamps. This is needed because the GetSRT method (called by the animation controller) is passed a periodic position in seconds which must be converted to ticks. This is the means by which correct bounding keyframes are found.

D3DXPLAYBACK_TYPE *Playback*

This parameter is used to inform D3DX how we would like the mapping between global time (the time of the track the animation set is assigned to) and the animation set's local time (the periodic position) to be performed. You will recall that before the animation controller calls ID3DXAnimatonSet::GetSRT, it must first map the global track time the animation set is assigned to into the animation set's local time using the ID3DXAnimationSet::GetPeriodicPosition function. It is this function that returns the local animation time that is passed into GetSRT. With this parameter we can choose how this function calculates the periodic position of the animation set and thus how the animation set behaves when the track time exceeds the animation sets total period.

For example, we can configure the GetPeriodicPosition method such that if the track time passed in exceeds the period, the periodic position is wrapped around, causing the animation set to continuously loop as the global time climbs ever higher. Therefore our application can repeatedly call ID3DXAnimationController::AdvanceTime without worrying about whether the accumulated global time of the controller (and each of its tracks) is inside or outside the period of the animation set.

Alternatively, we can choose for the mapping to occur such that if the global time exceeds the period of the animation, the animation set essentially stops playing (remains frozen at its last keyframe). Using this mapping, as soon as the track time exceeds the period of the animation set assigned to that track, the animation set stops playing.

Finally, we can make the GetPeriodicPosition method map the track time to a periodic position using ping-ponging. As discussed previously, when this mapping is used, when the animation set period is exceeded, its periodic position starts to backtrack towards the beginning of the local timeline. When the beginning is reached, the timeline direction is flipped again so that the periodic position starts moving forwards towards the end of the timeline, and so on.

We can specify the three possible behaviors of the animation set we are creating using a member of the D3DXPLAYBACK_TYPE enumeration:

```
typedef enum _D3DXPLAYBACK_TYPE {
    D3DXPLAY_LOOP = 0,
    D3DXPLAY_ONCE = 1,
    D3DXPLAY_PINGPONG = 2,
    D3DXEDT_FORCE_DWORD = 0x7fffffff
} D3DXPLAYBACK_TYPE;
```

To better understand how the three modes cause the GetPeriodicPosition function to map global track time to periodic positions differently, let us examine the case of an animation

set that has a period of 25 seconds. Let us also assume that the track time we wish to map to a periodic position (to feed into the GetSRT function) is currently at 30 seconds.

D3DXPLAY_LOOP
If the animation set is created with this option, then when a global track time of 30 seconds is reached by the animation controller, the GetPeriodicPosition method of the animation set will return a periodic position of 5 seconds. This is because the animation set has reach the end and is now five seconds (30 – 25) into its second loop.

D3DXPLAY_ONCE
If the animation set is created with this option, then after 25 seconds the animation would stop playing. The frame matrix would be essentially frozen in the position specified by its final SRT keyframes. At 30 seconds of global track time, the animation would have stopped playing 5 seconds earlier.

D3DXPLAY_PINGPONG
If the animation set is created with this option, then at 30 seconds global track time, the GetPeriodicPosition method would return a periodic position of 20 seconds. This is because the period of the animation set was reached 5 seconds earlier (at 25 seconds) and has backtracked 5 seconds from the end towards the beginning (25 – [30-25]).

UINT *NumAnimations*
When we create an animation set we must specify the maximum number of frames in the hierarchy it should be capable of containing animations for. As previously discussed, each animation contains a frame name and SRT keyframe arrays for that frame. Although we are allocating room for the maximum number of animations at animation set creation time, the keyframe data will be added to each animation as a separate step once it has been created. We shall see this in a moment.

UINT *NumCallbackKeys*
CONST LPD3DXKEY_CALLBACK **pCallKeys*
These parameters will be covered later in the chapter when we discuss the D3DX animation system's callback mechanism. Just know for now that you have the ability to pass in a series of callback keys. Each key contains a timestamp and a collection of data. When one of these callback keys is encountered in the timeline during an animation update, this data can be passed to an application defined callback function that performs some arbitrary task (e.g. playing a sound effect or disabling the animation track). Callback keys are defined per animation set instead of per animation. While they too are defined using ticks, they are handled quite differently by the controller and animation set. For this reason, we will forget about them for now and revisit them later. For now, let is just assume that we will pass in NULL as these two parameters. This informs D3DX that this animation set will not have any callback events registered with it.

LPD3DXKEYFRAMEDANIMATIONSET **ppAnimationSet*
As the final parameter to this function we must pass in the address of an ID3DXKeyframedAnimationSet interface pointer. On successful function return, it will be a pointer to the interface for the newly created animation set object.

An important thing to note is that in order for animation sets to be used, they must be *registered* with an animation controller. This is because the ID3DXAnimationController::AdvanceTime function ultimately controls all animation processing. If the animation set is not registered with the animation controller, the animation controller will have no knowledge of the animation set and will not use it. Therefore, we can think of this function as returning an animation set that is currently a detached object (i.e., not yet plugged into the animation subsystem). We will shortly discuss how to manually create an ID3DXAnimationController and how to register animation sets with it, but for now you can rest assured that when we use D3DXLoadMeshHierarchyFromX and specify an X file that contains animation data, all of this will be handled for us automatically.

Note as well that when D3DX loads an X file that contains multiple animation sets, although all animation sets will be registered with the returned animation controller, only the last animation set defined in the X file will be assigned to an active track on the animation mixer (track 0). This is why we do not have to configure the animation controller passed back to our application in Lab Project 10.1. The X file in that project contains only a single animation set and it is automatically assigned to track 0 on the animation mixer by the D3DX loading function. Thus it is ready for immediate playback. If an X file contains multiple animation sets, and the last animation set is not the first one you would like to playback, you can use the ID3DXAnimationController interface to assign a different animation set to that track (or to another enabled track if you intend to do animation blending).

Manually Populating the Animation Set

After a keyframed animation set has been manually created, it is initially empty and contains no SRT data. The next task of the application will usually be to add the SRT data for each frame in the hierarchy that this animation set intends to animate. We call the ID3DXKeyframedAnimationSet::RegisterAnimationSRTKeys method to place the SRT data for a single frame in the hierarchy into the animation set. In other words, if you wanted your animation set to animate five frames in your hierarchy (five animations), then you would call this method five times. Each call would specify the SRT data for a single frame. The method is shown below with a description of each of its parameters.

```
HRESULT RegisterAnimationSRTKeys
(
    LPCSTR pName,
    UINT NumScaleKeys,
    UINT NumRotationKeys,
    UINT NumTranslationKeys,
    CONST LPD3DXKEY_VECTOR3 *pScaleKeys,
    CONST LPD3DXKEY_QUATERNION *pRotationKeys,
    CONST LPD3DXKEY_VECTOR3 *pTranslationKeys,
    DWORD *pAnimationIndex
);
```

LPCSTR pName
This parameter is how we inform the animation set which frame in the hierarchy the keyframe data we are passing in is intended for. This string should contain the name of a frame in the hierarchy and thus

this also becomes the name of the animation itself. This is the animation name you would use in calls to methods like ID3DXAnimationSet::GetAnimationIndexByName if you wished to retrieve the index of the animation within the animation set's internal animation array.

UINT NumScaleKeys
UINT NumRotationKeys
UINT NumTranslationKeys
These three parameters (any of which may be zero) inform the animation set how many separate scale, rotation and translation keyframes we are going to register with the animation set for this animation. This allows the function to allocate the internal SRT arrays of the animation to the requested size. It also informs the function how many keys to expect in the arrays we pass in using the next three parameters.

CONST LPD3DXKEY_VECTOR3 ***pScaleKeys***
CONST LPD3DXKEY_QUATERNION ***pRotationKeys***
CONST LPD3DXKEY_VECTOR3 ***pTranslationKeys***
These three parameters are used to pass in the already allocated and populated arrays of the scale, rotation and translation keyframes. The application should have allocated these arrays and populated them with keyframe data prior to registering them with the animation set. The animation set will copy these keyframes into its internal SRT arrays and thus, these arrays may be released from memory after the function has returned. Any of these pointers can be set to NULL, indicating that there is no keyframe data of that type. For example, if the pScaleKeys parameter is set to NULL then this animation does not contain any scale animation data. You should also make sure that if this is the case, the NumScaleKeys parameter is also set to zero.

DWORD ***pAnimationIndex***
For the final parameter we can pass in the address of a DWORD which on function return will contain the index of the animation we have just created. The application may wish to store this away and use it later to access the animation keys without having to first call GetAnimationIndexByName to retrieve the index first. You may pass NULL as this parameter if you do not wish to store the index of the animation about to be created.

To better understand the creation process, the following example code will create an ID3DXKeyframedAnimationSet and will add animation data to it for a frame in the hierarchy called 'MyFrame'. In this simple example, the animation data will contain just two scale keys at timestamps of 0 and 2000 ticks. This animation set will be created with a ticks per second ratio of 100. This means the first keyframe will be executed at 0 seconds and the second keyframe will be executed at 20 seconds (2000 / 100).

```
// Create new keyframed anim set called "Anim1" with a 100m ticks per second
// It is looping, will contain 1 animation and will have 0 callback keys (0,NULL)
ID3DXKeyframedAnimationSet * pAnimSet = NULL;
D3DXCreateKeyFramedAnimationSet("Anim1",100,D3DXPLAY_LOOP, 1, 0, NULL, &pAnimSet);

// Let us now allocate an array of two scale keys. At time zero the frame matrix
// is scaled by 5 and at time 2000 ( 20 seconds ) the matrix is scaled 10x
D3DXKEY_VECTOR3 ScaleKeys[2];
ScaleKeys[0].Time = 0;
ScaleKeys[0].Value= D3DXVECTOR3( 5 , 5 , 5);
ScaleKeys[1].Time = 2000;
```

```
ScaleKeys[1].Value= D3DXVECTOR3( 10 , 10 , 10);

// Now add a new animation to the animation set for 'MyFrame'. It has:
// 2 scale key, 0 rotation keys, 0 translation keys. We pass in the ScaleKeys
// array and pass NULL for the other two key types. We also pass in NULL as the
// animation index which we do not require in this example.
pAnimSet->RegisterAnimationSRTKeys("MyFrame",2,0,0,ScaleKeys,NULL,NULL,NULL);
```

At this point we have an animation set with keyframe data for a single frame in the hierarchy but it is still not plugged into the D3DX animation system. For that to happen we must register the animation set with the animation controller (covered shortly). Once that is done, we can assign it to tracks on the animation mixer and play it back in response to calls to ID3DXAnimatonController::AdvanceTime by the application.

In the next section we will finally discuss the ID3DXAnimationController interface. While it exposes a great many methods (thus making it very flexible), do not feel intimidated. We have already learned that using the animation controller can be very straightforward for basic animation tasks (see Lab Project 10.1). At its simplest, we can call a single method (AdvanceTime) to play our animations. However, we can do many more exciting things with this powerful interface, so let us begin to explore how it works.

10.7 The ID3DXAnimationController Interface

As discussed in the last section, there may be times when D3DXLoadMeshHierarchyFromX is not an option available to us for loading animation data. In those cases, we will have to tackle things manually. Just as there are D3DX functions to manually create keyframed animation sets, there is also a global D3DX function that allows us to create an animation controller to manage them. This function is called D3DXCreateAnimationController. Examining the parameter list to this function will help us to better understand the various internal components of animation controller objects and how they work together. So we will break with tradition and cover the manual creation of the animation controller first. But before we cover this function and its parameters, let us first briefly review, at a high level, what the D3DXAnimationController is and what its responsibilities are in the animation system. This is the interface we are returned from D3DXLoadMeshHierarchyFromX and often is the only interface in the D3DX animation system that our application will work with directly. You are reminded that you do not need to create an animation controller manually if you are loading the data from an X file (D3DX creates the animation controller for you and returns it from the loading function). However there may be times when the animation controller created by D3DXLoadMeshHierarchyFromX is not suitable for our application's needs. In such cases, we will need to know how to create or clone a new controller.

Animation Set Manager

Just as the ID3DXKeyframedAnimationSet can be thought of as an animation manager, the ID3DXAnimationController can be thought of as an ID3DXAnimationSet manager. The

ID3DXAnimationController interface can be used to assign any of its currently managed animation sets to tracks on its internal animation mixer. These tracks can be played back individually or blended together to create complex animation sequences. Each track on the animation mixer has several properties which can be set (speed, position, weight, etc.) to influence the way a given animation set assigned to the track plays back at runtime.

Manually creating an animation controller starts us off with an empty container (much like manually creating an animation set). On its own it is not much use because it does not currently have any animation data assigned to it for management purposes. So the first thing we will usually do after creating an animation controller is call its RegisterAnimationSet method to register various (already created) animation sets. Once an animation set has been registered with the animation controller, it will need to be assigned to a mixer track if we intend to use it during playback to influence the matrices in our frame hierarchy. From there, any calls to AdvanceTime will cause the animation set to update the appropriate nodes in the hierarchy as defined by the artist/animator.

Animation Set Mixer

Animation set registration does not activate the animation -- the animation set must be assigned to an active mixer track for the pre-recorded sequence to be played. When an application calls ID3DXAnimationController::AdvanceTime, only currently active tracks on the animation mixer will have their periodic positions updated. Actually, it is the track the animation set is assigned to which has its own local time which is updated and not the animation set itself. It is the track's time that is used to generate the periodic position of the animation set which in turn is used to generate the SRT data. Therefore, when we call the AdvanceTime method of the animation controller, this elapsed time is also added to the local clocks of each track. By using the track time to generate the periodic position of its assigned animation set, we have the ability to forward or rewind the timeline of individual animation sets on their tracks.

While an animation controller might have many animation sets registered with it, it might currently have only one set assigned to an active track. This would be the only set used to update the hierarchy during the AdvanceTime call. This approach allows the application to play different animation sets at different times simply by assigning animation sets to active tracks when they need to be played. If we have multiple animation sets assigned to active tracks on the mixer, all of those animation sets will affect their respective frames in the hierarchy simultaneously. The final transformation for a given frame in the hierarchy will be the blended result from each animation in each active animation set that is linked to that specific frame.

The ID3DXAnimationController interface has many functions that govern how animation sets are assigned to the various tracks on the mixer and how much weight those sets will contribute to the final blended result. Animation set weighting allows us to play, for example, two animations that might both manipulate some of the same frames in the hierarchy, but allows one set to have more influence over the final result than the other. For example, the first animation set might influence a given frame at 75% of its full weight while the second set only influences the same frame at 25% of its full weight. So while both animation sets have influenced the hierarchy, there was a 3:1 influence ratio in favor of the first set (thus the animations stored in set one would be more visually dominant than those in set two).

Frame Matrix Updates (Animation Outputs)

We have said on a number of occasions that the animation controller uses its animations to manipulate frames in the hierarchy. In truth, the animation controller is really only concerned with the frame matrices themselves for a given named animation. In truth, we could connect them to any arbitrary matrices we choose -- not necessarily only matrices in a frame hierarchy. We will see momentarily that the animation controller maintains a list of pointers to all the frame matrices in the hierarchy that it needs to animate. Internally these matrix pointers are stored in an array so that the animation controller can quickly access them when it needs to rebuild them (when AdvanceTime is called). These matrices that will receive the final SRT output from the mixer are referred to as "Animation Outputs" by D3DX. Thus, as we will see in the next section when we build an animation controller manually, in addition to registering all of the animation sets with the controller, we must also register all of the output matrices in the hierarchy that the animation controller will need to update, so that it has access to those matrix pointers. If a frame's matrix is not registered with the animation controller, then it cannot be manipulated by any of its registered animations (even though those animations are linked to frames in the hierarchy by name). In fact, when we register a matrix with the animation controller, we must also give it a name. This matrix name must match the name of the animation that will be used to animate that frame.

Of course, all of this is handled on our behalf if we use D3DXLoadMeshHierarchyFromX. D3DX will assign each animation within an animation set the name of the frame that it animates (if one exists) and the matrix of that frame will also be registered with the animation controller using the same name as the animation. If we have a frame in our hierarchy called 'RotorBlades', then when D3DX creates the animations(s) that animate this frame, they too will be assigned the name 'RotorBlades'. Furthermore, the transformation matrix of that frame will be registered as an animation output in the animation controller's matrix table and assigned the name 'RotorBlades' as well. This clearly establishes the relationship between the matrix and the animation which alters its value with animation results.

When we manually create our own animation controllers, we will register frame matrices using the ID3DXAnimationController::RegisterAnimationOutput function. It is important to note however that because of the nature of hierarchical data structures (any changes to a matrix will affect all child frame matrices) we must register *all* matrices that the animation controller needs to rebuild. This means that in our example, we must not only register the transformation matrix of our RotorBlade frame, but all child frame matrices of the RotorBlade frame as well. This allows the animation controller to correctly update all affected matrices. While this sounds rather tedious, fortunately there is a global D3DX function to handle this matrix registration with a single function call -- it is called D3DXFrameRegisterNamedMatrices and we will look at it a little later. Basically, we just pass this function a pointer to the root frame of our hierarchy and a pointer to our animation controller interface, and it will step through the hierarchy and register all of the matrices that belong to 'named' frames in the hierarchy. Thus we can manually register all of our matrices with the animation controller with a single function call.

> **Note:** D3DXLoadMeshHierarchyFromX will automatically create the animation controller and register all animation sets and matrices. This means that the returned animation controller interface can be used immediately for hierarchy animation as seen in Lab Project 10.1.

You might have a concern about the dependency of the system on names, given our earlier discussion about the optional nature of frame names in X files. Not to worry however. While it is true that an X file frame data object may not be assigned a name, this will not be the case if that frame is being animated. Remember that inside the X file the Animation data object (i.e. keyframe data) is linked to a frame by embedding the frame's name inside the Animation object as a data reference object. If the frame did not have a name, it could not be bound to any animation inside the X file either. So we can be confident that animated frames within the X file will always have assigned names. D3DX will thus have what it needs to register both the animation assigned to a frame and its matrix with the animation controller, to sustain the link between them.

Memory Management

Animation controllers have a number of restrictions that can be imposed on them by the application or by D3DX at creation time. These limitations allow us to create more memory-friendly animation controllers that conserve space. For example, if we only plan to use one animation set at a time, then we know that we only need to use one track on the animation mixer. It would be wasteful if the mixer was always created with 128 tracks for example. Likewise, it would be wasteful for the animation controller to be created with a matrix pointer array large enough to animate a maximum of 1000 matrices if we only wish to animate a single matrix in our hierarchy. The same is true with regards to how many animation sets must be set up for management. If we know that we will only register four animation sets in total with the controller, it would be wasteful to create an animation controller that was capable (at the cost of some internal memory overhead) of managing 20 animation sets.

While these figures are arbitrary, the important point is that when an animation controller is created manually (using the D3DXCreateAnimationController function), such size restrictions are set at this point and remain fixed for the lifetime of the controller. In the case of the D3DXLoadMeshHierarchyFromX function, D3DX will create the animation controller for us, so setting these limitations is out of our hands. We will see in a moment exactly what the limitations of the animation controller created by D3DX are when we cover manually creating one.

While these restrictions are fixed for a given controller after creation, the ID3DXAnimationController does include a Clone function which allows us to create a new animation controller from an existing one (such as the one D3DX created on our behalf). Much like we saw in Chapter Eight when discussing the cloning of meshes, when we clone a new controller we will be able to extend the capabilities of the original controller. Therefore, if the capabilities of the animation controller that D3DXLoadMeshHierarchyFromX created for us did not meet our requirements, we can clone the animation controller into a version that does. The new controller would retain all of the registered animation sets and keyframe data, so we do not have to rebuild or re-register them. This allows us to make a copy of the animation controller but extend its features (ex. increase the maximum number of tracks or maximum number of matrices, etc.) much as we did with meshes in Chapter Eight.

Sequencing

The animation controller also implements an event scheduler referred to as the sequencer. Using methods exposed by the ID3DXAnimationController interface, we can set events on the controller's *global* timeline which modify the properties of a specific mixer track (or its clock) when that event is triggered. When we register events with the sequencer, we must make sure that we understand which timeline those events are being scheduled for. For example, we know that every time we call AdvanceTime, the elapsed time passed into the function is added to the global time of the animation controller. Not an awful lot happens with the global time of the animation controller if sequencing is not being used. Essentially it is just a running total of elapsed time. To be clear, this global time is *not* the time used to map to a periodic position in an animation set. That is the track time. We discussed earlier in this chapter that when we call AdvanceTime and the global time of the controller is updated, the same elapsed time is also added to the timers of each active track on the mixer. It is the timer/clock of a track that is used to map to a periodic position in its animation set prior to any GetSRT calls.

It may seem strange at first for the controller to maintain a global timer and a timer for each track when essentially the same elapsed time passed into the AdvanceTime function is added to all of the timers simultaneously. If this is the case, then it would seem that the global time of the controller and the timers of each track would always have the same time as one another. After all, they all start off at zero and have the same elapsed time added to them every time AdvanceTime is called by the application. While this is certainly true if we are performing nothing more complex than simple AdvanceTime calls, we will see that we can decouple the global timer from the track timers by adjusting the properties of each track. The sequencer allows us to schedule events in global time that will alter the properties of given track or even its timer. For example, we could set an event that is triggered at a global time of 10 seconds which disables a specific track and its assigned animation set. We could also set another event at 20 seconds (global time) that would re-enable that same track. At this point, the timer of the track would be different from the global timer because it was not being updated along with the global timer after it was disabled. Thus, in this scenario, when the global time has accumulated to 25 seconds, the track (which was disabled for 10 seconds) would have a timer that contains 15 seconds of accumulated time. Again, it is the 15 second track time that would be mapped into a periodic position and used to fetch the SRT data of animations in its assigned animation set.

Another example demonstrating that sequencer events are added to the global timeline is one in which we intend to alter the timer of a track at a specific global time. For example, imagine we have an animation set with a period of 20 seconds. Let us also imagine that we set an event on the sequencer at 20 seconds that will set the timer of the track back to zero. Let us also assume that this animation set is not configured for looping, that is to say, it is designed to play through only once.

In this scenario, the application would call AdvanceTime repeatedly, thus updating both the global time of the controller and the track time of the animation set by the same amount. At 20 seconds global time, an event is found on the global timeline that alters the track timer of our animation set back to zero. At this point, the track time would be zero and the global time would be 20. At 30 seconds global time, the animation set would be 10 seconds into its second iteration even though the animation set was not configured to loop. This is because we manually set the track timer back to zero at a global time of 20 seconds, which starts that track playing from the beginning again. As far at that animation set is

concerned, it is like it is playing for the first time. What would happen at a global time of 40 seconds? Would the track, having reached the end of its period for a second time, loop back to the beginning again? No, it would not. We have already said that the animation is not set to loop and as we have no event set on the sequencer for 40 seconds, no action is taken. At 41 seconds, the track time will be set at 21 seconds. When the track time of 21 is mapped to the periodic position of the animation set, it is found to have exceeded its period. Since the animation set is not configured to loop, at 21 seconds (track time) the animation has finished.

Finally, imagine that we had also scheduled an event that reset the track time back to zero again at a global time of 100 seconds. When a global time of 100 seconds was reached, the animation would start to run from the beginning again (once) for the next twenty seconds, until the track timer once again exceeded 20 seconds (the period of the non-looping animation set). Therefore, for the global time period 100-120 seconds, the track timer was once again in the range 0-20 seconds.

Other possible sequencing events include the ability to alter the playback speed of a given animation set at a particular moment, and the ability to dynamically change a mixer track blending weight at a certain global time so that the animation set assigned to that track can contribute more or less to the final result at the given timestamp.

> **Note**: Sequencer events are registered with the controller's global timeline. Even if an animation set is set to loop or ping-pong, the event will only ever be triggered once, when the global time passes the event on the timeline. This is true even if we reset the track timer. If we had an event scheduled at 20 seconds on the global timeline which reset the timer of a track to zero, the event would not be triggered again when the same track time reaches 20 seconds for a second time. This is because we are only resetting the track time and not the global time. The global time continues to increase with each call to AdvanceTime and would at this point be at 40 seconds. We will see in a moment how we can also reset the global time.

As with all other capabilities, when we create an animation controller, it will have a maximum number defining how many sequencing events can be simultaneously set. When we create the animation controller manually, we can set this value according to the needs of our application. But when using D3DXLoadMeshHierarchyFromX (where the animation controller is created on our behalf), the maximum will be 30 key events scheduled at any one time. If we need to schedule more key events than this, then we will have to clone the animation controller into one with greater event management capabilities. Do not worry; using the sequencer will be explained in detail momentarily. Just know for now that it exists to provide us the ability to script changes for mixer tracks at specific global times.

10.7.1 D3DXCreateAnimationController

Now that we have a basic idea of what the animation controller has to offer, we can begin to examine the specifics. While our application will not normally need to create an animation controller from scratch (because D3DXLoadMeshHierarchyFromX will do it for us), it helps to examine the process since it provides good insight into the internal data layout and inner workings of the animation controller. Remember that if you are loading your animation data from a custom format and cannot use the D3DXLoadMeshHierarchyFromX function, you will also need to manually build your keyframe animations and animation sets in addition to the animation controller used to playback that data.

The D3DX library provides a global function called D3DXCreateAnimationController for creating animation controllers. This function takes several parameters which define the limitations of the newly created animation controller. The function is shown below, followed by a discussion of its parameters.

```
HRESULT D3DXCreateAnimationController
(
      UINT MaxNumAnimationOutputs,
      UINT MaxNumAnimationSets,
      UINT MaxNumTracks,
      UINT MaxNumEvents,
      LPD3DXANIMATIONCONTROLLER *ppAnimController
);
```

UINT MaxNumAnimationOutputs

This parameter represents the maximum number of hierarchy frame matrices that the animation controller can manipulate during a single `AdvanceTime` call. By default, when our animation has been loaded via `D3DXLoadFrameHierarchyFromX`, this value will be set to the number of frames in the hierarchy that will be animated by the data stored in the file, including any child frames they may own. D3DX will register all of these matrices with the animation controller on our behalf when using D3DXLoadMeshHierarchyFromX.

To register additional matrices with the animation controller returned from D3DXLoadMeshHierarchyFromX we will need to clone the animation controller and adjust the MaxNumAnimationOutputs setting to provide space for those additional matrices. Individual matrix registration can be accomplished via the ID3DXAnimationController::RegisterAnimationOutput function, which we will study in a short while. This function will not generally be of concern to us when using D3DXLoadMeshHierarchyFromX, but it is needed for manual controller creation.

UINT MaxNumAnimationSets

This parameter describes the maximum number of animation sets that can be managed (registered via its RegisterAnimationSet method) at any one time by the animation controller. When loading the animation from an X file using D3DXLoadMeshHierarchyFromX, the default value is the total number of animation sets actually stored in the file. To register additional animation sets with the animation controller, we must clone a new one and update this value according to our needs. As mentioned earlier, many of the popular X file exporters currently support exporting only a single animation set. Thus the animation controller created will only provide storage for a single animation set to be registered. We can determine how many sets are registered with the controller using its GetMaxNumAnimationSets method.

UINT MaxNumTracks

This is the maximum number of mixer tracks that the controller should simultaneously support. Essentially it represents the maximum number of animation sets that can be simultaneously assigned to mixer tracks for blending. By default, this value equals 2 when we load animation data from an X file via D3DXLoadMeshHierarchyFromX. If we need additional tracks, we will simply clone a new controller to support however many animation mixer tracks are required.

Note that when we clone a new controller to add tracks, we can specify as many new tracks as we want, but each track will occupy roughly 56 bytes of memory (before data is assigned to it). Again, the

number of available tracks determines the maximum number of animation sets that can be simultaneously blended. Of course, we may have many more registered animation sets than available tracks on our animation mixer. For example, we might have 6 animation sets that should be played back (and blended) in groups of two, such that sets 1 and 2 might be played together, sets 3 and 4 might be played together and sets 5 and 6 might be played together. In this situation we would want to create the animation controller with a 'MaxNumTracks' of 2 but a 'MaxNumAnimationSets' of 6 since we need to manage six different animation sets but only need to playback two at a time.

UINT MaxNumEvents
This parameter allows us to specify the maximum number of key events that can be registered with the animation controller's sequencer. The animation controller sequencer is analogous to a MIDI sequencer used for music composition. Those of you that have worked with MIDI sequencer applications should recall that the sequencer allows for MIDI events to be placed on a given MIDI channel. These MIDI events might include instructions to change the keyboard instrument being used to play that track at a certain time or change the volume of a certain instrument at a certain time. With regards to animation sequencing, this feature affords us the ability to schedule special events to be triggered at certain points in the global timeline of the animation controller. These events include changing the playback speed of a specified track, modifying track blend weights, or jumping to/from locations on a track's local timeline at a specified global time. We will cover the sequencing functions a little later in the chapter.

The default animation controller created by D3DXLoadMeshHierarchyFromX is capable of storing a maximum of 30 key events. If this is not suitable, then we can clone the animation controller to extend the sequencing capabilities.

LPD3DXANIMATIONCONTROLLER *ppAnimController
The final parameter to this function is the address of a pointer to an ID3DXAnimationController interface. On successful function return, it will point to a valid interface for a D3DXAnimationController object.

10.7.2 ID3DXAnimation Controller Setup

The animation controller returned via the manual creation method discussed in the last section is initially empty. The first thing we will want to do is register all of the matrices we need the animation controller to animate, along with any animation sets we have created. While this will not be the case when using D3DXLoadMeshHierarchyFromX, we will need to understand the process when managing our own custom data.

Registering Frame Matrices

While it would not be difficult to write code that recursively steps through the hierarchy and registers any animated frame matrices, D3DX exposes a global function that will do this for us. It is called D3DXFrameRegisterNamedMatrices and is shown below along with a description of its parameters. We will pass this function a pointer to a D3DXFRAME structure from our hierarchy and it will register that

frame's matrix, along with any child frame matrices, with the animation controller passed in as the second parameter. Usually we will pass in a pointer to the hierarchy root frame so that all frame matrices (that have names) are registered with the animation controller.

```
HRESULT D3DXFrameRegisterNamedMatrices
(
    LPD3DXFRAME pFrameRoot,
    LPD3DXANIMATIONCONTROLLER pAnimController
);
```

LPD3DXFRAME pFrameRoot

This is the top level frame where hierarchy traversal will start. The function will register this frame's matrix (if it is named) and subsequently traverse its children, registering any named matrices it encounters. Passing the hierarchy root frame will ensure that all frame matrices that can be animated in the hierarchy are properly registered with the animation controller.

LPD3DXANIMATIONCONTROLLER pAnimController

The second parameter is a pointer to the animation controller that we would like the hierarchy matrices registered with.

While this function makes our job easy, there is one small issue which we must resolve. Recall that during animation controller creation, we will need to specify the maximum number of matrices that the controller will manage (MaxNumAnimationOutputs). As a result, we will need to know the count of named frame matrices in our hierarchy *before* the controller is created. While we could write our own traversal counting routine, D3DX again steps up to make our job easier by providing a global function called D3DXFrameNumNamedMatrices.

```
UINT D3DXFrameNumNamedMatrices
(
     LPD3DXFRAME pFrameRoot
);
```

The function takes a single parameter -- a pointer to a frame in our hierarchy (usually the root frame). It will return the number of named frames (including the passed frame) that exist in the subtree, including all named children of the passed frame. We can use the value returned to create the animation controller and then register the matrices using the previously discussed function.

Example

The following code snippet creates an animation controller and registers the matrices of the hierarchy. In this example it is assumed that pRoot is a D3DXFRAME pointer to the root frame of an already created hierarchy.

```
ID3DXAnimationController * pAnimController = NULL;
UINT MaxNumMatrices = D3DXFrameNumNamedMatrices ( pRoot );
D3DXCreateAnimationController ( MaxNumMatrices , 4 , 2 , 10 , &pAnimController );
D3DXFrameRegisterNamedMatrices ( pRoot , pAnimController );
```

The example builds an animation controller that is capable of managing four animation sets. It has an animation mixer with two channels (which means it is capable of blending only two animation sets at once) and can have ten key events set in its internal sequencer.

> **Note:** We remind you once again that these steps are only required when we manually create an animation controller. D3DXLoadMeshHierarchyFromX does all of this work on our behalf before returning a fully functional animation controller interface.

Registering Animation Sets

Once we have created our animation controller and registered all matrices that will be animated by our animation sets, it is time to register those animation sets with the animation controller. Until we do, the animation controller has no animation data (it has is a list of matrices, but no idea about how to fill them with animation results).

For each animation set that needs to be registered with the animation controller we call the ID3DXAnimationController::RegisterAnimationSet method. It accepts a single parameter -- a pointer to a valid ID3DXAnimationSet interface. By 'valid' we mean that it should already contain all of its keyframe data. This function would be called once for each animation set to be registered with the animation controller.

```
HRESULT RegisterAnimationSet( LPD3DXANIMATIONSET pAnimSet );
```

> **Note:** When an animation set is being registered, the controller calls the animation set's GetAnimationIndexByName function for each frame. Its goal is to retrieve either a valid index via the pIndex output parameter and D3D_OK, or D3DERR_NOTFOUND via the function result. Caching the animation indices bypasses the need to look up the index on the fly. It also tells the controller exactly which frames even have any animation data (those which resulted in D3DERR_NOTFOUND do not have a matching animation). Once this process is completed, AddRef is called to indicate the controller's use of the animation set that has just been registered.

It is important to realize that the number of animation sets we register with the controller must not be greater than the MaxNumAnimationSets parameter passed into the D3DXCreateAnimationController function. If you did not create the animation controller yourself and would like to know the maximum number of animation sets that can be registered with the animation controller, you can use the ID3DXAnimationController::GetMaxNumAnimationSets method of the interface as shown below. The function returns the total number of animation sets that can be registered with the animation controller simultaneously.

```
UINT GetMaxNumAnimationSets(VOID);
```

Assuming that we have previously created four animation sets and wish to register them with our animation controller, the code might look something along the lines of the following. The next code snippet assumes that pRoot points to a valid D3DXFRAME structure, which is the root frame of our hierarchy. It also assumes the four animation sets (and their interpolators) have already been created.

```
ID3DXAnimationController *pAnimController = NULL;
ID3DXAnimationSet *pAnimSet1= ‘ Valid Animation Set’
ID3DXAnimationSet *pAnimSet2= ‘ Valid Animation Set’
ID3DXAnimationSet *pAnimSet3= ‘ Valid Animation Set’
ID3DXAnimationSet *pAnimSet4= ‘ Valid Animation Set’

// Create animation controller
UINT MaxNumMatrices = D3DXFrameNumNamedMatrices ( pRoot );
D3DXCreateAnimationController ( MaxNumMatrices , 4 , 2 , 10 , &pAnimController );

// Register Matrices
D3DXFrameRegisterNamedMatrices ( pRoot , pAnimController );

// Register Animation Sets
pAnimController->RegisterAnimationSet ( pAnimSet1 );
pAnimController->RegisterAnimationSet ( pAnimSet2 );
pAnimController->RegisterAnimationSet ( pAnimSet3 );
pAnimController->RegisterAnimationSet ( pAnimSet4 );
```

At this point the animation controller will have all of the data (e.g. keyframe data and the matrices they manipulate) it needs to animate the hierarchy. However, no animation sets have yet been assigned to tracks on the mixer. This last step is something that will need to be done before we call AdvanceTime. We will discuss mixer track assignment in a moment.

Our application can retrieve the current number of animation sets that have been registered with the controller using the ID3DXAnimationController::GetNumAnimationSets method. This allows us to query how many of the animation set slots allocated for the controller are already occupied with animation sets. We can only register another animation set with the controller if:

```
pController->GetMaxNumAnimationSets() > pController->GetNumAnimationSets()
```

The function that retrieves the current total of registered animation sets is:

`UINT GetNumAnimationSets(VOID);`

Unregistering an Animation Set

Just as we can register animation sets with the animation controller, we can also unregister them. This might be useful if you have decided that you are finished with an animation set and will not need it again in the future. In this case you can unregister the set and then release its interface. It is also useful when you have more animation sets than your current animation controller can handle. Let us say for example that you had 10 animation sets which you planned on using but for some reason your animation controller was created to support only five registered sets at any one time. In this case you could register animation sets when they are needed and then unregister them when they are no longer needed to make room for other animation sets. The function is shown below and takes a single parameter -- a pointer to the ID3DXAnimationSet you wish to unregister.

`HRESULT UnregisterAnimationSet(LPD3DXANIMATIONSET pAnimSet);`

Note that to remove the animation set we must pass in the interface pointer. This function will call Release on the animation set when it relinquishes control (assuming that it owns the animation set we requested to be unregistered). So if we wanted to unregister an already existing animation set being managed by the controller that we do not currently have a pointer to, we would need to get access to it first. The following code uses the GetAnimationSet method of the ID3DXAnimationController interface (which we have not covered yet) to retrieve the ID3DXAnimationSet assigned to slot 3 in the animation controller's animation set array. We then unregister the animation set and finally release it.

```
LPD3DXANIMATIONSET pAnimSet;

// Fetch interface to 4th registered animation set
m_pAnimController->GetAnimationSet( 3, &pAnimSet );

// At this point, the animation set 'pAnimSet',
// will have a reference count of '2'.
m_pAnimController->UnregisterAnimationSet( pAnimSet );

// Release has been called, reference count is now '1'
pAnimSet->Release(); // Animation set deleted.
```

In the above code you can see that we retrieved the fourth animation set being managed by the controller (the one at index 3). Now that we have unregistered it, passing 3 to GetAnimationSet on a subsequent call will return a pointer to the animation set which used to exist at index 4. In other words, unregistering an animation set will shuffle all of the other animation sets that follow it back one slot in the animation controller's internal animation set array. It is also worth noting that any unregistered animation set will be removed from the mixer track if it is currently assigned to one. Any calls to GetTrackAnimationSet for the track which previously owned it will now return NULL until another animation set is assigned to that track.

When we call ID3DXAnimationController::Release, all of the registered animation sets are unregistered and their reference counts decremented. Therefore, we do not have to explicitly call UnregisterAnimationSet for each registered animation set before we release the animation controller interface.

> **Note:** When using D3DXLoadMeshHierarchyFromX to load animation data from an X file, all animation sets contained in the X file are created and registered with the animation controller on our behalf. There is no need to call the above function unless you need to register additional animation sets (not contained in the X file) with the animation controller. In that case you will probably need to clone the animation controller to make room for your extra animation sets.

Registering Matrices

As discussed previously, D3DXFrameRegisterNamedMatrices does all of the hard work of registering the matrices in a given hierarchy with an animation controller. This function is basically just traversing the hierarchy that we pass it and calling the ID3DXAnimationController::RegisterAnimationOutput method of the animation controller interface for each named matrix that it finds. If you need to manually

register some or all of your matrices with the animation controller, you can do so yourself using this method.

```
HRESULT RegisterAnimationOutput
(
    LPCSTR Name,
    D3DXMATRIX *pMatrix,
    D3DXVECTOR3 *pScale,
    D3DXQUATERNION *pRotation,
    D3DXVECTOR3 *pTranslation
);
```

LPCSTR Name
The first parameter is the name that you would like the output to be registered under. This name should match the name of an animation in an animation set.

D3DXMATRIX *pMatrix
The matrix pointer passed into this function is stored by the animation controller so that it can update the frame matrix with SRT data without traversing the hierarchy each time. When we use the D3DXLoadMeshHierarchyFromX function to load an X file which has animation data, this function will be called multiple times to store the matrix of each named frame in the hierarchy in the controller's matrix pointer table. While this may sound complicated, bear in mind that all we are doing is informing the controller about a matrix (usually the matrix of a D3DXFRAME structure) that is to receive the SRT data from animations with the passed name. This allows the controller to build a matrix pointer array for quick updates of the frame hierarchy matrices.

D3DXVECTOR3 *_pScale_
D3DXQUATERNION *_pRotation_
D3DXVECTOR3 *_pTranslation_
This function was updated in the 2003 summer update of the SDK and now NULL can be passed as the matrix parameter and the SRT data stored as separate components. This allows an application to store the SRT data from a given animation in either a matrix, or have it stored in a separate scale vector, a rotation quaternion and a translation vector instead. While an automatically created animation controller (one created by D3DXLoadMeshHierarchyFromX) will have this function called for each named frame with the final three parameters set to NULL, and will only register the frame matrix as an animation output, this does provide applications with the flexibility to store the SRT data output from a given animation in separate variables. For example, an application performing its own animation blending that still wishes to use the animation controller for SRT generation (keyframe interpolation) might decide not to have the output stored in a matrix but as a separate scale, rotation and translation that it can later blend into a matrix using its own custom techniques. If any parameter (except the first) is set to NULL, the associated SRT data will not be output. For example, if the pMatrix, pScale and pTranslation parameters are set to NULL and only a rotation quaternion pointer is registered, then only the rotation portion of the SRT data will be output. When using the full D3DX animation system, it is not likely that you will ever want the pMatrix parameter set to NULL, as this is usually a pointer to the matrix of a frame in the hierarchy that you wish to be updated when AdvanceTime is called. It is often the case that both the matrix will be registered as an animation output along with some or all of the final three parameters. This allows the animation controller to update the frame in the hierarchy (pMatrix) and also return SRT data to the application, which may be used to calculate physics for example.

It is important that you do not register more outputs with the animation controller than the maximum number allowed. The maximum number of output that can be registered with the controller is set when the animation controller is created (the MaxNumAnimationOutputs parameter) using the D3DXCreateAnimationController function. You can retrieve the maximum number of supported outputs by calling the ID3DXAnimationController::GetMaxNumAnimationOutputs function.

```
UINT GetMaxNumAnimationOutputs(VOID);
```

This function returns an unsigned integer value describing the maximum number of outputs that can be registered with the animation controller at any one time. As a result, this value also tells us the maximum number of frame matrices that can be simultaneously animated by the controller. A single output can be a combination of a matrix, a scale and translation vector and a rotation quaternion.

We have now covered how to create and configure the animation controller, and how to register all required matrices and animation sets. So the animation controller now has all of the data it needs for animating our hierarchy matrices. Again, we will rarely need to perform any of these tasks if we are simply loading animated X files, because D3DXLoadMeshHierarchyFromX will do the work for us.

The next step is to understand how to use the methods of the ID3DXAnimationController interface to configure the animation mixer. This will allow us to start experimenting with how our animation sets are played back in our application.

10.8 The Animation Mixer

Although we have registered our animation sets with the animation controller (or it has been done for us by D3DXLoadMeshHierarchyFromX), we are not quite ready yet to start playing them back. Earlier we learned that we will use the ID3DXAnimationController::AdvanceTime method to progress along its global timeline and animate the hierarchy. While this is certainly the case, keep in mind that we might have multiple animation sets registered with the animation controller and that we will want the ability to play back only a subset of those animation sets at any given time. For example, if we had an animated character hierarchy with three animation sets (‘Walk’, ‘Swim’, ‘Die’), we will probably want to play back only one of these sets at any given time.

The animation mixer allows us to select the animation set(s) we wish to use for animating the hierarchy each time AdvanceTime is called. It also allows us to have multiple animation sets assigned to different tracks so that they can be blended together to produce more complex animations.

When the animation controller is first created, it is at this time that we determine the maximum number of mixing tracks that the animation mixer will be able to use. This lets us scale the animation mixer to suit our needs so that memory is not wasted by maintaining tracks that our application will never use. You should recall from our discussion of the D3DXCreateAnimationController function that the MaxNumTracks parameter defines the maximum number of tracks for the animation controller. To use the analogy of an audio multi-track mixing desk once again, these mixing desks come in different shapes and sizes. The more tracks an audio mixing desk has, the more individual sounds we can simultaneously mix together. For example, guitar, bass, drums, and vocals are generally assigned their own separate tracks when your band is recording an album. This allows the studio sound engineer to isolate and tweak each individual instrument sound for better results (or to add effects, etc.). Although each track maintains only the data for that particular instrument, all tracks will be played back simultaneously on the final album, blended together to produce the song in its complete form.

With the animation mixer, the number of tracks defines the maximum number of animations sets that can be blended together at any one time. So in order to play an animation set, we must first assign it to a track on the animation mixer and then enable that track. Tracks can be enabled and disabled by our application at will, so we have total control over the process in that respect. Next we will discuss how to assign animation sets that have been registered with the animation controller to tracks on the animation mixer. This way they will be ready for use the next time our application calls the ID3DXAnimationController::AdvanceTime function.

10.8.1 Assigning Animation Sets to Mixer Tracks

When an animation controller object is *manually* created and its animation sets are registered, by default none of these animation sets will be assigned to any tracks on the animation mixer. Before we play an animation we must select the appropriate animation set(s) and assign them to the mixer track(s) we wish to use. This is analogous to the painter who has many jars of colored paints in his workshop, but will only put a few blobs of paint on his palette to use in the current painting. We can think of the registered animation sets as the available jars of paint. Some of these sets will be placed into the mixer (the palette) to be used to create the final animation (the painting). Note that the artist may decide to smear some of the paint blobs together on his palette to create new color blends for the painting. We can do the same thing with our animation mixer.

Assuming that we have registered our animation sets with the animation controller, we can assign any animation set to a valid track on the animation mixer. By a ‘valid’ track, we simply mean a track with an index in the range [0, MaxNumTracks - 1]. Unlike the DirectX lighting module, where we can assign lights to any arbitrary lighting slot index just so long as we do not enable too many lights simultaneously, animation mixer tracks are always zero-based and consecutive in their numbering scheme. Therefore, if we created an animation controller that supports a maximum of eight mixer tracks, this means that we can assign a different (registered) animation set to tracks 0 through 7 on the

animation mixer. Note that the index of an animation set is not related to the index of the track to which it can be assigned. The index of an animation set is merely representative of the order in which it was registered with the controller. It is perfectly acceptable to assign animation set 5 to animation mixer track 2 for example.

Keep in mind that when the animation controller is created during the D3DXLoadMeshHierarchyFromX call, all animation sets will be registered, but only the last animation set defined in the file will be assigned to a track (track 0, specifically). By default, the animation controller will support a maximum of two tracks and the second track will be disabled with no assigned animation set. If you require additional tracks to produce your animations, you must clone the animation controller to extend its capabilities.

We assign an animation set to a mixer track on the animation mixer using the ID3DXAnimationController::SetTrackAnimationSet function. The first parameter is the zero-based number of the track we want the animation set assigned to. The second parameter is the interface pointer of the animation set being assigned.

```
HRESULT SetTrackAnimationSet( DWORD Track,
                              LPD3DXANIMATIONSET pAnimSet );
```

The animation set passed in must already be registered with the controller. Any previous animation set already assigned to the specified track will be unassigned before the new animation set assignment takes place.

If you do not have the actual interface of the animation set handy, but you know the index of the animation set (based on when it was registered) then you can use the ID3DXAnimationController::GetAnimationSet function to retrieve its interface.

```
HRESULT GetAnimationSet( DWORD iAnimationSet,
                         LPD3DXANIMATIONSET *ppAnimSet );
```

We pass this function the index of the registered animation set interface we want to retrieve and the address of an animation set interface pointer which will store the returned result. This function will increment the reference count of the object before returning the interface, so be sure to release it when you have finished with it.

Next we see some example code that acquires an interface pointer for the third registered animation set (AnimationSet[2]) and assigns it to track 7 on the animation mixer. This code assumes that the animation controller was created with a minimum of an 8-track animation mixer.

```
// Set up track 0 for the animation mixer
LPD3DXANIMATIONSET pAnimSet;
m_pAnimController->GetAnimationSet( 2, &pAnimSet );
m_pAnimController->SetTrackAnimationSet( 7, pAnimSet );
pAnimSet->Release();
```

It is much more intuitive to find animation sets by name (ex. “Jump”) and as we might expect, we can also retrieve the animation set interface by name also. This function, which is shown next, accepts a string containing the name of the animation we are searching for and the address of a pointer to an ID3DXAnimationSet interface. On successful function return this will point to a valid animation set.

```
HRESULT GetAnimationSetByName( LPCSTR pName,
                               LPD3DXANIMATIONSET *ppAnimSet);
```

In the following example, we show how we might assign an animation set called “Shoot” to mixer track 3 (i.e., the fourth track).

```
// Set up track 0 for the animation mixer
LPD3DXANIMATIONSET pAnimSet;
m_pAnimController->GetAnimationSetByName( “Shoot”, &pAnimSet );
m_pAnimController->SetTrackAnimationSet( 3, pAnimSet );
pAnimSet->Release();
```

So as you can see, we have two useful ways to retrieve the interface for a registered animation set that we wish to assign to a track. We can retrieve its interface by name or by index.

```
HRESULT GetTrackAnimationSet( DWORD Track,
                              LPD3DXANIMATIONSET *ppAnimSet );
```

ID3DXAnimationController exposes another animation set retrieval function called GetTrackAnimationSet which allows us to specify a track number and get the interface for the animation set currently assigned to that track. This is handy if we wish to fetch the animation set assigned to a given track on the mixer and assign it to another track. It is also useful if we want to unregister the animation set because we have no further use for it. Note that unregistering an animation set will also remove its track assignment.

The function takes two parameters -- the first is the index of the mixer track containing the animation set we wish to obtain an interface for, and the second is the address of an ID3DXAnimationSet interface pointer. The latter parameter will point to a valid interface to the animation set on function return. If no animation set is assigned to the specified track, the interface pointer will be set to NULL.

Once again, we must remember to release the interface when we are finished with it so that the underlying COM object will be properly cleaned up when it is no longer needed by any modules.

The following code shows how we might assign three animation sets (sets 2, 5, and 8) to animation mixer tracks 0, 1, and 2. It assumes that the animation controller has already been created with a minimum of 9 pre-registered animation sets and at least a 3-track mixer. This example will be typical of code that might be executed in response to a certain action or event taking place in our game logic. For example, imagine that this particular animation controller is managing the hierarchy of an animated character and that the animation sets are mapped as follows:

Set 2 = Walk
Set 5 = Fire Weapon
Set 8 = Act Wounded

If the character was currently experiencing all of these states then we could assign them to the first three tracks of the animation mixer. Then the next time we call AdvanceTime, the character will be animated using the blended result of these three animations sets. As a result the character would fire his weapon while walking along, behaving like he has sustained injuries. This next example will assume that the PlayerAction variable is a DWORD that has bits set that our application identifies with the walking, firing, and wounded action states.

```
if ((PlayerAction & WALK) && (PlayerAction & FIRING) && (PlayerAction & WOUNDED) )
{
      LPD3DXANIMATIONSET pAnimSet2 = NULL;
      LPD3DXANIMATIONSET pAnimSet5 = NULL;
      LPD3DXANIMATIONSET pAnimSet8 = NULL;

      m_pAnimController->GetAnimationSet( 2, &pAnimSet2 );
      m_pAnimController->GetAnimationSet( 5, &pAnimSet5);
      m_pAnimController->GetAnimationSet( 8, &pAnimSet8);

      m_pAnimController->SetTrackAnimationSet( 0, pAnimSet2 );
      m_pAnimController->SetTrackAnimationSet( 1, pAnimSet5 );
      m_pAnimController->SetTrackAnimationSet( 2, pAnimSet8 );

      pAnimSet2->Release();
      pAnimSet5->Release();
      pAnimSet8->Release();
}
```

The code block above sets the animations we want to play on this animation controller (at least until the character enters another action mode). When we call ID3DXAnimationController::AdvanceTime in our render loop, these animations can then be blended together for our final on-screen result. However, this is not all we will usually have to do. After all, we need to find the right balance between these three animations to make sure that the results are correct. Mixing animations is more an art than a science, and we will often have to experiment a bit to find good blends that work for us. Fortunately, each track on the animation mixer has several properties that can be set to control how the animation applied to that track is played out and how that track is blended with animation sets assigned to other tracks.

In the next section we will examine how to set up the individual tracks of the animation mixer so that they play their assigned animations in the desired way.

10.8.2 Animation Mixer Track Configuration

Every animation mixer track has five configurable properties which determine the behavior of the track and thus the animation set assigned to it.

The first property **enables/disables** the track. If a track is disabled it will not be used in the AdvanceTime call regardless of whether it contains an animation set. Being able to enable/disable tracks on the fly is a useful feature in a game. Imagine that we have two animation sets assigned to our mixer: track one stores a ‘Walk’ animation which we repeatedly loop as the character navigates the world. On

the second track we store a short animation called ‘Wave’ which makes the character wave his hand to other characters in the world in greeting as he passes them by. Since we would only want the second animation to play when the character spots a friend, we would disable this track by default. At this point, every call to AdvanceTime would only update the hierarchy using the ‘Walk’ animation set assigned to track one. But once the character spots a buddy, we could enable track two for a set period of time (a few seconds perhaps) before disabling it again. In the few seconds that track two is enabled, any calls to AdvanceTime would blend the two animation sets together such that the character model would be walking and waving at the same time.

The next important mixer track property is **weight**. Going back to our audio mixing desk analogy, we can think of the weight of a track as being akin to the volume knob. Increasing the volume of a track will make the instrument assigned to that track louder in the final mix. The weight property of the animation track is similarly a way to scale the influence of its assigned animation set on the hierarchy. The track weighting value is usually in the range [0.0, 1.0] where a value of 1.0 means the animation set assigned to that track manipulates the hierarchy at its full strength. A value of 0.0 means the animation set will not influence the hierarchy at all. This value can be set higher than 1.0 although the resulting hierarchy transformation might not be what you expect. We will look at a track’s primary weight value in more detail in a moment.

The third configurable property of a track is its **speed**. Speed is a scalar value which allows us to define how fast we want the animation set to be played back. A speed value of 1.0 means ‘normal speed’ (i.e. the speed that it would play at by default as intended by the animation creator). Specifying a value of 2.0 for instance means the animation set assigned to the track would play out twice as fast. This might sound like a strange feature to have, but it is actually nice to have the flexibility to play the animation sets back at different speeds (imagine that you wanted to do a slow-motion sequence where all animations ran at half time). Setting the speed of a track is another feature that allows us to decouple the global time of the controller from the timer of a given track. We can think of the speed parameter of a track as being a scalar that is multiplied by the elapsed time passed into the Advance Time call prior to being added to the track timer. As an example, let us imagine that we pass into AdvanceTime an elapsed time of 2 seconds. We know that the global timer of the controller would have two seconds added to it. However, before this elapsed time is also added to the timer of each track, it is scaled by the speed parameter of that track. If the speed of the track was set to 0.25, then the actual elapsed time added to the track would be ElapsedTime*0.25 = 0.5. As you can see, although the global time and the rest of the animation tracks have moved along their time lines by 2 seconds, the track in question has only had its timer updated by ½ a second. Therefore, the animation set assigned to this track appears to be playing back in slow motion compared to other sets being played. In this example, it is playing back at ¼ of the speed of the global timer. Obviously, speed values greater than 1 (the default) will make the animation set play back faster than global time. For example, a speed value of 2 will cause the animation to play back at twice its speed.

The fourth property of a mixer track is a time value called ***position***, which is essentially the value of the timer for that track. Therefore, in DirectX terminology, the global time is the time of the animation controller which is the sum of total elapsed time, and the position is the current value of a single track timer (which itself is the sum of all elapsed time passed onto that track during updates). The ***periodic position*** is the value of the track ***position*** mapped into the period of the animation set, taking into account looping and ping-ponging. It is the track position that is passed into the

ID3DXAnimationSet::GetPeriodicPosition function to generate an animation set local time that is ultimately passed on to the ID3DXAnimationSet::GetSRT function.

To understand the three layers of time used by the D3DX animation system, below we show a simplified pseudo-code version of how the ID3DXAnimationController::AdvanceTime function would apply updates.

```
AdvanceTime(  ElapsedTime )
{
    // Add elapsed time to the animation controllers global time
    GlobalTime += ElapsedTime;

    // Loop though each enabled track
    For (Each Enabled Track)
    {
       // Update the position of the track timer scaling by track speed
       Track->Position += (ElapsedTime * Track->Speed)

       // Fetch animation set assigned to current track
       AnimationSet = Track->GetTrackAnimationSet( )

       // Map the track timer ( position ) into a periodic position for the set
       PeriodicPositon =AnimationSet->GetPeriodicPosition( Track->Position )

       // Use periodic position to generate SRT data for each animation in this set
        For ( Each Animation In Animation Set)
        {
              AnimationSet->GetSRT( PeriodicPosition , Animation ,
                                    &scale , &rot , &trans )

          .. Do other stuff with SRT data here …
        } // Each Animation

     } // End Enabled Track
}
```

We will usually want to set the position of a track to zero before the animation set is played for the first time, so that the animation set assigned to that track starts at the beginning.

While we will often have no need to interfere with the local time (the position) of a mixer track and will usually allow the animation controller to advance them on our behalf when we call AdvanceTime, we do have the ability to override this behavior and offset a track's animation set to a specific track local time. Imagine that we initially assigned two animation sets to tracks 1 and 2. We could set track 1's position to 0 and track 2's position to 5. When we start playing our animation using AdvanceTime, track 1 would start playing its animation set from the beginning while track 2 would start playing from 5 seconds in (assuming the period of the animation was at least 5 seconds long). This is probably a more useful feature if your animation set is actually a container filled with multiple animations (as is often the case for the default export of X files). In such a case your engine would need to know where particular animation routines started and ended in the set (ex. 'Run' animation from 0 seconds to 2 seconds, 'Shoot' animation from second 3 to second 6, etc.) and pass these times appropriately. It is a bit more complicated of course because your engine will also need to control when the animation should stop and

be reset to play again from the beginning (which is why splitting up animation sets according to individual animation routines makes life much easier – as we will do in Lab Project 10.2).

The fifth and final property that we can assign to a mixer track is a **priority** value. With it, each track can be assigned one of two possible priorities: high or low. Low priority tracks are actually blended together separately from high priority tracks. Later, the two blended results are blended together using the animation mixer's **priority blend weight** (which is another weight we can set). For example, assume that we have an 8-track mixer and we assign the first four tracks a low priority and the second four tracks a high priority. When we call AdvanceTime, the low priority tracks (0-3) would be blended together using their respective per-track weights and the high priority tracks (4-7) would be blended together using their respective per-track weights. Finally, the results of both blends for a given frame are blended together using the priority blend weight set for the mixer. This is a single property value for the entire animation mixer that we can configure as needed. If it was set to 0.25 for example, it means that after the low priority tracks have been blended (we will call this Result 1) and the high priority tracks had been blended (we will call this Result 2), the final transformations applied to the hierarchy would be a combination of 25% of Result1 and 75% of Result2. This provides another layer of animation blending control beyond the per-track blend weights. Figure 9.8 gives us a graphical idea of the concepts just discussed. It demonstrates an 8-track mixer with all of the configurable properties outlined previously, along with the input (animation sets) and output (transformations).

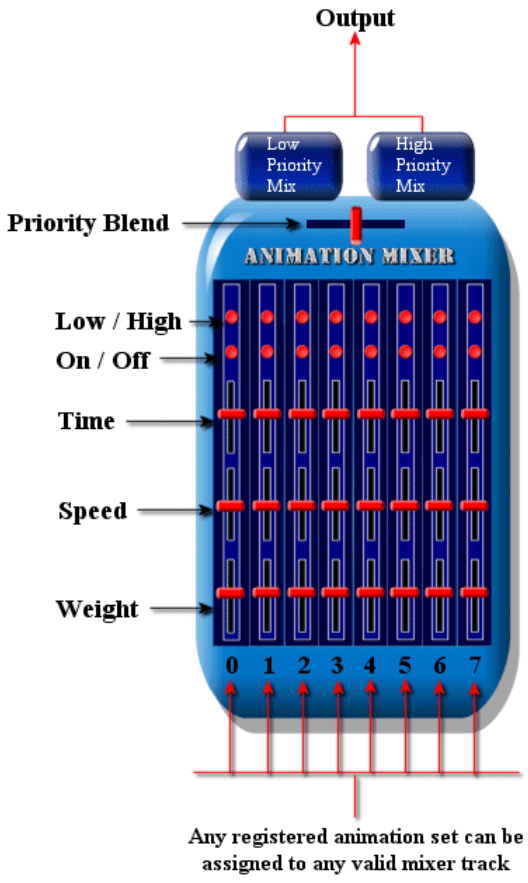


Figure 9.8

Enabling / Disabling a Track

The first thing we will usually want to do when we assign an animation set to a track is make sure that track is enabled. This will ensure that the track and its assigned set are used in the next call to AdvanceTime. We enable and disable tracks using the ID3DXAnimationController::SetTrackEnable method.

```
HRESULT SetTrackEnable( UINT Track, BOOL Enable );
```

The first parameter to this function is the index of the mixer track we wish to enable or disable. The second parameter is either TRUE or FALSE depending on whether we would like to enable or disable the mixer track respectively. To mix a track with other tracks, this flag must be set to TRUE. Conversely, setting this flag to FALSE will prevent the specified track from being mixed with other tracks. You should not leave tracks enabled if they have no animation sets assigned to them.

Setting Track Weight

Setting the weight of a track controls the influence of the animation set assigned to it (i.e. how strongly it manipulates the hierarchy). We can set the per-track weight value using the ID3DXAnimationController::SetTrackWeight function.

```
HRESULT SetTrackWeight( UINT Track, FLOAT Weight );
```

The first parameter is the index of the track we are specifying the weight for and the second parameter is the floating point weight value itself. This is the primary track weighting value and it will generally be specified in the [0.0, 1.0] range. Although you can specify values outside of this range if it serves your purpose, there is the potential for some strange results. All weights for all active tracks are essentially normalized anyway so if you have only one track and set its weight to 0.5, it will essentially have a weight of 1.0 anyway. The controller makes sure that the sum of all track weights equals one prior to the blending process.

Let us imagine that we have a single cube in our scene hierarchy, and that we have two separate animation sets that will manipulate that cube. The first animation set translates the cube 100 units to the right and the second set translates the cube 100 units to the left. If both of these sets were placed in separate tracks, and both had a weight of 1.0, nothing would actually happen to the cube. Each set would produce translations which counteract one another:

```
(100 * 1.0) + (-100 * 1.0) = 0
```

However if we were to use a weight of 0.4 for the first set (which moves the cube 100 units to the right) the cube itself will have moved 60 units to the left by the end of the animation:

```
(100 * 0.4) + (-100 * 1.0) = -60
```

While this example is very simple, you can certainly understand the basic principles involved here. This is a generic blending formula that we have seen many times before (in Chapter Seven for example). In a game, we might use the weight value for blending an animation set of a character firing a gun (with only the associated animations applied to the arms), with a recoil animation set that we can blend at different strengths based on the type of weapon being fired.

It is worth noting that, by definition, the weight value can be used to define the strength of an animation, even in cases where hierarchy frames are not being manipulated by more than one track. Although keep in mind that it will have no effect on the animation. For example, if we had two tracks and neither manipulated the same hierarchy frames as the other one, the weight would not scale the strength of the animation applied to the respective matrices. You will probably set your per-track weights to 1.0 most of the time so that each animation set affects the hierarchy in the exact way intended by the creator of the animation data. This is certainly true if your animation sets generally influence their own unique portions of the hierarchy.

As discussed previously, the per-track weights are blended with other tracks assigned to the same priority group (high or low). The results of each priority group are then blended together using the priority blend weight of the animation controller to produce the final SRT data for a given frame. Therefore, even if a track is assigned a weight of 0.5, it does not necessarily mean that it will influence the hierarchy at half strength. The final strength of influence may be reduced or boosted depending on how the two priority groups are combined in the final weighting stage.

Setting Track Speed

Recall that while we pass an elapsed time (in seconds) to the controller's AdvanceTime method to update the global timer of the controller, each track maintains it own local timer which is also updated with the elapsed time passed in. The current track time is referred to as the track's position. For each track we can set a speed value (a single scalar) that is essentially used to scale the elapsed time we pass in and thus the amount that we wish to increment the timer of each track. If this scalar is set to 1.0 (the default) then the animation set will play back at its default speed -- the speed intended by the animation creator -- and the elapsed time passed into the AdvanceTime function will be added directly to the timer of the track without modification. Alternatively, if we set this value to 0.5, then the animation set assigned to that track would play out at only half the speed. This is because the elapsed time is scaled by the track speed before being added to the track's timer. A track with a speed setting of 0.5 will progress at half the speed of the global timeline of the controller. If a track is initially set with a speed value of 0.25, then at twenty seconds of global time, the track's timer will be at 5 seconds. As it is the track's timer that is mapped to a periodic position and used to generate SRT data, this directly effects the speed at which the animation set assigned to the track plays out.

```
HRESULT SetTrackSpeed( UINT Track, FLOAT Speed );
```

The first parameter should be the index of the track you wish to set the speed for. The second parameter is a floating point value indicating the desired speed scale value.

Setting Track Animation Position

As discussed earlier, each track maintains its own local timer. Every time the AdvanceTime method is called and the global timer is updated, so too are the timers for each track. The elapsed time passed in will be scaled by the speed of a track before being used to increment the track timeline. The current value of a track's timer is referred to as its position.

Not only do we have the ability to control the speed at which a track's counter updates using the elapsed time and its speed, we also have the ability to set the track timer to any arbitrary position. This allows us to cause the animation set to jump to a specific local time at a specific global time.

Usually, we will set the initial position for each track to zero before we play any animations, to ensure that all of the animation sets start from the beginning. Nevertheless, we can call the ID3DXAnimationController::SetTrackPosition function whenever we wish to set (or offset) the local timer of a specific track to a specific track position. We could, for example, have an animation set that is looping but needs to always restart from the beginning every time an event happens in the game, regardless of its current periodic position.

```
HRESULT SetTrackPosition( UINT Track, DOUBLE Position );
```

The first parameter is the track we wish to set the time for and the second parameter is the position we wish to set the track to. The next time we call the AdvanceTime method, all additions to the timeline will be relative to this new track position. As it is the track time that is mapped into a periodic position in the animation set, setting the position of a track directly effects the periodic position also.

The next code snippet demonstrates how we might want to set position of the mixer to start from the beginning (regardless of where this track may currently be in its timeline) in response to the 'FireWeapon' command. This will cause the animation set assigned to that track to restart regardless of whether it is configured to loop or not. It is assumed when looking at this code that the fTime parameter contains the elapsed time (in seconds) that has passed since the last frame. This is the value that will be added to the global time of the controller and used to increment the timer of each track (scaled by track speed). It is also assumed that there are multiple animation sets assigned to tracks on the animation mixer and that these animation sets will loop when they reach their end. When the fire button is pressed however, the animation set assigned to track 2 on the mixer restarts because we set the track time to zero, effectively forcing a restart of just that animation set. This will not affect any of the other animation sets assigned to other tracks; they will continue to play out as normal without any knowledge of the restart in track 2.

```
void UpdateAnimations ( double fTime , ID3DXAnimationController * pController)
{
      if (FireButton)
            pController->SetTrackPosition ( 2 , 0.0f );

      // Set the new  global time
      pController->AdvanceTime ( fTime );
}
```

It is worth remembering that although we set the track timer to zero, we then proceed to call the AdvanceTime method passing in the advanced time. Therefore, the next time the SRT data for this animation set if generated, the position of the track will in fact be 0 + ElapsedTime, as we would fully expect. This track time would be mapped to the periodic position of the animation set and used to fetch the two bounding keyframes used for interpolation.

> **Note:** Remember, the AdvanceTime method updates the matrices of the individual hierarchy frames. It is only when you traverse the hierarchy and combine the newly updated matrices that you will be ready to draw the final results.

Setting Track Priority

This function allows us to assign each track to one of two blending groups: a high priority group or a low priority group. Each group will have its tracks blended together separately using the per-track weight and eventually the blended results for each group will be blended into a final result used to update the hierarchy matrices. As we have the ability to alter the way in which the two priority blend groups are combined (using the controller Priority Blend Weight which we will discuss in a moment) this provides us a second layer of blend control.

This method is shown below and as you can see it takes two parameters. The first is the track index and the second is a member of the D3DXPRIORITY_TYPE enumeration.

```
HRESULT SetTrackPriority( UINT Track, D3DXPRIORITY_TYPE Priority);
```

The D3DXPRIORITY_TYPE enumeration is defined by D3DX as:

```
typedef enum _D3DXPRIORITY_TYPE
{
   D3DXPRIORITY_LOW = 0,
   D3DXPRIORITY_HIGH = 1,
   D3DXEDT_FORCE_DWORD = 0x7fffffff
} D3DXPRIORITY_TYPE;
```

As you can see there are two choices (D3DXPRIORITY_LOW or D3DXPRIORITY_HIGH) indicating which of the two possible groups the track should be assigned to. Naming these groups High Priority and Low Priority is perhaps a little misleading as it incorrectly suggests that tracks assigned to the high priority groups will always have a higher influence on the hierarchy than those in the low priority groups. In actual fact, we will see in a moment how the animation controller lets us set a priority blend weight for the entire controller (a value between zero and one) which allows us to control how the high and low priority blend groups are blended. A value of 0.5 for example would blend both groups with equal weight. Alternatively, this value could also be set such that the low priority group has a greater influence. Rather than thinking of these groups as high and low priority, it is perhaps easier to think of them as being just two containers which can have arbitrary priority assigned to them. We will see how to set the priority blend weight of the animation controller in a moment.

Setting Track Descriptors

We have now seen how to set a track's speed, weight, priority group and position as well as how to enable or disable the track at will. The functions we have looked at are typically going to be called while our animation is playing so that we can adjust the track properties as needed, perhaps in response to some game state change. As it turns out, we can also setup these values (typically when we first create the animation controller) using a single function call. This function is called ID3DXAnimationController::SetTrackDesc and it allows us to set the speed, weight, priority groups and position of a track with a single call. The method is shown below.

```
HRESULT SetTrackDesc( UINT Track, D3DXTRACK_DESC *pDesc );
```

The first parameter is the number of the track we wish to set the properties for and the second parameter is the address of a D3DXTRACK_DESC structure containing the values for each property. The structure is shown below followed by a description of each member. The meaning of each member should be obvious to you given the functions we have covered in the previous section.

```
typedef struct _D3DXTRACK_DESC
{
    D3DXPRIORITY_TYPE Priority;
    FLOAT Weight;
    FLOAT Speed;
    DOUBLE Position;
    BOOL Enable;
} D3DXTRACK_DESC, *LPD3DXTRACK_DESC;
```

DWORD D3DXPRIORITY_TYPE
This parameter should be set to either `D3DXPRIORITY_LOW` or `D3DXPRIORITY_HIGH`. This allows us to assign the track to one of two blend groups: a high priority group or a low priority group as discussed earlier. Each group will have its tracks blended together separately and eventually the blended results for each group will be blended into a final result used to update the hierarchy matrices.

FLOAT Weight
This value has exactly the same meaning as the 'Weight' parameter we pass to the SetTrackWeight method. It allows us to set the current weight of the track which determines how much influence the assigned animation set has on the hierarchy.

FLOAT Speed
This member has exactly the same meaning as the 'Speed' parameter in the SetTrackSpeed function. It allows us to set a scalar value that is used by the controller to scale the animation time update for a given animation set. A value of 1.0 will run the animation at its default speed while a value of 2.0 will run the animation set at twice the default speed, and so on.

DOUBLE Position
This member has exactly the same meaning as the 'Position' parameter in the SetTrackPosition function. It allows us to set the timer of a track to a specific position without affecting any other tracks.

As a simple example, this allows us to restart the animation set assigned to a single track on the mixer without affecting other tracks.

BOOL Enable
This member is a Boolean variable where we pass in 'TRUE' or 'FALSE' to enable or disable the track, respectively.

This single function can be used instead of all the standalone functions we discussed in the previous sections. Whether you are initialising the properties of each track or simply changing the properties of a track midway through your game, this function provides a nice way of assigning multiple properties to a track with a single function call.

Finally, our application can retrieve the properties of a given track by using the ID3DXAnimationController::GetTrackDesc function.

```
HRESULT GetTrackDesc( DWORD Track, D3DXTRACK_DESC *pDesc );
```

The first parameter should be the track index we wish to retrieve the property information for and the second parameter should be the address of a D3DXTRACK_DESC structure to be filled with results.

Priority Blending

Each mixer track can be assigned to either a low priority group or a high priority group. The tracks of each group are blended together and then the resulting transformations for each group are blended together using what is referred to as the *priority blend weight* of the animation mixer. This is a global setting for the animation mixer and it controls how the low priority blend result is combined with the high priority blend result. We use the ID3DXAnimationController::SetPriorityBlend function to set this weight as a floating point value between 0.0 and 1.0.

```
HRESULT SetPriorityBlend ( FLOAT BlendWeight );
```

Tracks are assigned to priority groups using the either the SetTrackPriority function or the SetTrackDesc function discussed in the last section. Group assignment is based on one of the following flags:

D3DXPRIORITY_LOW – Track should be blended with all other low priority tracks ***before*** mixing with the high-priority result.

D3DXPRIORITY_HIGH – Track should be blended with all other high priority tracks, ***before*** mixing with the low-priority result.

Let us return to an earlier example to get some more insight into this concept. Recall that we have two tracks: one translates 100 units to the right and the other translates 100 units to the left. When each had a per-track weight of 1.0 we ended up with no movement because they cancelled one another out. However, if we were to specify them uniquely as low/high priority tracks, we see the following:

```
Track1: ( 100 * 1.0 ) = 100       // High priority track
Track2: ( -100 * 1.0 ) = -100     // Low priority track

// First Test
BlendWeight = 0.25 // One quarter high, three quarters low

Output = Track1 + ((Track2 - Track1) * BlendWeight)
Output = 100 + ((-100 - 100) * 0.25) = 50
Output = One quarter from 100 (high) and three quarters from -100 (low)

// Next Test
BlendWeight = 0.5       // Half way between low and high
Output = Track1 + ((Track2 - Track1 ) * BlendWeight)
Output = 100 + ((-100 - 100) * 0.5) = 0
Output = Half way between -100 (high) and 100 (low)

// Last Test
BlendWeight = 0.75      // Three quarters high, one quarter low

Output = Track1 + ((Track2 - Track1) * BlendWeight)
Output = 100 + ((-100 - 100) * 0.75) = -50
Output = Three quarters from 100 (high) and one quarter from -100 (low)
```

You can see that this is really just a simple linear interpolation between high and low priority tracks.

Our application can retrieve the current priority blend mode of the animation mixer by calling the ID3DXAnimationController::GetPriorityBlend function. It returns a single floating point value as a result.

```
FLOAT GetPriorityBlend( VOID );
```

10.8.3 Animation Mixer Configuration Summary

You should now be comfortable with the notion of assigning animation sets to tracks on the animation mixer and modifying track properties to effect the blended animations that are output. The following code snippet demonstrates how we might assign animation sets to two tracks in the animation controller and configure them in different ways. This code assumes that the animation controller has already had its animation sets registered.

```
pAnimController->SetTrackAnimationSet ( 0 , pAnimSetA );
pAnimController->SetTrackAnimationSet ( 1 , pAnimSetB );

D3DXTRACK_DESC Td;
Td.Priority =     D3DXPRIORITY_HIGH;      // Assign High Priority Group
Td.Enable   =     TRUE;                   // Enable Track
Td.Weight   =     1.0f;                   // Set Default Weight
Td.Speed    =     1.0f;                   // Set Default Speed
Td.AnimTime =     0.0f;                   // Start animation set at beginning
pAnimController->SetTrackDesc ( 0, &Td );
```

```
Td.Flags    =     D3DXPRIORITY_LOW ;      // Assign Low Priority
Td.Enable   =     TRUE;                   // Enable Track
Td.Weight   =     1.0f;                   // Set Default Weight
Td.Speed    =     0.5f;                   // Play track 1 at half its actual speed
Td.AnimTime =     12.0f;                  // Start this animation set 12 seconds in
pAnimController->SetTrackDesc ( 1, &Td );

// We have now set the track properties.
// Let us set the priority blend weight to distribute blending
// between high and low priority groups equally (a 50:50 blend)
pAnimController->SetPriorityBlend ( 0.5f );
```

Over time, you will find lots of creative ways to make use of animation mixing in your applications. Perhaps in one application you will find that you need only per-track weighting to achieve your desired results and you will forego using the priority blending system. In another application you may decide that you will mix two types of animation methods together (ex. keyframe animation with inverse kinematics) and find that the priority blending system works well for you. Either way, we have certainly seen thus far that D3DX provides quite a sophisticated system that, in the end, can save us a good deal of coding time.

10.8.4 Cloning the Animation Controller

Earlier in the chapter we learned that during the creation of our animation controller we will specify certain limitations such as the maximum number matrices or maximum number of animation sets that will be managed. While this presents no problem when we manually create an animation controller, because we can set the limits the animation controller to suit our needs, we might find ourselves disappointed with the default restrictions specified by D3DXLoadMeshHierarchyFromX when we load our animation data from an X file. The animation controller returned from D3DXLoadMeshHierarchyFromX has the following default limits:

MaxNumMatrices = Number of animated matrices in the X file hierarchy
MaxNumAnimSets = Number of animation sets in the X file (usually 1)
MaxNumTracks = 2
MaxNumEvents = 30

The one limitation that may be the hardest to accept is the two-track animation mixer which restricts us to blending only two simultaneous animations. It may also be problematic (as logical as the design decision was) to limit ourselves to the number of animation sets defined in the X file being the maximum number that can be registered. For example, although the X file might only contain a single animation set, we may want to generate another animation set programmatically and register that with the controller too. We would not be able to do so under the current circumstances, as this would exceed the maximum number of animation tracks that can be registered with the controller.

Fortunately, we are not locked in to the defaults that D3DXLoadMeshHierarchyFromX imposes. Just as we are able to clone a mesh to extend its capabilities (Chapter Eight), we can also clone an animation controller and modify its capabilities. Cloning creates a new animation controller with the desired

capabilities while preserving the animation, matrix, and animation set data of the original controller. That data will be copied into the newly generated controller such that it is ready to animate our hierarchy immediately. Once we have cloned the animation controller, the original animation controller can be released.

We clone an animation controller using the ID3DXAnimationController::CloneAnimationController function shown next. It is nearly identical to the D3DXCreateAnimationController function, so the parameter list should require no explanation.

```
HRESULT CloneAnimationController
(
    UINT MaxNumAnimationOutputs,
    UINT MaxNumAnimationSets,
    UINT MaxNumTracks,
    UINT MaxNumEvents,
    LPD3DXANIMATIONCONTROLLER *ppAnimController
);
```

> **Note:** We will cover events (parameter four) later in this chapter when we cover the animation sequencer.

10.8.5 Hierarchy Animation with ID3DXAnimationController

Once we have the animation controller that suits our needs, we are ready to use it to animate our hierarchy. While we have looked at quite a few functions for setup and configuration for both our animation controller and animation mixer, once all of that is done, actually playing the animations could not be easier. In fact, there is really just a single function (AdvanceTime) that we need to use.

AdvanceTime takes as its first parameter the time (in seconds) that has elapsed since the last call to AdvanceTime (which will be zero the first time we call it) and then updates the internal timer of the controller and the timer of each animation track (scaled by track speed). It then maps the timer of each track into the periodic position of its assigned animation set and uses this periodic position to call the animation set's GetSRT method for each animation it contains to generate the new SRT data for the frame to which it is attached. If multiple tracks (animation sets) are being used, then it is possible that there may be an animation in each animation set that animates the same frame in the hierarchy. In that situation we know that there will be multiple sets of SRT data for that single hierarchy frame. The animation mixer will blend those SRT sets together to calculate the final transformation matrix for that frame based on the properties we discussed earlier. The AdvanceTime function is shown next. Please note that this function takes a second optional parameter which allows us to pass in a pointer to a callback function. We will discuss the callback feature of the animation system at the end of this chapter, so for now just assume that we are passing in NULL as this parameter.

```
HRESULT AdvanceTime( DOUBLE Time,
                     LPD3DXANIMATIONCALLBACKHANDLER pCallbackHandler);
```

Simply put, once the animation controller has been configured, playing animation involves nothing more than calling this function in your game update loop, passing in the time that has elapsed since the previous call. The next code example uses our timer class to get the number of seconds that have passed since the last call and passes it into the AdvanceTime method of the animation controller. After this call, all the parent-relative matrices in the hierarchy will have been updated.

```
void MyClass::UpdateAnimations ( )
{
      double ElapsedTime =  m_Timer.GetTimeElapsed() ;
      m_pAnimController->AdvanceTime( ElapsedTime );
}
```

This single function call will calculate all of the current animation data and update the hierarchy frame matrices so that our meshes can be scaled, rotated, and translated according to the animation being played. Once the above function has been called, the hierarchy is ready to be traversed (where we will calculate the world matrices) and rendered as discussed earlier. Our approach to rendering the hierarchy is not altered at all by the fact that we are animating it. The animation controller simply changed the values stored in the relative matrices of our frame hierarchy so that the next time it is updated and rendered the meshes appear in their new positions.

If your animations are set to loop, you do not have to worry about keeping a running total of the sum of elapsed time or wrapping back round to zero after exceeding the length of the longest running animation set. This is because once the track timers are updated, they are mapped into the periodic position of the assigned animation set. If an animation set is configured to loop or ping-pong, then regardless of how high the value of the track's timer climbs, it will always be mapped into a periodic position within the bounding keyframes of the animation set.

If your animation sets are not configured for continuous play, then some care will need to be taken when calling AdvanceTime. Once a track timer exceeds the period of its animation set, the animation set will cease to play (technically, it has ended at this point). Of course, we have seen that you have the ability to set the position of a track back to zero to cause this animation set to play again, even if the global time exceeds the length of the animation set. It is helpful that the global time is decoupled from the track timers in this way.

As an example, imagine that we have an animation set with a period of 15 seconds which is not set to loop. It also has a track speed of 1.0, so initially there is a 1:1 mapping between global time, track time and the periodic position of the animation set. We might decide to perform out own looping logic so that we can control when the animation set starts playing. Imagine that although the animation set has a period of 15 seconds, we only want it to start playing again at a global time of 20 seconds, thus causing 5 seconds of inactivity between the time the first animation loop ends and the second one begins. The following code would achieve this (note that it assumes that the animation set is assigned to track 0 on the mixer):

```
void ProcessAnimations ( double ElapsedTime )
{
      static double WrapTime  = 20.0;

      double GlobalTime = pController->GetTime();
```

```
      if ( GlobalTime >= WrapTime )
      {
            pController->SetTrackPosition( 0 , GlobalTime-WrapTime );
            WrapTime+=20.0f
      }

      pController->AdvanceTime ( ElapsedTime );
};
```

Notice the call to the controller's GetTime method. This is a new method which we have not yet discussed. GetTime returns the global time of the controller. Remember, the global time is really the sum of all elapsed times that have been passed into our AdvanceTime calls since the animation began.

DOUBLE GetTime(VOID);

The previous code initially sets the wrap around time at 20 seconds global time. When this time is reached, the track timer is wrapped around to zero and a new wrap around time of 40 seconds is set. At 40 seconds the track timer will be wrapped around to zero and a new global wrap around time of 60 seconds would be set, and so on. While the period of the animation set is only 15 seconds and is not configured to loop, the above code would reset the track timer to 0 at every 20 second global time boundary. This clearly shows the distinction between the global timer which is ever increasing with each AdvanceTime call, and the track timers which can be reset, positioned or stopped independent of the global timer.

For no other reason than to better understand this concept, let us take a quick look at how we might write a simplified AdvanceTime function of our own that works with multiple animation sets. This will let us see how the timers are incremented. We will not worry about animation mixing in this example and will assume that each animation set influences its own section of then hierarchy. This will give us a rough idea of what is happening behind the scenes in the D3DXAnimationController::AdvanceTime function. Obviously there is a lot missing here, mainly the mixing of multiple frame SRT sets and the callback and sequencing systems which we will discuss shortly. However, this example does allow us to get the basic idea of how the update works and how the controller interacts with each track and its assigned animation sets. Fortunately, we will never have to write a function like this since the D3DX animation controller does it all for us.

```
void MyAnimController::AdvanceTime( double Elapsed )
{
    LPD3DXKEYFRAMEDANIMATIONSET pAnimSet = NULL;
    LPD3DXFRAME pFrame = NULL;

    D3DXVECTOR3 Scale, Translate;
    D3DXQUATERNION Rotate;
    D3DXMATRIX mtxFrame;
    ULONG i;
    char AnimName [1024];

    m_GlobalTime+=ElapsedTime;

   // Loop through each track
   for ( uint TrackIndex = 0; TrackIndex < GetNumTracks() ; TrackIndex++ )
```

```
   {
      // Increment track timer scaled by track speed
      m_Track[TrackIndex].TimerPositon+=ElapsedTime*m_Track[TrackIndex].Speed;

      // Get Anim set assigned to this track
      pAnimSet = GetAnimationSet( TrackIndex , &pAnim );

      // Map track time to animation set time
      float PeriodicPosition = pAnimSet->GetPeriodicPosition(
                                          m_Track[TrackIndex].TimerPosition );
      // Get the number of animations in this animation set
      ULONG NumAnimations = pAnimSet->GetNumAnimations();

      // Loop through each animation in this animation set and get the new SRT data
      for ( Animation = 0; Animation < NumAnimations; ++Animation )
      {

         // Get name of current animation
         // should match the name of the frame it animates
         pAnimSet->GetAnimationNameByIndex( Animation , &AnimName );

         // Generate the Scale, Rotation and Translation data for this animation
         // for the current periodic position
         // We looked at GetSRT earlier.
         pAnimSet->GetSRT( PeriodicPosition, Animation ,
                         &Scale, &Rotate, &Translate );

         // Generate a matrix from the SRT data.
         // This global D3DX function generates a 4x4
         // transformation matrix from a scale vector, a quaternion
         // and a translation vector. Check out the docs for details.
         D3DXMatrixTransformation( &mtxFrame, NULL, NULL, &Scale,
                                   NULL, &Rotate, &Translate );

         // Find the frame that this interpolator animates in the hierarchy
         pFrame = D3DXFrameFind(m_pFrameRoot, AnimName );

         // Update the frames matrix with out new matrix
         pFrame->TransformationMatrix = mtxFrame;

    } // Next Animation

    // Release the anim set we no longer need it
    pAnimSet->Release();

  } // Next Track
}
```

The first thing this function does is update the global time of the controller. This global timer may seem useless at the moment, but when we examine callbacks, you will see how the global timer becomes a much more useful feature. Next, we loop through each track and increment its timer. In this case we scale the elapsed time about to be added by the speed property of the track. We then convert the new track time into an animation set periodic position which we can feed into the GetSRT function. We then loop through each animation stored in the animation set and, for each one, call ID3DXAnimationSet::GetSRT to generate the new scale, rotation and translation information. We then

use the returned information to construct a matrix. Once the matrix is constructed, we search the hierarchy for a frame with the same name as the animation and replace its frame matrix with the newly generated one. The D3DX animation controller would not search the hierarchy in this way as it would be far too slow, which is why it stores the matrices in a separate array that can be accessed quickly. Indeed, this is why we register animation outputs in the way discussed earlier -- so the controller can know exactly which matrix is paired with which animation and quick matrix updates can be performed without the need for frame hierarchy traversal. However, as this function has been written with clarity of process in mind, we will forgive ourselves for bypassing this optimization.

One thing you may have noticed is that we are not multiplying the current frame matrix by the newly generated animation matrix. This is because all of the keyframe animation data stored inside an animation is ***absolute***. This is true of both the data in the .X file itself as well as in the data output by the SRT functions (by definition, because it is stored this way in the file). To be clear, what is meant by 'absolute' is that the keyframe data is not relative to what came before it (i.e. it is not incremental). Each keyframe is a complete snapshot that describes the transformation state of the object at that particular moment on the timeline. The transformations are still defined relative to the parent frame of course (it's still a parent-relative matrix), because we want the spatial hierarchy relationships to remain intact during animation. This means that we are able to overwrite the frame matrix without fear of having to preserve or take into account previous transformations. Each time we call AdvanceTime, the frame matrix will be repopulated with the next set of absolute SRT values. In other words, we get a new frame matrix for each animation update. To make the system work incrementally would be more challenging and would require that we track more data between update calls. Since this is typically unnecessary and does not add much value to the system, absolute values are preferred.

> **Note:** Although we are searching through the frames here (using D3DXFrameFind) to find the correct matrix in the hierarchy to modify, the animation controller does not need to do this. Recall that it has access to a pointer for each matrix in the hierarchy along with the name of the frame it is associated with. For more information you can refer back to our discussion of the ID3DXAnimationController::RegisterAnimationOutput function discussed earlier.

ResetTime

The final function we will cover in this section is called ResetTime. It allows the application to wrap the global time of the animation controller back to zero, much like we did in the earlier code with the track timers. This is especially handy if we have many animation sets that do not loop and would cease playing once the sum of elapsed time passed into the AdvanceTime method exceeded its period. This function causes the entire animation system to restart, taking smooth wrapping of track timers into account. This is especially useful when considering sequencing which we will discuss in the next section.

For now, just know that sequencer events (called key events) are registered on the global controller timeline (not the per-track timelines) and as such, once an event has been triggered when the global time has reached its timestamp, it will never be triggered again unless the global time is restarted. So we can imagine that a complex group of animation sets might wish to be looped at the global level so that the key events set on the global timeline are also re-triggered each time. If we simply configured each

animation set to loop, the animations themselves would loop but each key event on the global timeline would only be triggered once.

It is also worthy of note that one might also choose to reset the global time of the controller even if the sequencer is not being used, simply to stop the global time value reaching an extremely high value. Obviously this would only be a concern if an animation was left to play for a considerable period of time. The method is shown below.

```
HRESULT ResetTime(VOID);
```

The ResetTime method is actually a little more complicated than it might first seem. Not only does it reset the global timer of the controller back to zero, but it also wraps around each of the track timers. It does not simply set them to zero as this would cause jumps in the animation. Instead, it wraps them around such that the track timer is as close to zero as possible without altering the periodic position of the animation set currently being played.

During the call to ResetTime, the animation set's GetPeriodicPosition function is called, passing in the current track time. If the D3DXTRACK_DESC::Position was 137 prior to ResetTime(), then this is the position that gets passed to the GetPeriodicPosition call. Normally, GetPeriodicPosition returns the current time, after it has been mapped into the set's local timeline. In the case of looping for example, we can assume that this is a simple fmod() of the current track time with the period of the animation set as discussed earlier. During ResetTime, the information returned by GetPeriodicPosition is taken as a 'snapshot', and all internal time data is updated using this snapshot. The information returned by GetPeriodicPosition is used to update the track position. You can prove this by examining the track timer (its position) both before and after the ResetTime call. Meanwhile the controller’s global time is reset to 0.0.

To summarize, let us look at an example of what is happening here. Imagine we had an animation set with a period of 10 seconds and let us make the call to ResetTime after 35 seconds of application time have elapsed. Prior to the ResetTime call, both our track containing the animation set, and our global time contain the value 35.0 (assuming we maintained a constant track speed of 1.0). At this point we make our call to ResetTime. During the call, the animation set's GetPeriodicPosition function is called and it returns what is essentially fmod(TrackPosition, pAnimSet->Period) -- therefore a value of 5.0. Once the call has completed, we find that the controller’s global time has been reset to 0.0, and the track position has been merely wrapped back into a sensible range, and now contains a value of 5.0.

> **NOTE:** No other animation set function is called during the Reset procedure. In addition, there are implications with respect to the callback mechanism. We will discuss this later when examining the D3DX animation callback mechanism.

So we have now looked at how to advance our animations during runtime using a simple function call. We have also seen how we can retrieve the global time of the controller if we wish to allow the application the freedom to manipulate a certain track at key global times. However, while we could allow our application to control the track properties at certain global times using the method shown earlier, this is precisely what the animation sequencer is for, and is the subject of our next section.

10.9 The Animation Sequencer

Earlier in the chapter we mentioned that the animation controller contains a very useful event scheduler, referred to as the **sequencer**, which allows us to apply and adjust track properties at user defined global times. In this section we will discuss the animation sequencer; another key component of the D3DX animation controller. What we will see is that the global timer of the controller is more than just a counter for elapsed time passed into AdvanceTime calls; it is actually the heartbeat of a powerful tool.

Recall that the elapsed time that we pass to AdvanceTime increments both global and local timelines. The global time is maintained at the controller level and is the value that is returned in response to a GetTime function call. It is ultimately the amount of time that has passed in seconds since calls to AdvanceTime began (assuming that you have not called ID3DXAnimationController::ResetTime to reset the global time back to zero). Unlike the animation set's GetSRT function which uses track times, the sequencer works using the controller's global time value of the controller.

For example, let us imagine that we would like to schedule an event that disables an animation track at the global time of 12 seconds. Further, let us assume that the animation set we are working with is only 10 seconds in duration, but is configured to loop. In this example, the animation set would stop playing exactly 2 seconds into its second iteration. This event would trigger only occur once -- when a time of 12 seconds or greater is first reached on the global timeline. This same event will *not* be triggered again with further calls to AdvanceTime (unless ResetTime is called).

If we want an event to be periodic (i.e., triggered once every N seconds), then the application is responsible for providing the logic that wraps the global time before it calls AdvanceTime again. For example, using our 12 second (global time) trigger described above, if we were calling the following function repeatedly (passing in the time in seconds that has elapsed since the last frame), the event would initially be triggered 12 seconds into the animation loop. Notice however, that every 20 seconds we wrap the time back to zero. Thus, after the first time the event has been triggered, it is then re-triggered every 20 seconds thereafter (i.e. every time CurrentGlobalTime reaches 12 seconds again).

```
void AnimateHierarchy ( double TimeElapsed )
{
    CurrentGlobalTime = pAnimController->GetTime();

    if ( CurrentGlobalTime >= 20.0 ) pAnimController->ResetTime();

    pAnimController->AdvanceTime( TimeElapsed );
}
```

Just try to remember that events are scheduled in global time while animation sets use track time to loop independently. If your track speed is 1.0 and you have not altered the position of the track, then a 1:1 mapping will be maintained between global time and track time.

Let us look at another example of why this is useful. We will assume that we have a hierarchy that contains the mesh of a space station and the mesh of a space ship, and that we have defined two looping animation sets. The first animation set slowly rotates the space station frame along its local 'up' axis.

The second animation set is a 20 second animation set that animates the frame of the space ship so that it starts off docked inside the space station and then flies out of the space station and off into deep space (perhaps through a jump gate or wormhole). This sequence will make a space simulation more realistic as we come in to dock our ship, since we will see other space ships making use of the station as well. As you might imagine, simply looping the space ship animation set presents a bit of a problem. Seeing a new space ship emerge from the space station precisely every 20 seconds makes it quite obvious to the player that this is just a looping animation. We will generally prefer a less uniform and more random series of events as would be the case in the real world (using the term loosely of course given the circumstances). Making use of our sequencer provides an opportunity to improve our situation. We could very easily make the pattern a lot less obvious simply by choosing a more random distribution of global times to start and stop the animation (i.e. enable/disable the track). Imagine for example, that we set events for the second track on the mixer (the track our space ship animation is assigned to) to occur at the following global times (in seconds). Keep in mind that the space ship animation lasts for 20 seconds before looping.

Event Number	Global Time (GT)	Event Type
1	20	Track Disable
2	30	Track Enable
3	70	Track Disable
4	100	Track Enable
5	160	Track Disable
6	180	Track Enable

Our accompanying animation update function might look something like the following:

```
void AnimateSpaceSceneHierarchy(FLOAT TimeElapsed)
{
       if ( pAnimController->GetTime() > 200.0 )  pAnimController->Reset();
       pAnimController->AdvanceTime( TimeElapsed );
}
```

We see immediately that our sequencer loop is now on a much larger scale of 200 seconds with some event distribution in between. This should break up the pattern nicely over time and provide some additional realism. Here is how everything would play out…

The space ship track would start off enabled and the space ship animation would play out to completion once (it lasts for 20 seconds). Our first event occurs immediately (GT = 20 secs) which turns off the track, creating a 10 second gap where no animation is being played for the space ship. 10 seconds later (GT = 30 secs) our second event occurs which re-enables the space ship track. Note that during the 10 second time between the first two events, the animation controller will ignore the disabled track and will not increment the track's timer when AdvanceTime is called. Therefore, our space ship mesh would be frozen somewhere off in the distance (hopefully far enough away so as not to be visible!). Notice as well that we are very careful to disable the track on 20 second boundaries so that we do not disable the animation while the space ship is still in the middle of its sequence.

The track then plays for 40 more seconds causing the animation to play two more times (looping) before our next event occurs (GT = 70 secs). This third event disables the track again. Because the animation is

always being frozen on a 20 second boundary, we can be sure that whenever we enable it again it will start off at a track position close to zero where the ship is back inside the space station. Our fourth event (GT = 100 secs) re-enables the track and we let the track play for another 60 seconds. This means that the animation will loop three times, one immediately after another. We then disable the track again at event five (GT = 160 secs) and do not enable it again until our sixth event (GT = 180 secs) leaving a 20 second gap where no ships leave the space station. Finally our sixth and last event (GT = 180 secs) re-enables the track. Note that the looping would remain enabled and we would see ships take off every 20 seconds were it not for the logic in our AnimateSpaceSceneHierarchy function. Rather than continue to increment the global time, we roll it back to zero once we have had 200 seconds elapsed in total. Thus, the whole cycle would start again. Our final event which re-enables the space ship animation would actually play twice before being disabled again at the rolled around global time of 20 seconds.

Admittedly, this very simple example only scratches the surface of some of the creative ideas you can come up with for using the animation sequencer. But it is clear enough that just by registering a few track enable/disable events with the sequencer we have turned a 20 second looping animation into a 200 second animation sequence that is far less uniform and perceptible to the player. The gap between ships leaving the station would no longer seem fixed and it is unlikely that the player would pick up on this pattern. You could probably imagine experimenting with additional values like track speed as well so that the ships seem to fly faster or slower. Perhaps you might occasionally turn on blending with a second track that includes a different translation keyframe value so that ships fly off in different directions. Maybe you even would turn on an afterburner track at random intervals, etc.

With this high level overview in place, let us now examine how we can set key events on the global timeline using the controller's sequencing methods. We will also need to discuss the types of key events we can register.

10.9.1 Registering Sequencer Events

There are five different Event Key types that we can register with the animation sequencer. This is done via one of five corresponding methods exposed by the ID3DXAnimationController interface. So to set an event, we just call the function which matches the event type and we are done. It is very important that we do not try to register more events with the sequencer than the maximum number of events that the animation controller can process. Recall that we set this maximum number of events when we created/cloned the animation controller (the MaxNumEvents parameter).

> **Note:** D3DXLoadMeshHierarchyFromX creates an animation controller that can store a maximum of 30 events. Trying to register additional events beyond those 30 will fail. To increase the event pool size, we simply need to clone a new controller and specify the desired number of slots.

We can query the number of events the animation controller can have registered with it using the following method of the ID3DXAnimationController interface. This next function returns the maximum number of events that can be registered with the controller.

```
UINT GetMaxNumEvents(VOID);
```

Let us quickly discuss these five functions along with their parameters and the types of events they allow us to set. Notice how each of the event registration functions returns a D3DXEVENTHANDLE. We will discuss what these handles can be used for at the end of this section.

1. The KeyTrackEnable Function

This function allows us to schedule an event that will enable or disable a track on the animation mixer (a 'KeyTrackEnable' event). When a track on the mixer is disabled, any animation set assigned to that track is essentially frozen. It will not receive any updates from the AdvanceTime function and the track timer will not be incremented until it becomes re-enabled. Note that when we re-enable the track, it will not restart from the beginning -- it will resume from the time it was frozen. This allows us to freeze an animation at any point and then resume it whenever we wish.

```
D3DXEVENTHANDLE KeyTrackEnable(UINT Track, BOOL NewEnable,
                               double StartTime);
```

UINT Track
This parameter is the zero-based index of the mixer track we are registering the event for. For example, to disable the fifth track of the animation mixer (and its assigned animation set) at a specific global time, we would call this function with a value of 4 for this parameter.

BOOL NewEnable
This second parameter should be set to true or false depending on whether we wish to enable or disable the specified track at the specified time, respectively.

DOUBLE StartTime
The final parameter is the global time (in seconds) when we would like this event to occur.

Example:

```
pAnimController->KeyTrackEnable( 0 , FALSE , 35.0 );
pAnimController->KeyTrackEnable( 2 , TRUE , 100.0 );
```

The prior example registers two KeyTrackEnable events with the animation sequencer. In the first call to the function we specify that we would like the first track on the animation mixer (track 0) to be disabled 35 seconds into the animation (when the sum of elapsed time passed into the AdvanceTime function passes 35 seconds). In the second call to the function we register an event with the sequencer that specifies that at 100 seconds global time, we would like the third track of the animation mixer (track 2) enabled and to start playing its assigned animation set.

2. The KeyTrackPosition Function

The next type of event that we can register with the animation sequencer is referred to as a KeyTrackPosition event. This event allows us to set the timer of a track to a specific value (position)

when a specific global time is reached. In other words, we are saying that at a specific global time, we would like to instantly transition the track timer to a specific value regardless of the current global time. As it is the position of a track (the track timer) that is used to map to a periodic position, this function ultimately allows us to jump to a desired location in the animation set at a specified global time.

This can be a very useful event if you are using a single animation set that stores all of your animation sequences (ex. run, walk, jump, etc). Imagine that we had an animation set that contained only two animation sequences: idle and walk. You could quickly pre-script some AI-like events (or load them from a file) that basically has a character which idles for a few seconds and then starts walking, stops and idles again, walks a little more, etc. While we will do this differently in our demo engine (using separate animation sets and then enabling/disabling their tracks), if you are using single animation sets, this might be an approach to consider. Note that if you wanted your AI to make these decisions on the fly, rather than use a pre-programmed set of events, you would probably use the ID3DXAnimationController::SetTrackPosition to cause the timeline advancement to happen immediately. However, there are certainly cases where the event management concept can be put to good use. Your application could, for example, decide to register a track position change event to occur in 10 seconds time using the sequencing functions.

```
D3DXEVENTHANDLE KeyTrackPosition( UINT  Track, double NewPosition,
                                  double StartTime );
```

UINT Track
This is the index of the mixer track for which we would like this event to apply. It is the timer of this track which the event will manipulate.

double NewPosition
This parameter contains the new position that we would like this track's timer set to. For example, if this value was set to 200, then when this event is triggered, the track time would instantly be set to 200 and any future calls to AdvanceTime would add elapsed time relative to this. This advancement would happen at the global time specified in the StartTime parameter. Remember also that this is not the same as directly specifying a position in the animation set (although it can be). The track position is mapped to a periodic position so that looping is factored in, and it is the periodic position that is used to fetch the SRT data for each animation. Therefore, manipulating the timer of the track allows us to *indirectly* manipulate the periodic position generated for the animation set.

double StartTime
This is the global time (in seconds) when we would like this event to occur. When the global timer of the controller reaches or passes this value, the event will be triggered.

As another simple example, we might imagine that we have a zombie in our game that, five seconds after being hit by our bullet, disintegrates into a pile of dust and bones. Again, we are assuming that this disintegration sequence is part of a single animation set that might include other animation sequences like the zombie walking or attacking, etc. In the following example, the zombie animation set is assigned to track 0 on the animation mixer. When the zombie is hit by a bullet we register an event that advances the animation to the death sequence (position 200) in 5 seconds time (5 seconds being an arbitrary delay that we have chosen to delay the disintegration sequence).

```
if ( ZombieIsHitByBullet )
{
      double CurrentTime = pAnimController->GetTime ();
      pAnimController->KeyTrackPosition ( 0 , 200 , CurrentTime + 5.0 );
}
```

3. The KeyTrackSpeed Function

We mentioned earlier how the ID3DXAnimtionController::SetTrackSpeed function sets a scalar value (per track) to scale the amount that the track's local time is incremented using the passed global time. Setting this to 1.0 means that the animation set time is incremented normally. So we can see that each track has a clock and a speed value. We can set this speed value directly using the SetTrackSpeed function discussed earlier in the chapter or we can choose to let the sequencer do it at a certain global time using the KeyTrackAnimSpeed function.

```
D3DXEVENTHANDLE KeyTrackSpeed ( UINT Track, float NewSpeed,
                                double StartTime, double Duration,
                                DWORD Method );
```

DWORD Track
This is the index of the track we would like the event to be applied to.

float NewSpeed
This is the new speed value which we will set for this track. A value of 1.0 means the animation will play at its default speed (the speed intended by the animation creator). The speed value of each track is used to scale the amount by which the track's internal clock (i.e., the track position) is incremented. Setting this value to 3.0 will cause the animation controller to scale the elapsed time passed into the AdvanceTime method by 3, before adding it to the track timer.

double StartTime
As with all key event types that we can register with the sequencer, we always have to specify a global time at which this event will take place. If we set this value to 200, it means that this event will be triggered when the controller global timer reaches 200 seconds.

double Duration
Unlike the previous functions we discussed, this function allows us to specify an end time for our requested change so that we can transition gracefully between events. The `Duration` parameter specifies how long (in seconds) we want the transition between the old speed and the new speed to take. For example, assume that the current speed of the track is 10.0 and we set an event at 100 seconds global time to set the speed to 5.0. We also set the duration of the event to 10.0. Then starting at 100 seconds global time, the speed of the animation set assigned to this track would slowly decrease over the next 10 seconds until it finally reached the requested speed of 5.0. In other words, it would take 10 seconds to reach the requested speed of 5.0 -- we gradually ease in to it rather than abruptly change. The calculation used to scale between the current speed and the requested speed of the track is determined by the Method parameter discussed next.

DWORD Method
We use this parameter to pass a member of the `D3DXTRANSITIONTYPE` enumerator. It describes the method we would like to use to run the transition calculation between current and target values. There are two methods to choose from: `D3DXTRANSITION_LINEAR` provides a simple linear interpolation between the old speed and the new speed and `D3DXTRANSITION_EASEINEASEOUT` uses a spline-based curve to handle the transition. In other words, it is linear falloff versus exponential falloff (to refer back to some familiar material we discussed in Chapter Five).

Example

```
pAnimController->KeyTrackSpeed( 2 , 2.0 , 200.0 , 10.0 , D3DXTRANSLATION_LINEAR );
```

This example sets an event for the third mixer track (track 2) to be triggered at 200 seconds global time. It will begin to set the speed value for the track to 2.0, from whatever its current speed is, over a period of 10 seconds. Linear interpolation will be used to affect the changes in between.

4. The KeyTrackWeight Function

Every track on the animation mixer can be assigned a blend weight using the ID3DXAnimationController::SetTrackWeight function discussed earlier. This weight is used to scale the influence of the animation set on the respective frames in the hierarchy. We can also schedule a KeyTrackWeight event with the sequencer so that the weight of a track can be changed at scheduled global times.

Like the previous function discussed, we are able to apply our change over a specified duration. As one usage example, we might have an animation that violently shakes certain meshes in the hierarchy in response to a laser blast. We could schedule the weight of this 'shake' animation to decrease to zero over a period of N seconds, such that the effect of the blast on the hierarchy seems to dissipate with time (i.e. less and less noticeable shaking over time).

```
D3DXEVENTHANDLE KeyTrackWeight ( DWORD Track, float NewWeight,
                                 double StartTime, double Duration,
                                 DWORD Method );
```

DWORD Track
This is the track that we wish this event to be scheduled for.

float NewWeight
This is the new weight that we would like to set for this track. The default value is 1.0, so the animation affects the hierarchy at full strength. Setting this value to 0.5 for example would mean that the animation would affect the hierarchy at only half strength.

double StartTime
This is the global time when the event should occur.

double Duration
This is the span of time over which the transition from the previous weight to the new weight should take place. If we specified a new weight of 0.0 and the current weight was 1.0, and we used a Duration of 3 seconds, then once the specified global time was reached, the weight of the track would be slowly degraded from 1.0 to 0.0 over a period of 3 seconds.

DWORD Method
This parameter indicates the interpolation method that generates the intermediate values during the transition between current and target weight values. The two choices are linear interpolation (`D3DXTRANSITION_LINEAR`) or interpolation along a curve (`D3DXTRANSITION_EASEINEASEOUT`).

```
pAnimController->KeyTrackWeight(1, 0.0, 100.0, 3.0, D3DXTRANSITION_EASEINEASEOUT);
```

This example schedules a weight event to take place on track 1 at 100 seconds global time. The weight will be exponentially scaled down from its current weight to a value of 0.0 over a period of 3 seconds. Once done, the animation assigned to this track will not affect the hierarchy in any way.

5. The KeyPriorityBlend Function

The final event type we can register with the sequencer is the priority blending event. This is the sequencer replacement for the `SetPriorityBlend` function covered earlier. This function allows us to smoothly transition between weighting the blending between high and low priority track groups. The function is shown below with a list of its parameters. Notice that unlike the other sequencing functions we have discussed, there is no Track parameter. You should recall that this is because the priority blend is a property of the animation mixer itself, and not a specific track.

```
D3DXEVENTHANDLE KeyPriorityBlend( float BlendWeight,
                                  double StartTime, double Duration,
                                  DWORD Method );
```

float BlendWeight
This parameter is the new priority blend value for the animation mixer. It should be a value between 0.0 and 1.0. This value can be thought of as setting the strength of low priority tracks in the final blending operation. A value of 1.0 would mean that the high priority tracks do not influence the hierarchy at all.

double StartTime
The global time in seconds at which the event should be triggered.

double Duration
The length of time it should take to transition between the current and target priority blend weights.

DWORD Method
This parameter indicates the interpolative method that generates the intermediate values during the transition between current and target priority blend weight values. The two choices are linear interpolation (`D3DXTRANSITION_LINEAR`) or interpolation along a curve (`D3DXTRANSITION_EASEINEASEOUT`).

10.9.2 Event Handles and Working with Registered Events

We have now seen how easy it is to register an event with the sequencer; a simple function call and the work is done. However, there may be times when you wish to reset the global time of the controller back to zero, but do not wish a certain event to occur a second time through. In order to address this situation, we need a function that allows us to remove an event from the global timeline as well as register one. The ID3DXAnimationController provides us such a method. It also provides methods for querying upcoming events, query current events being executed, and validating events as still active or not.

In order to ask the animation controller for details regarding an event, we need some way to inform it which event we are enquiring about. You will likely have noticed that each of the functions that register a key event returns a D3DXEVENTHANDLE. This handle can be stored and used to enquire about that event at a later time.

`HRESULT UnkeyEvent( D3DXEVENTHANDLE hEvent );`

This function allows the application to remove a registered event from the sequencer. You simply pass in the handle of the event. Below we see an example of a TrackEnable event that has been registered to occur at 100 seconds global time. We then use the returned handle to later remove it from the timeline. Ultimately, this allows us to discard events which we no longer need, which can be useful if your animation controller has been configured to store only a small number of events.

```
D3DXEVENTHANDLE Handle;
Handle = pAnimController->KeyTrackEnable( 2 , TRUE , 100.0 );
..
..
..
pAnimController->UnkeyEvent( Handle );
```

As you can see, the handle returned from the KeyTrackEnable function is used to identify the event to the controller in the UnkeyEvent method.

`HRESULT UnkeyAllTrackEvents( UINT Track );`

This function does not require an event handle to be passed in its parameter list because it is used to remove *all* events scheduled for a given track. This will not affect any events that have been registered for other tracks. Of course, it cannot be used to unregister priority blend events, since priority blend events are global to the controller and are not assigned to any track. There is a separate function (discussed next) for removing all events of this type.

In the following example we register three events with the controller. Two of these events are registered for track 2 on the mixer at 100 and 300 seconds respectively, and an event is also registered for track 3 to occur at a time of 200 seconds.

```
pAnimController->KeyTrackEnable( 2 , TRUE , 100.0 );
pAnimController->KeyTrackEnable( 3 , FALSE ,200.0 );
pAnimController->KeyTrackEnable( 2 , TRUE , 300.0 );
…
…
pAnimController->UnKeyAllTrackEvents( 2 );
```

Notice that after the three events have been registered, later in the code we unregister all events assigned to track 2. In the above example, this would remove only two of the three events. The event that was registered for track 3 at a global time of 200 seconds would still remain on the global timeline.

HRESULT UnkeyAllPriorityBlends(VOID);

When priority blend events are scheduled using the KeyPriorityBlend function, these events alter a global setting of the controller, and as such are not specific to any track. Therefore, if we wish to remove all priority blend events that have been registered with the animation sequencer, we must use the UnkeyAllPriorityBlends function. This function will remove *all* events that have been previously registered with the KeyPriorityBlend function.

HRESULT ValidateEvent(D3DXEVENTHANDLE hEvent);

The ValidateEvent function can be used to test if an event is still valid. Valid events are events which either have not been executed yet (because the global time is less than the event timestamp) or events that are currently being executed.

In this next example we show an event that has been registered for track 2 at 100 seconds global time. Elsewhere in the code, the event is validated. If the event is found to be invalid then it means it has already been triggered and has completed. In this case, we then remove the invalid event from the timeline.

```
D3DXEVENTHANDLE Handle;
Handle = pAnimController->KeyTrackEnable( 2 , TRUE , 100.0 );
..
..
..
if ( FAILED ( pAnimController->ValidateEvent( Handle )) )
     UnKeyEvent ( Handle );
```

This method provides a way for our application to know whether a certain event has been triggered yet. However, you should be careful if you intend to reset the global time and wish the events to be triggered again each time through the global timeline. Once the event is gone, it is gone for good. If the application was then to call the ResetTime method resetting the global time of the controller to zero, the same event would not be triggered when the global time reaches 100 seconds (in the above example) a second time because it has been removed from the timeline

```
D3DXEVENTHANDLE GetCurrentTrackEvent( UINT Track,
                                      D3DXEVENT_TYPE EventType );
```

This function allows you to query the current event that is running on a particular track. This allows the application to fetch the event handle that is currently being executed. This event handle can then be passed into the GetEventDesc method (discussed below) to fetch the event details.

For the first parameter, the function is passed the index of the track for which we wish to fetch the handle of the event currently being executed. The second parameter allows us to specify a filter so that we can fetch the event only if it is of a certain type. If no event of the specified type is currently running on the specified track, the function will return NULL.
For the second parameter, we should pass in a member of the D3DXEVENT_TYPE enumeration:

```
typedef enum _D3DXEVENT_TYPE {
    D3DXEVENT_TRACKSPEED = 0,
    D3DXEVENT_TRACKWEIGHT = 1,
    D3DXEVENT_TRACKPOSITION = 2,
    D3DXEVENT_TRACKENABLE = 3,
    D3DXEVENT_PRIORITYBLEND = 4,
    D3DXEDT_FORCE_DWORD = 0x7fffffff
} D3DXEVENT_TYPE;
```

Passing in D3DXEVENT_PRIORITYBLEND to this function will always return NULL because a priority blend event is not a track event. The current code shows how we might query for the currently running track speed event (if any) on track 2 and output the speed value. This could be useful for debugging or perhaps for slowing down in-game MIDI music based on the speed of a track.

```
D3DXEVENTHANDLE Handle;
Handle = pController->GetCurrentTrackEvent( 2 , D3DXEVENT_TRACKSPEED );

if ( Handle )
{
     D3DXEVENT_DESC desc;
     PController->GetEventDesc( Handle , &desc );
     Double Speed = desc.Speed;

     if ( Speed < 0.5 ) PlaySlowMusic();
     else
                        PlayFastMusic();
}
```

In the above pseudo-code, the handle of any currently playing speed change event is requested. If a speed event is currently being triggered on track 2, we are returned the handle (or NULL if no speed event is currently being carried out).

If an event is being performed, then we use the GetEventDesc method of the controller (discussed shortly) to fetch the details of the event. They are returned in the passed D3DXEVENT_DESC structure. In this example, the speed of the event is queried and used to play different music depending on the speed at which the animation is playing.

```
D3DXEVENTHANDLE GetCurrentPriorityBlend(VOID);
```

This method is the sister function of the function previously described. As discussed previously, priority blend events are different from all other key events in that they are not assigned to a specific track. As such, a different function is exposed to allow the application to retrieve the event handle of any priority blend event that is currently being executed.

The function takes no parameters and returns the event handle of the current priority blend event being executed by the controller (or NULL if no priority blend event is currently in progress).
Once you have the event handle, you can then call the GetEventDesc method (just as we did in the prior code example) to fetch the details of the priority blend event. This will tell us things like its time stamp, its start time, weight, and duration.

```
HRESULT GetEventDesc( D3DXEVENTHANDLE hEvent,  LPD3DXEVENT_DESC pDesc );
```

This function is useful for extracting the information for any event for which the application has an event handle. By simply passing in the event handle as the first parameter and a pointer to a D3DXEVENT_DESC structure, on function return, the details of the event will be stored in the passed structure.

We used this function in the description of the GetCurrentTrackEvent example above, but it can also be used to retrieve the information of a priority blend event (if the handle to a priority blend event is passed in as the first parameter).

The D3DXEVENT_DESC will contain all the information about the event:

```
typedef struct D3DXEVENT_DESC {

    D3DXEVENT_TYPE      Type;
    UINT                Track;
    DOUBLE              StartTime;
    DOUBLE              Duration;
    D3DXTRANSITION_TYPE Transition;

    union
    {
        FLOAT  Weight;
        FLOAT  Speed;
        DOUBLE Position;
        BOOL   Enable;
    }

} D3DXEVENT_DESC, *LPD3DXEVENT
```

As we might expect, the first five members describe the details of the event itself (e.g. what type of event it is -- D3DXEVENT_TRACKSPEED or D3DXEVENT_PRIORITYBLEND). We are also returned the track number that the event applies to (not applicable to priority blend events) and the global time for the event trigger and the duration (in seconds) that the event will take to fully execute. We can also examine the transition type that is being used for this event to reach its desired final state.

We discussed the various events that can be scheduled earlier, and saw that duration and transition information is not applicable to KeyTrackEnable events or KeyTrackPosition events.

Finally, the last member of this structure is a union. The member that is active in this union depends on the type of event that it is. For example, if the Type parameter is set to D3DXEVENT_TRACKWEIGHT or D3DXEVENT_PRIORITYBLEND then the Weight member of this union will contain the Weight that this event will set the track to use or set the priority blend to. If the event type is D3DXEVENT_TRACKENABLE then the Enable Boolean will be set to true or false depending on whether this event is configured to enable or disable the current track.

```
D3DXEVENTHANDLE GetUpcomingTrackEvent( UINT Track,
                                       D3DXEVENTHANDLE hEvent );
```

This function allows us to pass in an event handle to get back the next event that is due to be executed from the current event (not including the event passed in) for the specified track. This function actually searches the global timeline from the event passed in to find the next event that is scheduled. When an event is found, not only is its handle returned, but it is also cached in the controller. While this does not alter the performance or playback of events, it does allow us to subsequently call this function repeatedly, passing NULL as the event handle. Each call will step to the next event in the event queue for the specified track, until the function returns NULL. NULL indicates that there are no more events for this track. This allows us to iterate through all future events until the end of the event queue is reached.

If we pass in NULL to the initial call to this function, the handle to the next scheduled event (from the current global time) will be returned and cached for future calls.

```
D3DXEVENTHANDLE GetUpcomingPriorityBlend( D3DXEVENTHANDLE hEvent );
```

This function is the priority blend event version of the previous function. We pass in the event handle of priority blend event (or NULL to start searching from the current global time) and it will return the handle of the next scheduled priority blend event.

This function (like the previous) can be called iteratively to step through all future priority blend events that may exist. When the function returns NULL, there are no further priority blend events scheduled on the timeline and we have reached the end of the event queue.

10.9.3 Animation Sequencer Final Notes

The sequencer does not attempt to optimize or compact its event set, so do not make any assumptions about its behavior. For example, each time you pass in a value with the same global time, even if the events are identical in every way, a new event is added to the internal queue. As you can imagine, we can very quickly hit our `MaxNumEvents` limit defined for the animation controller if we are not careful. The following code would actually register 5 events with the sequencer even though they are exactly the same.

```
m_pAnimController->KeyTrackEnable ( 0 , FALSE , 5 );
m_pAnimController->KeyTrackEnable ( 0 , FALSE , 5 );
m_pAnimController->KeyTrackEnable ( 0 , FALSE , 5 );
m_pAnimController->KeyTrackEnable ( 0 , FALSE , 5 );
m_pAnimController->KeyTrackEnable ( 0 , FALSE , 5 );
```

While we would probably not do something as obvious as the above example, we do have to be very careful that we do not register events inside frequently called snippets of code. For example, a careless programmer might intend to register a single event with the animation controller, but place the code that registers it inside his main animation or render loop:

```
void UpdateAnimations ( double Time )
{
      pAnimationController->KeyTrackEnable( 0 , FALSE , 5 );
      pAnimationController->AdvanceTime ( Time );
}
```

The above code does more than just waste cycles. Every time this function is called a new event will be registered that is the same as all of the others. Our available event slots would fill up very quickly (potentially within a fraction of a second) and once the animation controller event list is full, any future calls to register additional events will fail. Therefore, you have to make sure that you set events only where and when you need them and make sure that you only set them once.

10.10 The D3DX Animation Callback Mechanism

In the DirectX 9 summer update of 2003, Microsoft added a very useful callback mechanism to their animation system. This feature allows our application to register callback events within an animation set by registering one or more callback keys. Callback keys are similar to SRT keys in that they each have a timestamp, which is specified in ticks within the period of the animation. Unlike SRT keys which are registered per-animation however, callback keys are global to all animations in the set. When the animation set is first created, these callback keys must be allocated and passed into the creation function. With each callback key, we also have the ability to pass in a pointer to a context (i.e., a pointer to any application specific data we require). When the callback event is triggered as the periodic position of the set reaches the callback key's timestamp, this context data is forwarded to an application defined callback function.

> **Note:** We have mentioned previously that the period of an animation set can be thought of as the S, R, or T keyframe within all animations with then highest timestamp (converted to seconds). As callback keys are also defined in ticks, and make up the fourth key type, they too are defined within the period of the animation set. Therefore, if we have an animation set with one animation whose last keyframe has a timestamp of 20 seconds, we would say that the period of the animation is 20 seconds. However, if we also registered a callback key at 25 seconds, the period of the animation would now be 25 seconds. It is very important that you think of callback keys as no different than SRT keys in this regard. Thus, in reality it is the scale, rotation, translation, and callback keys define the period of the animation.

An obvious case where this callback mechanism might be useful is the synchronization of sound effects with your animations. You may wish your application to play a sound effect when a certain point in the animation is reached, perhaps an explosion, for example. Using this system, your application could register a callback key with the animation set in which the explosion sound is triggered when the explosion animation sequence starts. In this case, the callback time stamp would be equal to the time (in ticks) that the animation set's explosion animation would begin. When the key is registered, we could also register some user defined data, perhaps a string containing the name of the .wav file to be played. When the event is triggered by the controller, a callback function would be executed and would be passed the name of this .wav file. Your callback function could use the passed name to actually play the sound.

So in many ways, callback keys are similar to the event keys discussed in the previous section. The main difference is the timeline used by each. As we have learned, event keys are registered on the global timeline while callback keys are registered within the local timeline of the animation set.

In our earlier discussion of animation sets, we skipped over parameters and functions that dealt with callback keys. Now we will revisit the animation set discussion and review the callback mechanism. It is important to understand exactly how the animation set deals with the callback keys behind the scenes, especially if we intend to write our own custom animation sets in the future. Therefore, we will discuss how callback keys are stored and registered with an animation set and how the animation controller gets access to that key data in order to execute the callback function.

10.10.1 Allocating Callback Keys in the Animation Set

Earlier we discussed the global function D3DXCreateKeyFramedAnimationSet, which an application can use to manually create a keyframed set of animations. Recall that we skipped the discussion of two parameters to this function; they are highlighted in bold below.

```
HRESULT WINAPI D3DXCreateKeyframedAnimationSet
(
        LPCSTR pName,
        DOUBLE TicksPerSecond,
        D3DXPLAYBACK_TYPE Playback,
        UINT NumAnimations,
        UINT NumCallbackKeys,
        CONST LPD3DXKEY_CALLBACK *pCallKeys,
        LPD3DXKEYFRAMEDANIMATIONSET *ppAnimationSet
);
```

As you may have already gathered from examining the function definition, it is at animation set creation time that we specify the maximum number of callback keys we intend to register. This allows the callback key array to be allocated when the animation set is created. Thus we see that the callback keys belong to the animation set and not to any particular animation in that set.

As the fifth parameter, we pass in the maximum number of callback keys our application might want to register with this animation set. With the sixth parameter, we are given a chance to populate this array with callback keys. While there is a separate function of the ID3DXKeyframedAnimationSet interface that allows us to store the key values in this array after the animation set has been created, often we will know the callback keys we wish to register when the set is created. So we can pass in a pointer to this application allocated callback key array at animation set creation time using this parameter. When the animation set is created, a callback key array of NumCallbackKeys will be allocated. If the sixth parameter is not NULL then this many keys will also be expected in the array passed in. The callback key data passed in is copied into the animation set's internal callback key array, so on function return, the array of D3DXKEY_CALLBACK structures can be deleted.

We now know that we allocate the memory for the callback keys at animation set creation time and can optionally pass in the callback keys at this time as well. So let us have a look at the D3DXKEY_CALLBACK structure to determine what needs to be passed into the D3DXCreateKeyFramedAnimationSet function. Keep in mind that each element in the input array represents exactly one callback key. Therefore, if we wished to register five callback keys, we would pass in a pointer to an array of five D3DXKEY_CALLBACK structures.

```
typedef struct _D3DXKEY_CALLBACK
{
    FLOAT Time;
    LPVOID pCallbackData;
} D3DXKEY_CALLBACK, *LPD3DXKEY_CALLBACK;
```

From the animation system's perspective, the only significant thing about the key is the first member of this structure. This is the timestamp of the event when we want this event to trigger a callback function. The important point to remember is that the timestamp should be specified in ticks (i.e., a periodic position) just like keyframes. As we know, this can be different from global time, especially if looping is enabled for this animation set. For example, if a looping animation set had a period of 10 seconds and we had callback key registered at 5 seconds, the callback key would be triggered at 5 seconds, and then every 10 seconds thereafter (i.e., track positions 5, 15, 25, 35, …). Once again, this is because the track time is mapped to a periodic position which is used to fetch SRT *and* callback keys that need to be executed.

> **Note**: Callback key timestamps are specified in ticks, just like keyframes. The animation set's 'TicksPerSecond' handles the conversion into seconds when needed. Callback keys are defined within the period of the animation set, just like SRT keyframes. This is important because if callback keys were registered on the global timeline (like event keys), then the callback key would not be triggered on looping animations. In our sound effect example, the sound would only play the first time though and never play again unless we manually reset the global time of the controller. Therefore, as callback events are used to allow the application to synchronize external events with animations being played, it is only logical for the callback keys and the animation data to be defined within the same timeline.

The second member of the D3DXKEY_CALLBACK structure is the context data, which will be passed to the callback function when the key is triggered.. This void pointer can be NULL or it can point to any application defined data/structure you desire. For example, let us imagine that we wanted to create an animation set which fired a callback at three different times throughout the animation. Assume the goal is to play sound effects: the first callback is triggered to play an explosion, the second is triggered to play a splashing water sound effect, and a third is triggered to play a door opening sound. We might set up the three callback keys and create the animation set like so:

```
// Somewhere in code the names of the sound effects are stored
TCHAR Sounds[3][128];
_tcscpy( Sounds[0] , "Explosion.wav" );
_tcscpy( Sounds[1] , "Splash.wav" );
_tcscpy( Sounds[2] , "DoorOpen.wav" );
..
..
..
D3DXKEY_CALLBACK keys[3];

//1st  Callback fired at a periodic position of 10 seconds
Keys[0].Time = 10.0f;
Keys[0].pCallbackData = (LPVOID)Sounds[0];

// 2nd Callback fired at a periodic position of 20 seconds
Keys[0].Time = 20.0f;
Keys[0].pCallbackData = (LPVOID)Sounds[1];

// 3rd Callback fired at a periodic position of 30 seconds
Keys[0].Time = 30.0f;
Keys[0].pCallbackData = (LPVOID)Sounds[2];

//Create an animation set called "MyAnim" which has 100 animations and has
// keyframes specified at
// 50 ticks per second. Also the set has three call-backs keys.
```

```
ID3DXKeyframedAnimationSet  *  pAnimSet = NULL;
D3DXCreateKeyFramedAnimationSet("MyAnim",50,D3DXPLAY_LOOP,100 ,3, &keys, &pAnim");
```

Two things about the previous code may seem odd when we consider how event keys work (see previous section). First, at no point do we specify the track number for which these events are to be assigned. Of course, that is because there is no need; callback keys are part of the animation set itself. Second, we are not specifying the callback *function* that is to be called when these callback events occur. As we will see in a moment, a pointer to this callback function, or to a class that contains this callback function, is actually passed into the AdvanceTime method (perhaps you remember that second parameter?). When AdvanceTime is informed by the animation set that a callback event has happened, it will retrieve the context pointer of the callback key (in our example this was a string containing the name of a sound effect) and pass it to the application-defined callback function pointer passed into AdvanceTime.

One advantage of passing the callback pointer to AdvanceTime is that we can easily change the callback function as game conditions change. The downside is that all callback keys that are triggered during a single AdvanceTime call (on all tracks) must use the same callback function. This unfortunately encourages the development of callback functions that degenerate into huge switch statements that cater for all events that may have been triggered. It might have been nice to allow the application to register the callback function pointer with the callback key itself, just like we did with the context pointer. That way, each callback could have had its own callback handler function, leading to a cleaner implementation. However, this small disadvantage is something we can certainly put up with given the overall benefits of having a callback system at all.

10.10.2 Callback Key Communication

Earlier we looked at the communication pipeline between the animation controller and its animation sets. As long as the animation set implemented the eight functions of the base class ID3DXAnimationSet, the animation controller has all it needs. The controller calls the methods of the animation set base class to perform tasks such as map the track time to a period position, fetch the SRT data for that period position, fetch an animation by index or name or fetch the entire duration/period of that animation. When we covered the ID3DXAnimationSet interface (the base class) earlier in the chapter we examined all of these methods and how they work, except one.

The one method of the base interface which must be implemented by all animation sets is called GetCallback. It is responsible for returning a callback key back to the animation controller. The method is shown next along with a list of its parameters. We will explain how this function works in some detail, because if you intend to implement your own custom animation sets, you will need to know how to implement a function of this type. When discussing this function, we will discuss the way that ID3DXKeyframedAnimationSet implements it.

> **NOTE:** How this method works may seem a little confusing at first. It will start to make more sense when we examine the way the animation controller predicts and caches the time of the next callback key. This will prevent it from having to call ID3DXAnimationSet::GetCallback for each of its animation sets in every AdvanceTime call.

The GetCallback method is a callback key querying function with a few clever tricks up its sleeve. The animation controller passes in the time where it would like the search to start and the method will return the next callback key in the animation set's timeline that is scheduled for execution in the future. What is interesting is that the animation controller passes in the search start time in track time and it expects to get back the next scheduled event in track time as well. So the GetCallback function has to take the passed track time, map it to a periodic position in the set, and then use the periodic position to start the search for the next callback key. Once the key is found, its timestamp is converted into seconds and is added to the initial track position. This is important to note. The function returns (to the animation controller) the time of the next scheduled callback event as a track position, not as a periodic position. This track position is cached by the controller and when it is reached, the callback is triggered.

For example, let us imagine that the first time AdvanceTime is called, it calls the GetCallback method of its animation set (we will assume only one track is active for now) and passes in a position of 0 seconds (i.e., the initial track position). The GetCallback method would start its key search from 0 seconds and will return the first callback key it finds after that time. If we imagine that a key was registered for 100 seconds, then the function would return a CallbackPosition of 100 along with the context data pointer that was registered with that key.

At this point the controller knows that the next callback event will not happen for another 100 seconds. Therefore, it does not have to call GetCallback for this track again until the 100 second mark has been reached. All it has to do in future calls to AdvanceTime is test the current track position against the cached next callback key time of 100 seconds. Only when the track position reaches or exceeds the currently cached callback time does work have to be done. At the 100 seconds mark, the callback function which is passed into the AdvanceTime method is executed with the callback key context (also returned from GetCallback and cached along with the key track time) passed as input. In our earlier example, this was the sound effect filename. Once the callback function completes execution and program flow returns back to AdvanceTime, the function will ask the animation set (via GetCallback) for the next callback key. If one exists, it will be cached just like the previous key, and the process starts over again.

Before we look at this procedure in more detail, let us take a look at the ID3DXAnimationSet::GetCallback function and talk about how it must be called by the animation controller. Remember, the purpose of this function is to take a time value as its parameter and return the next scheduled callback key, so that the animation controller can cache it.

```
HRESULT ID3DXAnimationSet::GetCallback
(
    DOUBLE Position,
    DWORD Flags,
    DOUBLE *pCallbackPosition,
    LPVOID *ppCallbackData
);
```

DOUBLE Position

This parameter will contain the initial track time (in seconds) from which we would like the next callback key returned. Usually, when the AdvanceTime method calls this function, it will not actually

pass in the current track time but will instead pass in the previously cached callback track time. If this was not the case, we would run the risk of missing callback events between calls.

For example, assume that we have a non-looping animation with callback keys registered at 10 and 12 seconds. Initially (when AdvanceTime is first called) the key at 10 seconds would be cached by the controller. Now imagine that we were running at a very slow frame rate and the next time AdvanceTime was called, 13 seconds had passed. The AdvanceTime method would detect that the current track position (13 seconds) is higher than the currently cached next event time (10 seconds) and would trigger the 10 second callback. This is exactly how it should behave up to this point. Now that the callback has been handled, the controller will now try to cache the position of the next scheduled event. However, if the current track position of 13 seconds was passed into GetCallback, we would be incorrectly informed that no callback keys remain. But this is not true as we know there is one at 12 seconds. Unfortunately, because we began our search for the next event at 13 seconds, we skipped it. So to avoid this issue, instead of passing in the actual track position to GetCallback, we pass the current cached time for the callback event we just handled (10 seconds in our case). Therefore, even though we are at 13 seconds actual track position, we begin the search for the next event at 10 seconds. This returns the next scheduled event at 12 seconds which is cached by the controller and executed in the next call to AdvanceTime.

> **Note:** Recall that callback key timestamps are specified in ticks. GetCallback will convert the passed value (in seconds) into a periodic position in ticks using the animation set's TicksPerSecond value. This allows it to locate the correct next scheduled callback key. Once the key is found, the timestamp is converted back into seconds and added to the start position (track time). This gives us a timestamp in track time instead of a time within the period of the animation set. It is this track position which is returned and then cached by the controller.

The controller does not try to play 'catch up' in the AdvanceTime function; it will only trigger one event (per track) within a given call. So at the end of the AdvanceTime call in our example, we have a current track position of 13 seconds and a cached next event time of 12 seconds. If another 13 seconds passes before AdvanceTime is called again, this would put the actual track position at 26 seconds. The AdvanceTime method would correctly detect that the current track position (26 seconds) is greater than the cached key time (12 seconds) and would execute the callback (admittedly, 14 seconds late). It would then pass the cached position (12 seconds) into the GetCallback method to begin a new search for the next scheduled event. As there were only two events in this example and looping is disabled, no further event is returned and cached. If looping were enabled, then the search would loop around and the next callback key returned would be the first one at 10 seconds. However, it would correctly detect that a loop had been performed and take this into account when returning the time of the callback as a track position.

Initially, this function can be confusing because it accepts and returns a track time, but works internally with data defined as periodic positions (just like the GetSRT method). So why does this function not simply accept a periodic position rather than a track position? The answer is very simple; if this function is passed a periodic position, it would have no idea how many loops of the animation have happened before the initial search time. Therefore, even when the callback key is found (which we remember is defined in local time), the function has no way of mapping it to a valid track position. If we imagine that a looping animation set with a period of 10 seconds has its GetCallback method called with a track position of 55 seconds, the function can correctly calculate that the animation has looped 5 times (50

seconds) and is currently in the fifth second of the fifth loop. This is very important because the function will need to be able to determine a proper offset within the period. If the animation set had a callback key at 8 seconds, we would find this key next (8 seconds) and would add it to the number of seconds this animation has been played out *in full* (50 seconds) to give as a track position of 58 seconds. Notice that we are talking about *completed* animations when we deal with looping. In this instance for example, we know that the event happens on the eighth second of a ten second animation. That should always be consistent, so we must offset from the start of a new looping cycle when we calculate the track time to trigger the event. This value would then be returned to the controller and cached. Obviously, if this function was not passed a track position and received only a periodic position, in the above example, a value of 5 (instead of 55) would have been passed. While we would have successfully located the next callback key at 8 seconds local time, we would have no way of knowing how to map this to track time. For further review, there is a much more detailed discussion of how these individual values are calculated and used, along with source code examples, in the workbook accompanying this chapter.

As discussed earlier, in nearly all cases, the actual track position is not used by the callback mechanism to perform the search for callback keys. Rather, we are jumping from one cached time to the next. This means that in extreme cases, the actual position we are passing into the GetCallback function may be quite different from the actual track position. As AdvanceTime is called many times per second and callback events are typically not set very close together for a single track, the animation system can catch up quickly even if it lags slightly behind the track position. This is true regardless of whether the time update has skipped past the times of many keys. For example, even though only a single callback is dealt with in a single call to AdvanceTime, typically AdvanceTime will be called somewhere between 20 to 60 times per second. This provides adequate time to quickly process any queued events and get back in synch.

While the animation controller usually passes the currently cached callback key time into the Position parameter of the GetCallback function, this is not always the case. The exception to the rule happens when the controller is in its callback key setup phase. In that case, there is no currently cached time or data. Indeed the cache is going to be invalid at several times throughout the controller's life. For example, the first time AdvanceTime is called there is no previously cached callback time. When this is the case, the actual current track position is passed in and the search for the next callback key is done from there. The cache is also invalidated if the controller time is reset to zero using ResetTime or if the track position is altered using SetTrackPosition. In all of these cases, the cache is considered dirty and the next time GetCallback is called by AdvanceTime to cache the next scheduled key time, the actual track position is passed in. Just to make sure this is clear and we understand why this must be the case, imagine that we had a currently cached time in the controller of 100 seconds, but then our application manually set the track position back to a time of 10 seconds. If we did not flush the cache, then the next time AdvanceTime is called, it would not trigger a callback until a track time of 100 seconds (the previously cached time before the reset) was reached. However, there maybe callback keys at 11 and 20 seconds that would be ignored. So in this example, when the track position was reset to 10 seconds, the actual track position would be passed into GetCallback the next time round. This would return the next scheduled event at 11 seconds, which is then cached by the controller. For all further calls to AdvanceTime, the previously cached time would be used again as the base position of the search.

> **NOTE:** The *actual* track position used to perform the callback key search only when the cache is invalidated via manipulation of the global or track timers.

DWORD Flags

The second parameter to the GetCallback function is also vitally important. If you intend to derive your own custom animation set from ID3DXAnimationSet, then you will need to understand these flags and perform your callback key search correctly, when they are passed in by the controller. This value can be zero, one, or a combination of the following flags defined in the D3DXCALLBACK_SEARCH_FLAGS enumerated type:

```
typedef enum _D3DXCALLBACK_SEARCH_FLAGS {
    D3DXCALLBACK_SEARCH_EXCLUDING_INITIAL_POSITION = 1,
    D3DXCALLBACK_SEARCH_BEHIND_INITIAL_POSITION = 2,
    D3DXEDT_FORCE_DWORD = 0x7fffffff
} D3DXCALLBACK_SEARCH_FLAGS;
```

D3DXCALLBACK_SEARCH_EXCLUDING_INITIAL_POSITION

This flag indicates that the controller would like the animation set to search for a callback key starting at the passed time, but not to include any key that is scheduled at that time. If you develop your own animation set, you will find that the controller will always pass this flag, except when the cache has been invalidated. The reason is fairly obvious when we consider what we already know about the normal operation of the callback cache.

For example, imagine that the previously cached callback key time was 10 seconds and that it has just been passed and processed. At this point the controller wishes to search for the next callback key, starting at 10 seconds. Of course, we know that there is already a callback key at 10 seconds since it is the one we just executed. Since the search function would logically find this key first, we would wind up getting stuck processing the same event over and over again. So by passing the D3DXCALLBACK_SEARCH_EXCLUDING_INITIAL_POSITION flag, the controller is instructing the animation set to search for a callback key starting at 10 seconds but to ignore the key at 10 seconds.

This completely solves any infinite looping problem and raises the question of why this flag is needed at all. After all, why not just make this behavior the default for the GetCallback function all the time? We always wish to exclude the initial position, do we not? Actually, no. Consider what happens when the cache has been invalidated because either the global or track timer has been manually altered or that this is the first time AdvanceTime has ever been called. You will recall that when this is the case, we actually perform the search starting from the real track position. If we have no previous information in the cache, we absolutely do want to search for the next callback key and include the current position. Imagine that we have a callback key at time 0.0 seconds and that at 10 seconds of track time we reset the position of the track to zero (thus invalidating the cache). At this point, the GetCallback function would be called and the track position passed would be 0.0 seconds. In this scenario, if we passed this flag, then the callback registered at 0.0 seconds would be incorrectly skipped. Therefore, we recognize that when the cache has been invalidated and the real track time is used to perform the next key search, this flag should not be specified. For all other times, it is.

D3DXCALLBACK_SEARCH_BEHIND_INITIAL_POSITION
This flag is used if you wish to search backwards from the currently passed position to find a previous callback key in the animation set's callback array. The controller itself will not typically pass this flag to the GetCallback method, but it can be useful for an application to use to retrieve a previously executed callback. If you have implemented your own animation controller, this feature might be very useful for playing backwards animations.

DOUBLE *pCallbackPosition
This parameter is where the controller passes in the address of a double which, on function return, should contain the timestamp of the next scheduled callback event in track time (seconds). The controller will cache this time so that it knows that no work has to be done and no callbacks have to be executed until this time has been reached. The conversion of the next scheduled key's timestamp from ticks into seconds is performed by the function before the value is returned in this parameter.

LPVOID *ppCallbackData
The controller uses this output parameter to get a pointer to the context data that was registered for the next scheduled key. In our earlier example, each key stored a sound filename in its context data area, thus it is the pointer to this string that would be returned here. The animation controller caches this callback data pointer along with the cached time of the event. When the cached event time is reached, the callback handler is called and the cached callback data (i.e., context data) is passed to the handler for processing. In our example, the callback function would be passed the string name of the sound effect and it could then play that sound.

While the callback system may seem complicated at first, it is actually quite simple. The following few lines of pseudo-code should give you a basic idea of how it works (how callback data is cached, etc.). This is not necessarily how it is implemented inside D3DX, but it should help better illustrate the expected behavior of the system.

```
void AdvanceTime( … )
{
    // Callback cache is invalid ?
    if ( bCacheInvalid )
    {
        // THIS IS THE SETUP CASE!
        CachedCallbackData = NULL;        // <-- NULL so handler is not called !!
        CachedCallbackPos  = TrackPos;    // <-- Significant !!
        bCacheInvalid      = false;       // Cache No Longer Invalid

        // Search for next scheduled callback key and cache it
        ProcessCallbacks();

    } // End if must reinitialize cache

    // Natural progression, performed every time ( for every track )
    if ( TrackPos >= CachedCallbackPos ) ProcessCallbacks();

    // All the rest happens here (timer increments and SRT data fetches)
    …
}
```

Here we see what the initial section of the AdvanceTime function might look like. This example only deals with a single track/animation set, but of course in the real D3DX controller there would be a cache for each active track.

The function first tests to see if the cache is invalid. The cache will be invalid if the timer of the track or the global timer has been altered. The cache will also be invalid if this is the first time AdvanceTime has been called with the animation set assigned to the track. If the cache is invalid then the cached callback data pointer is set to NULL and the cached callback event time is simply set to the current position of the track, as discussed earlier. One important thing to notice in the setup phase is that the cached position is set to the value of the track timer *before* the timer has been incremented. That is, the search for callback keys will be performed from the previous track position (not including the passed elapsed time). In this example, the ProcessCallbacks function is then called to search for the next scheduled event on that track and cache it (along with the event context data).

Beyond the setup phase we see a line of code that will be called with every call to AdvanceTime. It compares the current track position to the currently cached callback position. If the track position is greater, then it calls ProcessCallbacks to execute the callback function and fetch the next event in the schedule. Note that ProcessCallbacks is actually a multi-purpose function. When called from the setup phase, it simply searches for the next scheduled event. When called from the compare line that happens every time, it is called when the event has been reached and its callback needs to be handled. The ProcessCallbacks function is shown next:

```
void ProcessCallbacks()
{
   ULONG Flags = (CachedCallbackData == NULL) ? 0 :
                                 D3DXCALLBACK_SEARCH_EXCLUDING_INITIAL_POSITION;

   // Call the callback handler if anything is available
   if ( CachedCallbackData )
        CallbackHandler->HandleCallback(TrackIndex,CachedCallbackData);

   // Get the next callback (notice how we always pass in the last
   // callback pos, not track time)
   TrackSet->GetCallback( CachedCallbackPos, Flags,
                          &CachedCallbackPos, &CachedCallbackData);
}
```

First let us examine what this function will do if called from the setup phase of the AdvanceTime function. The first thing it will do is set the flags value to 0 because the cached callback data was set to NULL when the cache was invalid. The next line is skipped because the cached callback data will be NULL. The final line calls the animation set's GetCallback function. As the first parameter it passes the currently cached time. Because this was called from the setup phase inside AdvanceTime, the cached callback time is actually the current track position. We also pass in 0 as the flags parameter because, as discussed earlier, when the cache is invalid, we do not want to exclude the initial time from the key search. If there is a key scheduled for the current track position, we want to retrieve and cache it. Finally, notice that the CachedCallbackPos and CachedCallbackData are passed into the handler function. On function return they will contain the time of the next scheduled event on the track and any context data associated with it. At the end of the setup phase, we have a new cached position which is

no longer the current track timer (most of the time) and it will be the next event that needs to be executed.

This function is also called when the current track position reaches the currently cached key time, and it behaves a little differently in this scenario. When called during the natural progression of the AdvanceTime function, it means a cached callback key time has been reached and needs to be handled. We can see that in this case, cached callback data will exist and therefore the flags will be set to exclude the initial position in the next search for a future key. Because there is callback data, we know that we must have called this function previously and a cached event needs to be executed. So in the next line we execute the callback handler function (more on this in a moment). The final line is called to retrieve a new next event time for caching purposes. However, you should notice that when this function is called this time, the cached time is not the track position. The input time to GetCallback is the time of the event that was just handled. This way, even if the track position is many seconds in front, we do not skip any events between the last cached event and the current time.

> **Note:** The pseudo-code we are examining has been greatly simplified. For example, in ProcessCallbacks we are assuming that if there is no callback data defined then no handler needs to be called. But in fact, it is quite possible to register a callback key and assign it no context (i.e., set its callback data to NULL). There is no requirement that you always include context data, and indeed you might not need to send data into your own callback functions. So in truth, our pseudo-code design is slightly incorrect, but hopefully the general concept of key caching is clear.

We have seen how to register keys with an animation set and how the animation controller uses the animation set's GetCallback function to schedule upcoming events on a track. We have also looked at how each callback key can have user-defined data which can be passed to the callback function when the event is triggered. We even have some concept of how the AdvanceTime method executes the callback function. What we have yet to discuss is how we set this application defined callback function. This will be the purpose of our next section.

10.10.3 Setting the Callback Function

When we discussed the AdvanceTime function earlier in the chapter, we deliberately neglected to explain the second (optional) parameter. This parameter will now be examined as it is the means by which we inform the AdvanceTime function about the callback function that should be executed when a callback event is triggered. Recall that the AdvanceTime function definition is:

```
HRESULT AdvanceTime
(
    DOUBLE TimeDelta,
    LPD3DXANIMATIONCALLBACKHANDLER pCallbackHandler
);
```

As you can see, if a second parameter is passed into this function, it should be a pointer to a class of type ID3DXAnimationCallbackHandler. If this parameter is set to NULL then the function will not attempt to process any callback code.

If we take a look at the d3dx9anim.h header file, we will see that ID3DXAnimationCallbackHandler is an interface with a single method:

// Excerpt from d3dx9anim.h

```
#define INTERFACE ID3DXAnimationCallbackHandler

DECLARE_INTERFACE(ID3DXAnimationCallbackHandler)
{
      STDMETHOD(HandleCallback)(THIS_ UINT Track, LPVOID pCallbackData) PURE;
};
```

This interface is similar to the ID3DXAllocateHierarchy interface (Chapter Nine) in that it does not have an associated COM object. It is just an abstract base class that is exposed so that applications can derive their own classes from it. Your application will never be able to instantiate an instance of ID3DXAnimationCallbackHandler, so it must derive a class from it that implements the HandleCallback function. Just as the D3DXLoadMeshHierarchyFromX function is passed a pointer to an ID3DXAllocateHierarchy derived class (which it uses to callback into the application during hierarchy loading), an instance of an ID3DXAnimationCallbackHandler derived class can be passed into the AdvanceTime call. Its only method (HandleCallback) will be called by the AdvanceTime function when a callback event is triggered. As you can see, the function accepts the index of the track on which the callback event was triggered and a void pointer for the callback key context data.

Because you are responsible for implementing the HandleCallback function in your own derived classes, you can program your code to do anything you require. For example, let us continue building on our previous example where we registered three callback keys to play sound effects. We will begin by deriving our own class from ID3DXAnimateCallbackHandler and implement the HandleCallback method. In this example, we will call our derived class CSoundPlayer:

```
class CSoundPlayer: public ID3DXAnimationCallbackHandler
{
    public:
    STDMETHOD(HandleCallback) (THIS_ UINT Track, LPVOID pCallbackData);
};
```

Now we will implement the HandleCallback function so that the name of the .wav file passed into the callback function (as pCallbackData) can be passed into a function that plays a sound.

```
HRESULT CSoundPlayer::HandleCallback( UINT Track, LPVOID pCallbackData )
{
    // cast the past string name back into a TCHAR pointer
    TCHAR * WavName = (TCHAR*) pCallbackData;

    // Play the sound
    PlaySound( WavName , NULL , SND_FILENAME);
}
```

Here we see that the name of the .wav file (pCallbackData) is cast back to a TCHAR pointer. It is passed into the Win32 PlaySound function to load and play the sound. (To be sure, this is not the optimal way to play sounds in your games; this is meant only to serve as a simple callback example).

If you have multiple callback events registered on different tracks, there is a very good chance that not all of these callback keys will simply want to play back sound effects. In this case, your callback function would need to account for a wider range of functionality. One approach might be for your context data to point to an application defined structure instead just of a sound filename. The first parameter of this structure might be a flags member that you define to identify the event type to be processed (PlaySound, StopSound, FadeOut, etc.). Your callback function would simply cast the context data pointer back to the correct structure pointer and examine the flags to determine its course of action.

Finally, with your callback handler class written, you simply have to instantiate an instance of it before calling the AdvanceTime method:

```
void UpdateAnimation( double ElaspedTime )
{
   CSoundPlayer Callback;
   pController->AdvanceTime( ElapsedTime , &Callback );
}
```

10.10.4 Getting and Setting Callback Keys

The ID3DXKeyframedAnimationSet interface exposes four methods relating to the callback system which we have not discussed. Please note that these functions are implemented for the application's benefit only; they are not part of the base ID3DXAnimationSet interface and they will never be called by the animation controller. Thus, the controller will never expect them to be implemented in any custom animation set classes that you develop.

The first method allows the application to query the number of callback keys that are registered with the animation set:

```
UINT GetNumCallbackKeys(VOID);
```

Next, while there exists no way to add additional callback keys to the animation set once it has been created (recall that this memory is allocated at animation set creation time), a function is provided that allows the application to alter the value of a callback key if we know its index. The index is simply the number of the key in the internal callback key array. In our earlier example, we created an animation set with three callback keys; their indices will be 0, 1, and 2 respectively.

In order to set the value of a pre-existing key, we pass the index of the key we wish to change along with the new key information into the SetCallbackKey function.

```
HRESULT SetCallbackKey
(
    UINT Key,
    LPD3DXKEY_CALLBACK pCallbackKeys
);
```

We examined the D3DXKEY_CALLBACK structure earlier in the chapter, and saw that it contains a timestamp and a void pointer that is used to pass application data to the callback handler.

Just as our application can set the value of a callback key, we also have the ability to query key details. To do so, we can use the GetCallbackKeys method and pass in a valid key index and the address of a D3DXKEY_CALLBACK structure. If the index is a valid key index, the key information will be copied into the passed structure:

```
HRESULT GetCallbackKey
(
    UINT Key,
    LPD3DXKEY_CALLBACK pCallbackKeys
);
```

Finally, the application can also request a copy of all callback keys registered with the animation set. The GetCallbackKeys function must be passed a pre-allocated array of D3DXKEY_CALLBACK structures large enough to hold all key information in the animation set. Therefore, before calling this function, you will usually call GetNumCallbackKeys first so that you know how much memory is needed for this array.

```
HRESULT GetCallbackKeys
(
    LPD3DXKEY_CALLBACK pCallbackKeys
);
```

The following code shows how one might use this method to extract all callback keys from an animation set. It is assumed that the animation controller and the animation set are already valid and that the animation set contains a number of callback keys.

```
// Get number of keys in anim set
NumKeys = pAnimSet->GetNumCallbackKeys();

// Allocate array of the correct size
D3DXKEY_CALLBACK *pKeys = new D3DXKEY_CALLBACK[NumKeys];

// Fetch a copy of the keys into our array
PAnimSet->GetCallbackKeys( pKeys );

// Do something with keys here
…
…

// When finished release key array
delete [] pKeys;
```

Conclusion

We have now thoroughly covered all of the fundamentals of mesh hierarchies and animation using DirectX. While the animation controller documentation is a little sparse in the SDK, it should be clear that D3DX provides us with access to a very powerful and relatively easy to use set of animation interfaces.

Before moving on to skeletal animation and skinning in the next chapter, we recommend that you work through the source code to the lab projects accompanying this chapter. The next chapter will make use of use many of the techniques we have examined here, so it would be wise to read through the workbook and make sure that you are comfortable with these topics.

Lab Project 10.1 is an application that demonstrates DirectX animation at its simplest -- loading an animated X file and playing it back. The demo will teach us how to work with and render the frame hierarchy returned to us by the D3DXLoadMeshHierarchyFromX function, as well as how to use the animation controller to play the animation back. We will take this opportunity to build out our CActor class code from the previous chapter by adding the methods exposed by the D3DX animation system. Moving forward, our CActor class will become a very useful class -- it will wrap the loading and rendering of frame hierarchies and expose functions for loading and playing back animations that affect those hierarchies.

In Lab Project 10.2 we will delve even deeper into the D3DX animation interfaces and build ourselves a very handy tool. Given an X file with a single animation set, our new tool will allow us to break that animation set into multiple named animation sets and then resave the data back out to a new X file.

Again, it is very important that you understand everything we have covered so far in the course. You certainly need to be very comfortable with hierarchies and how they are animated before continuing on to the next lesson concerning skeletal animation. On the bright side, you should be pleased to know that most of the hard work is behind us now. Skeletal animation and skinned meshes are really not going to be much more complicated than the material we learned about here. What we will discover in the next chapter is that the frames of the hierarchy will simply be perceived as the bones of a skeleton with often a single mesh (although there can be multiple meshes) draped over the entire hierarchy. So, once you have tackled the lab projects in this chapter, you will be ready to move straight on to the next lesson.

Workbook Ten: Animation

Lab Project 10.1: Adding Animation to CActor

In Lab Project 9.1 we implemented a CActor class that encapsulated the loading and rendering of hierarchical multi-mesh representations. In this lab project we are going to continue to evolve CActor by adding animation support for its internal frame hierarchy. As each actor represents a single hierarchy loaded from an X file, the actor will become the perfect base for modeling game characters as well as other animated entities. Each character is contained in its own frame hierarchy inside the actor and will have its own animation controller to play back its animations via the CActor interface. We must also remember that a single CActor object could also be used to animate an entire scene if all the meshes and animations in that scene were loaded from a single hierarchical X file.

In the Chapter 10 textbook, we learned that D3DX exposes an easy-to-use comprehensive animation system. We will now take the information we learned in that lesson and wrap it up inside of our CActor class. Lab Project 10.1 will use the new extended CActor object to load an animated scene from an X file and play it back in real-time. Figure 10.1 shows the code from lab project 10.1 in action.

Figure 10.1

The X file we will load contains a small futuristic scene with many moving meshes, including a space ship that takes off from a launch pad and flies off into the distance. There are also many other moving meshes such as revolving radar dishes and hanger doors that open and close. In this first simple example, a single X file will be loaded by our actor. The file will contain the entire scene and all animation data in a single animation set. Therefore, a single actor will contain all objects in the scene that you see in Figure 10.1.

Because a single animation set will contain the animations for all objects in our scene, playing back this animation could not be easier. The CActor::LoadActorFromX function will call the D3DXLoadMeshHierarchyFromX function to load the X file. This function will automatically create the animation controller and its animation set before returning it to CActor for storage. (The animation controller will be a new member variable that we will add to CActor.) The controller will then be used by the CActor member functions to play the animated scene in response to application requests.

Because the D3DXLoadMeshHierarchyFromX function will (by default) automatically assign the last animation set defined in the X file to the first track on the animation mixer, when the D3DXLoadMeshHierarchyFromX function returns the newly created controller back to the actor, we have absolutely no work to do. The only animation set defined in the X file in this example will have been assigned to the first mixer track on the controller and is ready to be played immediately. All our CActor has do at this point, is call the controller's AdvanceTime method with every requested update to generate the new frame matrices for the hierarchy. For this reason, Lab Project 10.1 is an excellent initial example of using the animation system. It clearly demonstrates the ease with which cut scenes or scripted sequences can be played out within a game engine. Notice that as the animation sequence plays out, the player still has freedom of movement within the scene. This allows the player to feel part of a dynamic scene instead of simply watching a pre-rendered sequence.

Although Lab Project 10.1 will only use a very small subset of the D3DX animation system's overall features, we will still implement all the animation functionality exposed by D3DX in CActor in this project. This will prevent us from having to continually revisit CActor later in the course when we wish to use animation features that have not previously been coded. This will mean of course that we will have to add many animation methods to our CActor interface so that an application can access all of the features offered by D3DX. For example, our CActor must provide the ability for an application to assign animation sets to tracks on the mixer, configure the properties of those mixer tracks, and allow the application to reset the global timer of the animation controller. The CActor interface must also expose methods that allow the application to register events with the event sequencer on the global timeline as well as expose the ability for scheduling of callback keys for a given animation set. While this sounds complicated, most functions will be simple wrappers around their ID3DXAnimationController counterparts. Once we have this task out of the way, we will have a CActor class that is reusable in all future applications that we develop. This will be a powerful tool indeed and will allow us to add animated objects to our scenes with ease in the future. Furthermore, we will need this animation system in place in the following chapter when we move on to the subject of character skinning and skeletal animation (something else that will be managed by our CActor class).

Expanding the Limits of the Controller

Another feature we would like our actor to expose to the application is the ability to easily upgrade the maximum limits of the controller. In the textbook we learned that the maximum limits of the animation controller must be specified at controller creation time. This is certainly a restraint we could put up with if we were always manually building our animation controllers, but when using the D3DXLoadMeshHierarchyFromX function, the controller is created for us and we are afforded no control over the maximum values. For example, the controller created by

D3DXLoadMeshHierarchyFromX will always have two mixer tracks. This may not be enough to satisfy the blending desires of our applications. Additionally, the maximum number of animation sets that can be simultaneously registered with the controller will always be equal to the number of animation sets defined in the X file. Once again, this is often acceptable, but sometimes our application may wish to programmatically build additional animation sets once the X file has been loaded, and then register these new sets with the controller. The controller returned from D3DXLoadMeshHierarchyFromX would have no room for these animation sets to be registered, so we will have to account for this limitation.

We will address this problem by exposing a method called CActor::SetActorLimits. With this function, we can specify the exact number of animations, animation sets, and mixer tracks that we would like our actor's animation controller to support. This function is very flexible because you can call it before or after the X file has been loaded. If you call it before you have call CActor::LoadActorFromX, then the maximum limits you pass in will be stored in the actor's member variables. When the call to CActor::LoadActorFromX is finally made and the animation controller is created, the function will automatically clone the D3DX-generated animation controller into one which matches the desired maximum limits. When CActor::LoadActorFromX returns control back to the application, the actor will contain its frame hierarchy with all animation data intact and an animation controller with the desired maximum limits. We can also call the CActor::SetActorLimits method even after the X file has been loaded and it will still work fine. If the X file is already loaded, the SetActorLimits method will simply clone the current animation controller being used into one with the desired maximums specified by the application.

> **Note:** When we clone the animation controller, we can specify different creation parameters from those used in the original (e.g., a higher number of mixer tracks). All the animation data stored in the original controller will be copied into the cloned controller, ensuring data integrity. Our CActor::LoadActorFromX and CActor::SetActorLimits methods use cloning to allow the application to override the default limits of the animation controller created by the D3DX loading function. This also allows our application to expand the limits of the actor's controller at any time, even when the application is running.

The following code shows how an application might use the CActor class to load an animated X file and then set the limits of the controller:

```
// Create Actor
CActor *pActor=new CActor;

// Register scene call back function to manage mesh resources
pActor->RegisterCallback( CActor::CALLBACK_ATTRIBUTEID, CollectAttributeID,this );

//Load an X file into the actor. All meshes in the managed resource pool
pActor->LoadActorFromX( "MyXFile.x", D3DXMESH_MANAGED, m_pD3DDevice );

// Set the controller so that it can handle AT LEAST 15 animation sets and 10
// blending tracks and capable of registering 150 sequencing events
pActor->SetActorLimits( 15 , 10 , 0 , 150 , 0 );
```

As the previous code demonstrates, changing the limits of the actor, even after its controller has been created, is perfectly safe. We will look at this function in detail later. For now, just know that if we pass in zero for any of the parameters, that property will be inherited from the original controller during the cloning process. For example, the third parameter to this function is where we can specify the number of

animation outputs we would like the actor's controller to handle. This will have already been set in the original controller (by D3DX) such that it can at least animate all the animated frames in the hierarchy. This is usually exactly what we want it to be. Unless we are adding additional frames to the hierarchy programmatically, we will normally not want to alter this value. Therefore, by passing in zero for this property, the SetActorLimits method knows that the new controller it is about to clone should have its maximum animation outputs value remain the same as the controller from which it is about to be cloned. This is useful because the application will not be forced to query the number of animation outputs currently being managed by the actor's controller, simply to pass that same value back into the SetActorLimits method unchanged.

The final parameter to this function is where we can specify the maximum number of callback keys that can be registered with any animation set. We will discuss why this is needed in the following section. It is also worth noting that the application can use the SetActorLimits method whenever it likes. For instance, in the above example we set the maximum number of mixer tracks to 10. However, later in the application we might decide to expand that to 15. We could do so simply by calling the function again with 15 instead of 10 as the second parameter. We could pass zero in for all the other parameters so that the newly cloned controller will inherit all the other properties from the original controller.

The Actor Exposes a One-Way Resize

For reasons of safety and ease of use, we made the design decision that the SetActorLimits method should only ever clone the controller if any of the specified maximum limits exceed those of its current controller. The function will never clone the controller if we specify maximum extents which are less than the current controller's maximums. There are a number of reasons we decided to take this approach.

First, we do not wish to burden the application with having to write code to query the current maximum extents of the controller. It is much more convenient if we can just specify the properties we need (such as the number of mixer tracks) without having to be aware of all the other properties that were setup automatically (e.g., the number of animation outputs). Second, we could accidentally break the controller's ability to animate the data loaded from the X file if we downsized its maximum extents such that it could no longer properly use the information stored in the original X file. For example, if the original controller created by D3DX needed to animate 50 frames in the hierarchy, it would have been created with the ability to manage 50 animation outputs. If we then called the SetActorLimits method and incorrectly set this parameter to some value less than 50, information would be lost in the clone operation and some or all of the frames in the hierarchy that should be animated would no longer be. This would essentially break the entire animated representation created by the artist. In order to avoid this, the application would first need to query the current number of animation outputs being used by the controller and would need to pass no less than this value into the SetActorLimits method. With our 'expand-only' philosophy, this entire burden is removed. We do not even have to know about the properties of the mixer that we have no interest in. We can simply specify that we require no less than a certain value for a given extent.

In the expand-only system, the SetActorLimits method will never clone an animation controller that is incapable of animating the data in the original controller, regardless of the values passed in by the application. This allows the application to call this method with any value without breaking the actor's ability to animate the original data loaded from the file. While this does mean that there may be times when the maximum limits of the controller may be superfluous to your applications requirements, this is often very rare, since the original animation controller will be created with the bare minimum capabilities needed to animate the original X file data. Therefore, you will usually only want to extend these capabilities and not reduce them. One exception to the rule might be if your application only wishes to use a single mixer track. We know from the accompanying textbook that the animation controller created by D3DXLoadMeshHierarchyFromX will always have at least two mixer tracks. In this case, the animation controller would have a mixer track that you have no intention of using so you could downsize. However, the memory taken up by a single wasted mixer track is certainly acceptable given the ease and safety at which the actor can now be used.

A Flexible Callback Registration Mechanism

One of the more frustrating limitations of using the controller's callback system is that the memory for the callback keys must be allocated at animation set creation time. You will recall from the textbook that when creating an animation set manually (using the D3DXCreateKeyframedAnimationSet function), we must specify how many callback keys we would like to register with the animation set and pass in a pointer to an array of callback keys. These callback keys are then allocated and stored inside the animation set. While this is a limitation we can live with when creating animation sets manually, we know only too well that when using the D3DXLoadMeshHierarchyFromX function, the animation controller and all its animation sets are created for us automatically. As it is very unlikely that you would have callback keys stored in your X file, we can assume that under most circumstances the application will want to register callback keys with the controller *after* the X file has been loaded. At this point however, the animation controller will have been created along with its animation sets (with no callback key data assigned to them). We cannot simply add callback keys to an animation set at this time, because the memory for our callback keys will not have been allocated when the animation set was created by D3DX. D3DX would have had no way of knowing that we intended to register anything at all. Suffice to say, cloning will come to the rescue here as well.

The system we designed to handle the post-load registration of callback data does not just involve data cloning. It also incorporates an application-defined callback function which will be registered and called by the actor to allow the application to fill an actor owned temporary callback key array. This callback function will be called by the actor in the CActor::LoadActorFromX function just after the X file has been loaded. The actor will pass the application defined callback function an array of callback keys which the function can fill with callback data. When the callback function returns, the actor will have an array of callback keys for a given animation set. It will now need to replace the respective animation set that was loaded by D3DX with a clone which has room for the callback data. We will not be cloning the animation controller but will instead manually create copies of the animation sets ourselves. That is to say, for each animation set currently registered with our controller, we will create a new animation set with the correct number of callback keys reserved. When we create these animation set copies, we will pass in the callback data that the application defined callback function stored in our temporary callback

key array. Once we have created copies of all the animation sets with the callback data registered, we will un-register and free the original animation sets and register the new ones (with the callback data) in their place.

As callback keys are defined on a per-animation set basis, the application defined callback function will be called once for each animation set loaded from the X file. This will allow the application to register callback data with any of the loaded animation sets. All this will happen inside the CActor::LoadActorFromX function, abstracting away the application from the entire process. All the application has to do is implement the callback function and register it with the actor prior to calling CActor::LoadActorFromX.

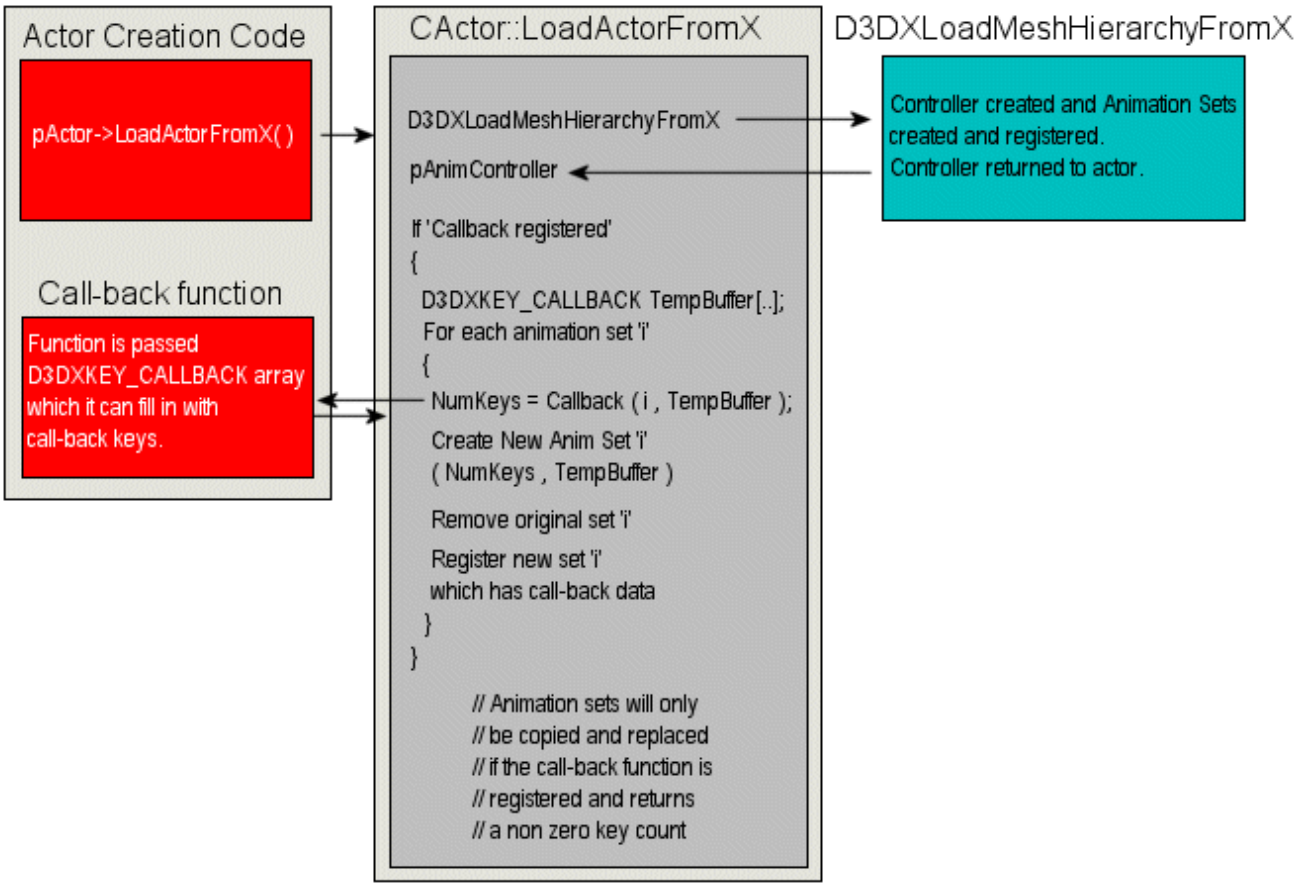

Figure 10.2

Figure 10.2 demonstrates the type of interaction that we will establish between the actor and the application. The application calls CActor::LoadActorFromX, which in turn calls D3DXLoadMeshHierarchyFromX to load the X file. If the X file contains animation data, the actor will be returned a pointer to an animation controller. At this point, if the application has registered a callback key callback function with the actor, it will allocate a temporary array of callback keys. It will then loop through each animation set registered with the controller and call the application defined callback function. This function will be passed the temporary callback key array which it can use to fill with callback keys for that animation set. The function should return an integer describing the number of callback keys it placed in this array. If this is non-zero, the actor will create a new animation set, passing

in this array of callback keys at creation time. The new animation set will not yet be attached to the controller at this point but will contain all the callback keys the application callback function specified for it. The next task will be to copy over all the animation data from the original animation set into the new animation set so that all animation data is maintained. At this point the new animation set will be a perfect clone of the original, with the exception that it now has the callback keys contained within. Finally, we un-register the old animation set from the controller and replace it with the new one. This will be done for each animation set registered with the controller, giving the application the chance to replace any animation sets that need callback key data.

The application defined callback function is also passed a pointer to the original animation set interface. This allows the callback function to check the name of the animation set for which it is being called so that it can determine if it wishes to register any callback keys for this set.

In our implementation, we decided to let the actor allocate the temporary callback key array that is passed into the callback function. One might wonder why we do not just let the callback function return a pointer to an application allocated array. In fact, this would present some problems. First, if the application allocated the array and returned a callback key array pointer to the actor, the programmer might be tempted to generate this array on the stack in the callback function. When the callback function returns the pointer to the actor, the stack information will be destroyed and the actor will have an invalid pointer. Second, even if the callback array is dynamically allocated on the heap in the callback function and returned to the actor, the application will need to implement a cleanup system where this memory is freed when the actor is deleted. This would need to be a little bit like the DestroyMeshContainer callback method that we used during frame hierarchy destruction. We certainly cannot allow the actor to free this application allocated memory in its destructor since it did not allocate this memory itself. It would not know for sure how the memory was allocated and therefore how it should be freed (e.g., we would not want our actor to use ‘delete’ instead of ‘free’ if the application had allocated the key array using malloc).

This is all a bit of a pain for the sake of a simple temporary buffer that is only used to communicate callback keys from the application to the LoadActorFromX function. After all, this temporary buffer is no longer needed once the new animation set has been created because the animation set creation function makes an internal copy of the callback data passed in. Therefore, what we decided to do is simply let the *actor* allocate a temporary buffer which is reused with each call to the callback function. The callback function can simply fill this buffer, which is then automatically accessible to the actor on function return. Furthermore, because the actor allocated this memory, it can release it with confidence after all the callback keys have been registered for each animation set.

Registering a callback key callback function with our actor will be done in exactly the same way we register texture and attribute callback functions. You will recall from the previous lab project that the actor maintains a callback function array (see CActor.h):

```
CALLBACK_FUNC               m_CallBack[CALLBACK_COUNT];
```

Each element of this array defines a single callback function contained in a CALLBACK_FUNC structure (see main.h):

```
typedef struct _CALLBACK_FUNC   // Stores details for a callback
{
    LPVOID  pFunction;          // Function Pointer
    LPVOID  pContext;           // Context to pass to the function

} CALLBACK_FUNC;
```

Each member of this structure contains two void pointers. The first member is where a pointer to the callback function should be stored. The second member is where we can store a pointer to arbitrary data that we would like passed to the callback function. In our projects we always use this to store a pointer to the instance of the CScene class in which the callback function is a static method. This is so the callback function can access non-static members.

You will recall that we store information in this array using the CActor::RegisterCallback function. We used this same function to store texture and attribute callback functions in the actor's callback function array in previous lab projects (see CActor.h):

```
bool RegisterCallback  ( CALLBACK_TYPE Type, LPVOID pFunction, LPVOID pContext );
```

This function (which we covered in a previous lesson) takes the passed function pointer and context pointer and stores them in a CALLBACK_FUNC structure in the actor's callback array. You will hopefully recall that the first parameter of this function should be a member of the CALLBACK_TYPE enumerated type which is defined within the CActor namespace:

```
enum CALLBACK_TYPE
{
    CALLBACK_TEXTURE = 0,
    CALLBACK_EFFECT = 1,
    CALLBACK_ATTRIBUTEID = 2,
    CALLBACK_COUNT = 3
};
```

This enumerated type describes the index in the actor's callback array where a particular callback function should be stored. For example, if we pass CALLBACK_TEXTURE into the CActor::RegisterCallback method, this pointer and context will be stored in the first element of the array. Using this enumerated type, the actor can quickly test the index of its callback array to see if a particular callback function has been registered by the application.

Previously, we only needed callback functions to parse textures and materials during X file loading, but now we need to add a new member to this enumerated type. We must also increase the CALLBACK_COUNT member so that we make room at the end of the actor's callback function array for a new callback function type. This callback function will be called by the actor (if it has been registered) to collect callback keys for animation sets during the loading process.

The updated CALLBACK_TYPE enumeration is now defined in CActor.h as:

```
enum CALLBACK_TYPE
{
 CALLBACK_TEXTURE = 0,
 CALLBACK_EFFECT = 1,
 CALLBACK_ATTRIBUTEID = 2,
 CALLBACK_CALLBACKKEYS = 3,
 CALLBACK_COUNT = 4
};
```

If element [3] in the actor's callback function array is non-NULL, it will contain the pointer to a callback keys callback function. Notice that because we have now set CALLBACK_COUNT to 4, the callback function array will be statically allocated in the actor's constructor to contain four elements instead of three.

So, registering our callback keys callback function will be no different from registering any of the attribute callback functions. In fact, the following example shows how the CScene class might allocate an actor, register an attribute callback and a callback keys callback function, before loading the animated X file into the actor. As you will see, it is simply an additional function call. Remember that the 'this' pointer passed into the CActor::RegisterCallback method (as the context parameter) allows the instance of the scene class access to the non-static member variables within the static function.

```
//Allocate a new actor
CActor * pNewActor = new CActor;

// Register an AttributeID call back ( non-managed mode actor )
pNewActor->RegisterCallback(CActor::CALLBACK_ATTRIBUTEID,CollectAttributeID, this );

// Register callback function to add callback keys to the actor
pNewActor->RegisterCallback(CActor::CALLBACK_CALLBACKKEYS, CollectCallbacks, this );

// Load the X file into the actor
pNewActor->LoadActorFromX( "MyXFile.x", D3DXMESH_MANAGED, m_pD3DDevice );
```

In order for the actor to be able to call the callback function, it must be aware of the function's parameter list and return type. Therefore, when we implement callback functions, we must make sure that we follow the strict rules laid down by the actor. When the CActor calls this new callback function, it will use a pointer of type COLLECTCALLBACKS (defined in CActor.h):

```
typedef ULONG (*COLLECTCALLBACKS ) ( LPVOID pContext,
                                     LPCTSTR strActorFile,
                                     LPD3DXKEYFRAMEDANIMATIONSET pAnimSet,
                                     D3DXKEY_CALLBACK pKeys[]
                                   );
```

This is a pointer to a function that returns an unsigned long (the number of callback keys placed into the passed array by the callback function). The function should also accept four parameters: a void pointer to context data (the instance of the CScene class for example), a string (the name of X file will be passed by the actor here), an ID3DXKeyframedAnimatonSet interface pointer (the animation set currently being processed by the actor which we may wish to register callback keys for), and an empty array of callback keys that the function will place its callback key data into if it wishes to register any for the passed set. We must make sure that our collect keys callback function is defined exactly in this way.

Below, we see how the CollectCallbacks method is defined in CScene.h. This is the callback function which will be registered with the actor for the processing of callback key data. Note how it matches the exact function signature described above. The details of the method itself will be discussed in a moment.

```
static ULONG CollectCallbacks ( LPVOID pContext, LPCTSTR strActorFile,
                                LPD3DXKEYFRAMEDANIMATIONSET pAnimSet,
                                D3DXKEY_CALLBACK pKeys[] );
```

Our callback functions must always be static if they are to be methods of classes. They must exist even if no instance of the class has been allocated. The function implementation would then be started like this:

```
ULONG CScene::CollectCallbacks( LPVOID pContext, LPCTSTR strActorFile,
                                LPD3DXKEYFRAMEDANIMATIONSET pAnimSet,
                                D3DXKEY_CALLBACK pKeys[] )
{
   // fill in array here with key data
}
```

Before we start to discuss how to fill in the callback key array, one thing may be starting to trigger alarm bells. How does our callback function know how big the empty D3DXKEY_CALLBACK array (passed in by the actor) is going to be so that it does not try and store more keys than the array has elements? Furthermore, this temporary array has been allocated by the actor before being passed to us. So how does the actor have any idea how much memory to allocate for this array? It would seem to have no means for knowing how many callback keys we might want to register for a given animation set.
But this is not the case. When we discussed the SetActorLimits method earlier, we deferred discussion of its final parameter, simply saying that this was where we specified the maximum number of callback keys that can be registered with a single animation set. This setting is unlike the other properties that we set via SetActorLimits in that it does not alter any properties of the controller -- it simply informs the actor how big to allocate this temporary callback array that will be passed into the callback function during loading.

For example, if we specify (via SetActorLimits) a value of 20 for the maximum callback key count, then a temporary array of 20 D3DXKEY_CALLBACK structures will be allocated in the LoadActorFromX method. This temporary array will be passed into the callback function each time it is called (for each animation set loaded). It stands to reason that we would never want to try and store more than twenty keys in the passed array in this example for a given animation set. As this same temporary buffer is used for key collection for all animation sets, it also stands to reason that the callback function must return the number of key's it placed into the array. If we decide for example, that we would like to register 10 keys for animation set 1 but only 5 with animation set 2, we would set the actor limits so that it had a maximum of 10 callback keys per animation set. When the actor was loaded, the callback function would be called twice. Both times an array of 10 elements would be passed that can be filled by the callback function for each set being processed. The second time the function was called (for animation set 2) the callback function would only use 5 out of the 10 possible array elements. Therefore, the return value of the function correctly informs the actor how many keys out of the possible 10 (in this example) were actually used for a given animation set. This value is then used to reserve space for callback keys

in the newly cloned animation set and the callback data copied. The temporary buffer is no longer needed and can be freed once all animation sets have been cloned.

Of course, the important point is how we might implement such a callback function. While we know that the D3DXKEY_CALLBACK structure is a simple structure that contains only two members (a timestamp and a void pointer to context data), it is exactly in the setting of this context data that certain problems arise which must be overcome. This leads on to our next section.

Safe Callback Data

One of the problems with registering context data with a D3DXKEY_CALLBACK structure occurs when the animation controller is released. Let us say for example, that we implement a callback key callback function that simply sets one callback key for an animation set called “Tank” inside an X file called “MyXFile.x”. We will assume that we wish to assign an arbitrary structure (which we shall call MyStruct) as the context data to this callback key. The members of this imaginary structure are not important -- it might contain sound effect data or a series of properties that need altering on the mixer track when this event occurs -- for this example. A naïve first approach might be to implement the callback registration function like so:

```
ULONG CScene::CollectCallbacks( LPVOID pContext, LPCTSTR strActorFile,
                                LPD3DXKEYFRAMEDANIMATIONSET pAnimSet,
                                D3DXKEY_CALLBACK pKeys[] )
{

    // Is it the right actor
    if ( _tcsicmp( strActorFile, _T("MyXFile.x") ) != 0 ) return 0;

    // Make sure we only assign it to the correct animation set
    if ( _tcsicmp( pAnimSet->GetName(), _T("Tank") ) != 0 ) return 0;

    // Allocate an arbitrary structure
    MyStruct * pData = new MyStruct;
    MyStruct->A = some data goes here
    MyStruct->B = some data goes here
    MyStruct->C = some data goes here
    MyStruct->D = some data goes here

    // store the data object in the call back structure along with the timestamp
    pKeys[0].Time          = 150.0;
    pKeys[0].pCallbackData = (LPVOID)pData;

    // Notify that we have one key
    return 1;
}
```

While this function makes a glaring error (which we will discuss in moment), it does show how the callback function can be used to add a key to a specific animation set. This function, when called by the actor during the loading process, would be returned a single callback key for the animation set.

This function will be called by each actor for which this function is registered. Therefore the first thing we do is test to see whether this function is being called by the right actor. In this example we are only interested in the actor created from the X file called 'MyXFile.x'. As the function is passed the name of the actor (which is the same as the X file it was created from), we use the _tcsicmp method to compare the name of the actor against the string of the X file we are interested in. If there is no match, then this function has been called by an actor that we are not interested in registering callback data for, so we exit.

Next we test the name of the passed animation set against the string "Tank", as we are only interested in registering a callback key for the Tank animation set. This is why it is very useful that the interface of the animation set for which the function is being called for is also passed in by the actor. It allows us to use the ID3DXKeyFramedAnimationSet interface to query the animation set to determine if it is an animation set we are interested in. Remember, although at this point in the function we know we have the actor we are looking for, this function will be called by that actor for every animation set it contains. As we are only interested in one of these animation sets, we perform the string comparison between the name of the animation set passed in and the name of the animation set we are looking for and return from the function if no match is found.

Finally, we allocate some arbitrary structure on the heap, assign it some arbitrary data and assign its pointer to the first callback key in the callback key array. A pointer to this structure will be passed to the callback handler passed into AdvanceTime, which may contain data such as the name of a sound effect to play. In this example we have set the timestamp of the callback key to 150 ticks. What these ticks mean in seconds is dependant on the ticks per second ratio of the animation set. If you wish to find that out so that you can convert the second value into a tick value, there is no problem there. Because the function is passed the ID3DXKeyframedAnimationSet interface, we can call its GetSourceTicksPerSecond method and use the returned value to map from one to the other.

So, we have a good idea now how our callback key callback function works. Obviously, this function might grow quite large if you wish to assign lots of different callback keys to lots of different animation sets during the loading process. But even in that case, the system is quite simple. So what was wrong with the above example?

The problem is tied into the procedure of destroying the actor and its underlying animation controller. When we destroy the actor, the actor releases its controller. The controller in turn releases each of its animation sets until it has all been unloaded from memory. The problem is that when the animation set is released, its callback key array is destroyed also (just as we would expect). However, in the above example, we allocated a structure on the heap inside the registration function and stored its address in the callback key's context data pointer. If the callback key structure is simply released, the only surviving pointer to that structure will be deleted also. We now have no way of freeing the memory of the context data structure that was allocated in the callback registration function. When the application terminates, we will have memory leaks, especially if lots of callback keys are being used which have had structures allocated for their context data in this way. This is an easy problem to fix, but we wish to use a solution that is elegant.

One approach might be to fetch all callback key structures from each animation set inside the actor's destructor before it releases its animation controller. We know that the ID3DXKeyframedAnimationSet interface exposes a GetCallback method to allow the controller to step through its list of callback keys. We can simply use this same function to get at the context pointer of each callback key in the animation set's callback key array. Before releasing the controller, we would loop through each animation set, and for each set, repeatedly call its GetCallback method until we have fetched all of its callback keys. You will recall from the textbook that each call to this method returns the time of the callback key and its context data pointer. We can use these context pointers to delete the structures that have been allocated and assigned to this pointer in the callback registration function.

But there is a problem with this approach too. When we fetch the callback context pointer (via the GetCallback method) we are returned a void pointer to the context data. We have no idea how the application allocated it or even what the pointer is pointing at. It could be the address of a structure or class allocated on the heap, in which case releasing it is exactly what we want to do. On the other hand, it could be the address of a constant global variable that was statically allocated. We would cause an error if the actor tried to release something like that. The actor simply has no idea what the context pointer of a callback key is pointing to and how the data it points to was allocated. Therefore, there is no way it can safely make any assumptions about how to delete it (or even if it should be deleted).

Now you might be thinking that one way around this would be to avoid forcing the actor to release this memory at all. Instead, when we allocate the structure inside the callback function, we could add a copy of its pointer to some CScene array. Therefore, even when the actor is deleted and all callback key arrays have been deleted, the scene object would still have the array of all the context data pointers which could be deleted in a separate pass when the application is shut down. This is not very nice though since we should not be happy with the application having to implement its own container class simply to handle a process that should be performed by the actor. Furthermore, we may wish to assign many different types of structures (as context data) to different callback keys, and they may not all be able to be derived from the same base class. In short, the application may have to maintain multiple arrays of callback key context data pointers for the various types that may be used. This approach is ungainly and simply will not do.

COM to the Rescue

If we think about the way that COM was designed, one of its aims was to eliminate this sort of problematic behavior. COM objects support lifetime encapsulation (i.e., a COM object is responsible for releasing itself from memory when it has no outstanding interfaces in use). All of our problems can be solved if our actor enforces the strict rule that the context data pointer of a callback key must be a pointer to a COM interface. In fact, it does not even have to be a COM object, just as long as its interface is derived from IUnknown. As we know, IUnknown is the interface from which all COM interfaces are derived and it exposes the three core methods: AddRef, Release, and QueryInterface. If our actor knows that the context data pointer for each callback key is a pointer to an IUnknown derived object, it knows that the object must also expose the Release method. Therefore, our actor need not concern itself with what type of object or structure it is pointing to, it can simply loop through each callback key in each animation set, cast the context data pointer to an IUnknown interface pointer, and

call its Release method. This will decrement the object's internal reference count. When the count reaches zero, the COM object will then unload *itself* from memory.

To be clear, we do not need to write a fully functional COM object for this system to work. Rather, we just have to make sure that the classes we allocate and assign as context data are derived from IUnknown and implement the three methods of the IUnknown interface. This is actually a useful thing for us to do because it will also go a long way towards educating you in the construction of a real COM object. We will create a class that is derived from IUnknown and behaves like a COM object in many respects. However, it will not be registered with the Windows registry like a real installed COM component; it will just be a class which we allocate using the new operator. However, this object will maintain its own reference count and delete itself from memory when this reference count reaches zero.

For this task, we will develop the CActionData class, but you can use any class you like just so long as it is derived from IUnknown and fully implements the three core COM methods.

Source Code Walkthrough – CActionData

The first class we will cover will be the CActionData class. It is a simple class and has no association with the CActor class whatsoever. In fact, this class is defined in CScene.h and will be used by our application as the class used to represent callback key context data. The class declaration is shown below:

```
class CActionData : public IUnknown
{
public:
    // Public Enumerators for This Class
    enum Action { ACTION_NONE = 0, ACTION_PLAYSOUND = 1 };

    // Constructors & Destructors for This Class.
             CActionData( );
    virtual ~CActionData( );

    // Public Functions for This Class
    // IUnknown
    STDMETHOD(QueryInterface)(THIS_ REFIID iid, LPVOID *ppv);
    STDMETHOD_(ULONG, AddRef)(THIS);
    STDMETHOD_(ULONG, Release)(THIS);

    // Public Variables for This Class
    Action  m_Action;       // The action to perform

    union                   // Some common data types for us to use
    {
        LPVOID  m_pData;
        LPTSTR  m_pString;
        ULONG   m_nValue;
        float   m_fValue;
    };
```

```
private:
    //-----------------------------------------------------------------------
    // Private Variables for This Class
    //-----------------------------------------------------------------------
    ULONG   m_nRefCount;    // Reference counter
};
```

There are a few very important points that must be made about this class. Firstly, it is derived from IUnknown, which means it can be treated like a normal COM object by the actor when it wishes to release it from memory. As far as the actor is concerned, it will see every valid callback key context data pointer as being a pointer to an IUnknown COM object and will simply call its Release method. Obviously, for this to work, this class must implement the QueryInterface, AddRef and Release methods set out in the base interface. Notice at the bottom of the declaration there is a private member variable called m_nRefCount. This will be used to represent the reference count of the object which will be incremented and decremented with calls to its AddRef and Release methods respectively. This will be set to 1 when the object is first created. The Release method will have additional work to do if it decrements the reference count of the object to 0. When this is the case, it means no code anywhere wishes to use this object any more, and it will delete itself from memory. We will look at this function in a moment.

So how does this class work? It is rather simple and can be easily extended to represents all sorts of callback key data types. As you can see, the class has defined a union so that at any one time it can store a void pointer, a string, an unsigned long, or a float. That covers virtually all bases when we consider that we could use the void pointer to point to arbitrary structures. As this is a union, all members share the same memory, so only one can be active at any one time. Which one is active depends on the setting of the m_Action variable, which can be set to a member of the Action enumerated type. Currently, this has only two members: ACTION_NONE and ACTION_PLAYSOUND. You can add different modes to this class and the code to properly release the memory for them in its destructor. For example, in Lab Project 10.1 we use the ACTION_PLAYSOUND action when we register callback key context data. We know that in this mode, the CActionData object will expect the name of a wave file to be stored as a string (i.e., the m_pString member of the union will be used). Therefore, in the destructor, if we test the m_Action member variable and find that it is set to ACTION_PLAYSOUND, we know that this represents sound effect context data and we can free the memory of the string. Obviously, if you added your own types, you would know what data it used, how it was allocated, and therefore how it must be de-allocated when the object destroys itself.

Before looking at the code to this object it will be helpful to take a look at the callback registration function implemented in CScene.cpp in Lab Project 10.1. This callback function is called by the actor when the X file is loaded. We use our new CActionData class to register two sound effect callback keys with an animation set called “cutscene_01”. This should give you a good idea about how the CActionData class is used before we discuss the code.

```
ULONG CScene::CollectCallbacks(     LPVOID pContext,
                                    LPCTSTR strActorFile,
                                    LPD3DXKEYFRAMEDANIMATIONSET pAnimSet,
                                    D3DXKEY_CALLBACK pKeys[] )
{
    CActionData * pData1 = NULL, * pData2 = NULL;
```

```
    // Bail if this is not right actor or right animation set
    if ( _tcsicmp( strActorFile, _T("Data\\AnimLandscape.x") ) != 0 ) return 0;
    if ( _tcsicmp( pAnimSet->GetName(), _T("Cutscene_01") ) != 0 ) return 0;

    // Allocate new action data objects for both callback keys
    pData1 = new CActionData();
    if ( !pData1 ) return 0;
    pData2 = new CActionData();
    if ( !pData2 ) { pData1->Release(); return 0; }

    // Setup the details for both callback keys (take off sound, and flying sound)
    pData1->m_Action  = CActionData::ACTION_PLAYSOUND;
    pData1->m_pString = _tcsdup( _T("Data\\TakeOff.wav") );
    pData2->m_Action  = CActionData::ACTION_PLAYSOUND;
    pData2->m_pString = _tcsdup( _T("Data\\Flying.wav") );

    // Store the two data objects at the correct times
    pKeys[0].Time          = 0.0;
    pKeys[0].pCallbackData = (LPVOID)pData1;
    pKeys[1].Time          = 5.0 * pAnimSet->GetSourceTicksPerSecond();
    pKeys[1].pCallbackData = (LPVOID)pData2;

    // Notify that we have two keys
    return 2;
}
```

When called by an actor, this function will return zero if the actor that called it was not loaded from a file called ‘AnimLandscape.x’ or if the animation set passed in is not called “Cutscene_01”.

If all goes well, then it will allocate two new CActionData objects because in this example we want to register two callback keys to play sound effects at some point along the animation set’s timeline. We then set the details of each CActionData object. The reference count of each CActionData object will be 1 at this point (via its constructor). We set the m_Action member of both to ACTION::PLAYSOUND. For the first CActionData object we set its string pointer member variable to point to a string containing the name of the wave file that should be played when this event is triggered (“Data\\TakeOff.wav”). We do the same for the second CActionData object, only this time we set the name of the wave file to “Data\\Flying.wav”. Notice that we are using the _tcsdup function which duplicates the string passed in. This means that the string data must be freed when the CActionData object is deleted in its destructor.

Once we have the context data stored in the CActionData objects, we assign them to the context data pointer for the first two keys in the passed D3DXKEY_CALLBACK array. The first event is triggered 0 seconds into the animation set’s period and the second event is triggered at 5 seconds. Finally, we return the count of two so that the actor knows that it must clone this animation set into a new one which has room for two callback keys.

> **Note**: At 0 seconds animation set time, the controller will call a callback function (more on this in a moment) which it uses to handle callback keys. This callback function will be passed the CActionData object associated with that key. The callback function can then extract the string “Data\\TakeOff.wav” from the passed object which informs it of the sound to play. At 5 seconds, this same callback function will be called again, only this time, when the string is extracted from the CActionData object, it contains “Data\\Flying.wav” causing a different sound to be played. We will discuss how the callback function should

be written later. At the moment, we are just focusing on a secure way to allocate and store the callback key context data inside the callback registration function.

You will see later that contrary to how we usually do things, when the CActionData object pointers are returned to the actor, the actor does not increment their reference count. This is because the callback function should really be seen as an extension of the actor itself, as it is called only by the actor during the loading process. Therefore, we can think of this function as allocating the object on behalf of the actor before storing its pointer in an actor-owned data structure (the callback key array). This is because we wish the reference count of each CActionData object to be exactly 1, so that when the actor releases the controller, we can fetch each callback key of each animation set and then cast its context data pointer to IUnknown. We can then call IUnknown::Release which will cause the reference count of the CActionData object to drop to 0 resulting in its unloading itself from memory. If the actor also incremented the reference count when the function returned, the CActionData objects would not destroy themselves on actor destruction because their reference counts would fall from 2 to 1 instead of from 1 to 0.

CActionData::CActionData()

The constructor sets the data area to NULL and the action of the object to ACTION_NONE. This is the default action of a newly created object which basically states that the object has no valid data which needs to be released on destruction. We saw in the above code that the callback function assigned the action to something meaningful (ACTION_PLAYSOUND) as soon as the object was allocated.

It is very important to note that we set the internal reference count of the object to 1. We wish this class to behave like a real COM object so we know that if the constructor has been called, then an instance of this class has been allocated and there will a single pointer to the object currently in use by the application.

```
CActionData::CActionData( )
{
    // Setup default values
    m_Action = ACTION_NONE;
    m_pData  = NULL;

    // ***********************************
    // *** VERY IMPORTANT
    // ***********************************
    // Set our initial reference count to 1.
    m_nRefCount = 1;

}
```

CActionData::AddRef

Just like all COM objects, our object should implement an AddRef method which increments the reference count of the object. An application should call this method whenever it makes a copy of a pointer to an object of this type. We never make any additional copies of our CActionData object in our

lab project since the only pointer to the object is stored in the D3DXKEY_CALLBACK structure. However, if your application does intend to store a copy of a pointer to this object somewhere, it should call AddRef after it has done so. This is how the object knows how many interfaces are in use by external code. We certainly would not want the object to unload itself from memory while an external code module still thought it could use its pointer to this object.

```
ULONG CActionData::AddRef( )
{
    return m_nRefCount++;
}
```

CActionData::Release

For any external code or objects that are using our object, the Release method is its way of letting us know that it is no longer interested in using it. We are used to calling the Release method of COM interfaces by now so this concept is nothing new. What is new however is the implementation of a Release method which must decrement the internal reference count and instruct the object to delete itself if the reference count reaches zero. It should now be clear why using an interface to a COM object that has been released will cause your code to crash. After the reference count reaches zero, the object and all its data simply do not exist any more.

```
ULONG CActionData::Release( )
{
    // Decrement ref count
    m_nRefCount--;

    // If the reference count has got down to 0, delete us
    if ( m_nRefCount == 0 )
    {
        // Delete us (cast just to be safe, so that any non virtual destructor
        // is called correctly)
        delete (CActionData*)this;

        // WE MUST NOT REFERENCE ANY MEMBER VARIABLES FROM THIS POINT ON!!!
        // For this reason, we must simply return 0 here, rather than dropping
        // out of the if statement, since m_nRefCount references memory which
        // has been released (and would cause a protection fault).
        return 0;

    } // End if ref count == 0

    // Return the reference count
    return m_nRefCount;
}
```

Studying the above function code you will note that the first thing the function does is decrement its internal reference count by one. If the reference count is still greater than zero then nothing much happens; the function simply returns the new reference count of the object. However, if the reference count reaches zero, then the object deletes itself from memory using the **this** pointer.

It is perfectly valid for an object to delete itself as long as you do not try to access any of the member variables from that point on. When delete is called to release the object, the destructor of the object will be called and therefore all member variables will have been released from memory. In the above code, you can see that we are very careful that we do not simply execute the last line of the function in the delete case. That is because the last line returns the value of a member variable which would no longer exist at this point and would thus cause a general protection fault. Therefore, inside the deletion case code block we return a value of zero for the reference count.

So we can see that the application should never explicitly delete an instance of this class but should instead treat it like a proper COM object using AddRef and Release semantics.

CActionData::~CActionData

The destructor of a class is the last method to be called. With our object, it will only be called once the Release method has issued the 'delete this' instruction in response to its reference count hitting zero. This is where the various modes of our CActionData objects can clean up their memory allocations. In our current object, there is only one real mode ACTION_PLAYSOUND. The object assumes that the string containing the wave filename was allocated using the _tcsdup function and as such will free the memory for this string as its last order of business.

```
CActionData::~CActionData( )
{
    // Release any memory
    switch ( m_Action )
    {
        case ACTION_PLAYSOUND:
            // Release duplicated string
            if ( m_pString ) free( m_pString ); // Allocated by '_tcsdup';
            break;

    } // End Action Switch
}
```

CActionData::QueryInterface

This function is quite an exciting one for us to look at. We have discussed how COM objects always expose this method as a means for checking the supported interfaces of an object. Indeed our object will expose two interfaces: the IUnknown interface (which all COM objects must expose) and the CActionData interface (our derived class). The CActionData interface will be used by the callback key registration callback function to assign context data to its member variables (such as the wave filenames in our example). The IUnknown interface will be used by the actor when it needs to release the callback data and has no idea of what type the context data actually points to.

As you will see, much of the mysteries of this function are removed when we look at how it is implemented in this simple example. Really, it is nothing more than a function that safely casts a pointer to the object (its 'this' pointer) to an interface/class of a specific supported type. Of course, a more

complex COM object might contain multiple classes such that some of the interfaces it exposes may work internally with completely separate objects, but in our case, there is only one object (a CActionData object). Therefore, this function is only concerned with returning one of two supported interfaces that allow the application to call the methods supported by this object.

As we have seen in the past, the QueryInterface method of IUnknown expects to be passed two parameters. The first is the alias of the GUID. As we discussed in Chapter Two, every interface has a GUID -- a unique number that identifies it. We also discussed how each GUID will often also have an alias to make it easier to remember and use. These aliases are usually in the form of "IID_I***name***", where *name* is the name of the interface. For example, if we wish to enquire about an object's support for the ID3DXAnimationSet interface, we can simply specify that interface using the IID_ID3DXAnimationSet alias instead of using its harder to remember GUID. If we look in the D3DXAnim9.h header file for example, we will see that the GUID for this interface is assigned to the alias 'IID_ID3DXAnimationSet'. The header file or the manual that ships with a software component will usually be the place to obtain a list of all aliases/interface GUIDS supported by that installed component.

Because, we have added our own interface to the mix (CActionData), we have given this interface a unique GUID and have assigned it the alias IID_CActionData. If you look in CScene.h, you will see this alias defined as follows:

```
GUID IID_CActionData = {0x736FE02A, 0x717D, 0x491F, {0x87, 0xED, 0x4B, 0x16, 0x2, 0xC8, 0xF3, 0xCA}};
```

As you can see, IID_CActionData is a variable of type GUID. The values assigned to it (i.e., the numbers in the curly braces) are the GUID itself. You can generate unique GUIDS for your own classes/COM interfaces using the GuidGen.exe tool that ships with Microsoft Visual C++. The GUIDs generated are guaranteed to be unique with respect to the GUIDs of all other interfaces in existence, so our function can safely assume that when this GUID is passed, the caller is definitely asking whether the object supports our CActionData interface, which it does.

The second parameter passed into the function should be the address of a void pointer which on function return will contain the address of the requested interface, or NULL if the GUID passed in was for an interface type that the object does not support. The application can then cast the void pointer to the correct type.

As you can see by looking at the code below, it really is just a list of conditional statements that test the past GUID to see if it is of any of the types supported by the object. If it is, we cast the ***this*** pointer, a pointer to the C++ object itself, to the desired base class before casting again to the void pointer which is ultimately returned to the function.

```
HRESULT CActionData::QueryInterface( REFIID iid, LPVOID *ppv )
{
    // Double cast so compiler can decide
    // whether it needs to switch to an alternate VTable
    if ( iid == IID_IUnknown )

        *ppv = (LPVOID)((IUnknown*)this);
```

```
    else if ( iid == IID_CActionData )

        *ppv = (LPVOID)((CActionData*)this);

    else
    {
        // The specified interface is not supported!
        *ppv = NULL;
        return E_NOINTERFACE;

    } // End iid switch

    // Call addref since a pointer is being copied
    AddRef();

    // We're supported!
    return S_OK;
}
```

When this function returns, the caller will be passed a pointer (via parameter two) to the supported interface that they requested. Notice that this function must increment the reference count (AddRef) before the function returns, since we have issued a new interface pointer to the object and an additional pointer to this object is now in existence.

The only thing that may seem confusing about the above code is how we cast the object's pointer to the requested interface/base class type before casting it to a void pointer. As we are simply casting the object to a base class, why not just cast 'this' straight to a void pointer? In this particular situation we could do that, however the double cast ensures that our function will work correctly even if any of the interfaces are derived from multiple base classes (multiple inheritance). So we should practice this safe cast policy regardless. If for example, the CActionData interface was later revised such that it had more than one base class (IUnknown and some other base class), this would cause problems as the complier would have no idea which vtable to return to the caller when the object was cast straight to a void pointer. When a class is derived from multiple base classes, it actually has multiple vtable pointers stored in the member area of each instance. By casting the 'this' pointer to the correct interface type first, *before* casting it to void, we are allowing the compiler to determine which vtable should be used for accessing functions via this interface.

> **Note:** If you would like to understand more about implementing COM objects from C++ objects, you should check out the following excellent free tutorial. It takes you step by step through the process of turning a C++ object into a COM object. It discusses the topic of multiple inheritance and multiple vtables also. This tutorial is called 'From CPP to COM' and can be found at:
>
> http://msdn.microsoft.com/library/default.asp?url=/library/en-us/dncomg/html/msdn_cpptocom.asp

We have now implemented the three methods of IUnknown so that our object will obey the lifetime encapsulation rules set out by the COM specification. It also (as dictated by the COM standard) exposes a QueryInterface method that allows an application to ask our object if a particular interface is supported and have returned a pointer to that interface if it is. Our simple QueryInterface implementation is really just a function that allows the application to safely ask the question, "Can I cast this object pointer to a specific class type?"

We have now covered the first new class of this project (CActionData). In summary, it is a support class that allows us to store arbitrary data in an object that is capable of handling its own destruction. As discussed and demonstrated, we use an instance of this class to store the context data for each callback key that we register. In Lab Project 10.1, each callback key is used to play a sound, so the filename of the wave file is stored in CActionData object and assigned to the context data pointer of the D3DXKEY_CALLBACK structure contained in the actor's animation set. When the actor is being destroyed and the animation set is released, the actor will fetch every callback key and cast its context data pointer from a void pointer to an IUnknown interface. The actor can then call IUnknown::Release on this pointer, causing the CActionData object to destroy itself. The actor has no knowledge of what this pointer actually points to; only that it supports the Release method and will handle its own destruction. Therefore, the only rule that our actor class places on the callback system is that the context data pointer for a callback key must point to an IUnknown derived structure.

All of these pieces will fit together when we finally cover the CActor code. It was mentioned earlier that for the most part, the new methods we add to CActor should really only be lite wrappers around the underlying methods of the ID3DXAnimationController. After all, the ID3DXAnimationController handles most of the heavy lifting. We just have to assign animation sets to tracks on the mixer and play them back, right? Well, not quite! Things *should* be that simple, but unfortunately we will have to do some work just to get the animation system to work at all. This is due to a very nasty bug in ID3DXKeyframedAnimationSet.

Error in ID3DXKeyFramedAnimationSet::GetSRT

In the summer of 2003, the DirectX 9.0b SDK was released with a fully overhauled animation system. It is this new system that we have covered in this course. The changes to the animation system from previous versions were significant enough that code that had been written to work with previous versions would no longer compile.

The animation system was streamlined by the moving of animation data (keyframes) into the animation set's themselves. This had not previously been the case, as the animation data used to be stored in separate 'interpolator' objects which then had to be registered with an animation set. It is likely that this additional layer was disposed of to make the accessing of animation data by the animation set more efficient.

Previously, no AdvanceTime function existed either; in its place was a function called SetTime. Instead of passing in an elapsed time to this function, you had to pass in an actual global time which would in turn set the global time of the controller explicitly. This placed the burden on the application to keep track of the current global time of the animation controller by summing the elapsed time between frame updates. This burden has now been removed and the application now simply passes the elapsed time into the AdvanceTime call, allowing the controller to keep track of global time on our behalf.

In the 2003 summer update, the callback system was also added to the animation system. This is another worthy addition to the animation system, exposing better communication possibilities between an application and a currently playing animation.

While this animation system re-write undoubtedly caused some headaches for developers that had already coded their own animations using the previous system, the new animation system was arguably the better for the overhaul. However, in the re-write of the animation system, an error crept into the ID3DXKeyframedAnimationSet::GetSRT method, making the ID3DXKeyframedAnimationSet object essentially useless for serious development. This error seems to have gone unnoticed by the developers (and the beta testers) and as of the SDK summer update of 2004 (DirectX 9.0c) released a whole year later, the bug was still there.

The reason the bug has probably gone unnoticed for so long is that it does not always make itself apparent. For simple animated X files which play at a medium speed with basic animations, the GetSRT function seems to handle these cases fine and generates the correct SRT data for the periodic position of an animation. One such X file that seems to play without any problems using the new animation system is, ironically, Microsoft's tiny.x (ships with the SDK). This is probably the file that everyone uses to test the animation system, which might explain the oversight. Only when we began to use more complex X files did we discover the bug here in the Game Institute labs.

Indeed, the bug is actually quite hard to see if you are not paying very close attention to the screen, since the animations seem to play out correctly for the most part. However, it seems that at certain periodic positions in some animations, a single GetSRT function call will generate wildly incorrect data. This seems to happen almost at random. As the following call to GetSRT will once again generate the correct SRT data, this causes small but noticeable glitches in the animation being played. Basically, for only a few milliseconds, objects in your scene will skip or jump to completely incorrect positions in the scene as their matrices are built from bogus SRT data. A few milliseconds later, the objects are back in their correct position until the next time the GetSRT function generates invalid data. If you play the animation set from Lab Project 10.1 using the vanilla D3DX animation system, you will see these glitches as the animation plays out.

So what are the implications for the D3DX Animation System?

Since D3DXLoadMeshHierarchyFromX will always load AnimationSet objects defined in X files into ID3DXKeyframedAnimationSets, you might assume that the entire D3DX animation system that we have spent time learning about is now useless. But this is certainly not the case. We discussed in the textbook that both ID3DXKeyframedAnimationSet and D3DXCompressedAnimationSet are derived from the base interface ID3DXAnimationSet. We also learned that how we have the ability to derive our own classes from ID3DXAnimationSet so that we can create our own custom animation sets and plug them into the D3DX animation system. Provided our derived class implements the functions of the base class (GetSRT, GetPeriodicPosition, etc.) the animation controller will work fine with our derived classes. So in this workbook, we are going to write our own keyframed animation set and use that instead. Essentially we will replace all ID3DXKeyframedAnimationSets (created and registered with the controller when we load an X file), with our own CAnimationSet objects after the X file has been loaded.

On the bright side, working around this bug presents us with an opportunity to really get under the hood of the animation set object and learn how the keyframe interpolation and callback key searching is performed. Remember, it is the animation set that is responsible for generating the SRT data from its

keyframes and for returning the next scheduled callback key to the controller. We will have to implement all of this in our own animation set class, which will give us quite a bit of new insight.

> **Note:** Hopefully, by the time you read this, Microsoft will have fixed this bug, making our workaround unnecessary. However, this section will teach you how animation sets work as well as go a long way towards explaining how to create your own COM objects. It is therefore recommended that you read this section, even if the bug no longer exists. It will be helpful if you need to expand the D3DX animation system (or even write your own system from scratch) for your own reasons down the road.

Although we will not implement our animation set class as a true COM object (e.g., it will not be registered with the Windows registry), it will be close enough to the real thing. As such, we will need to implement the three methods from IUnknown (AddRef, Release, and QueryInterface), just like we did with our CActionData class.

Replacing the ID3DXKeyframedAnimationSets that have been loaded and registered with the animation controller (by D3DXLoadMeshHierarchyFromX) with our own CAnimationSet objects will be a trivial task. The CActor will have a function called ApplyCustomSets which will only be called by the actor after the X file has been loaded. The task of this function will be to copy the animation data (i.e., the keyframes) from each registered ID3DXKeyframedAnimationSet into a new CAnimationSet object. Once we have copied all the keyframed animation sets into their CAnimationSet counterparts, we will un-register each original keyframed animation set from the controller and release it from memory. We will then register our newly created CAnimationSet copies with the controller to take their place. The CAnimationSets will contain the same keyframe data and callback keys as the original ID3DXKeyframedAnimationSets from which they were copied. What we have essentially done is *clone* the animation information from each keyframed animation set into our own CAnimationSet objects. At the end of this process, our animation controller will now have *n* CAnimationSets registered with it instead of *n* ID3DXKeyframedAnimationSets. We will see how this works shortly.

The next class we will write in this lab project will be the CAnimationSet since it will be used by the code we add to CActor. It should also still be fresh in your mind after reading the textbook exactly what interaction between the animation controller and the animation set takes place. Certainly our class will need to answer requests from the animation controller in the proper way. It will need to be able to return the SRT data for a given periodic position (when the controller calls GetSRT for one of its animations) and it will also need to be able to search for the next scheduled callback key when one is requested by the controller, making sure that any passed flags (such as the one to ignore the initial position in the search) are correctly adhered to.

Source Code Walkthrough - CAnimationSet

The class declaration for CAnimationSet (see below) can be found in CActor.h and its implementation is in CActor.cpp. Notice how we derive our class from the ID3DXAnimationSet abstract base class. We did a similar thing in the last chapter when we derived our own class from ID3DXAllocateHierarchy. By doing this, we can plug our animation set object into the D3DX animation system and the controller will treat it as an ID3DXAnimationSet interface. Looking at the member functions, we can see that we must implement the three IUnknown methods (QueryInterface, AddRef, and Release) so that our object

follows the required lifetime encapsulation for COM compliance. We must also implement all of the methods from the ID3DXAnimationSet base interface because the animation controller will expect to them be implemented when asking our animation set for SRT data and callback key information.

```
class CAnimationSet: public ID3DXAnimationSet
{
  public:
     CAnimationSet( ID3DXAnimationSet * pAnimSet );
    ~CAnimationSet( );

    // IUnknown
    STDMETHOD(QueryInterface)(THIS_ REFIID iid, LPVOID *ppv);
    STDMETHOD_(ULONG, AddRef)(THIS);
    STDMETHOD_(ULONG, Release)(THIS);

    // Name
    STDMETHOD_(LPCSTR, GetName)(THIS);

    // Period
    STDMETHOD_(DOUBLE, GetPeriod)(THIS);
    STDMETHOD_(DOUBLE, GetPeriodicPosition)(THIS_ DOUBLE Position);

    // Animation names
    STDMETHOD_(UINT, GetNumAnimations)(THIS);
    STDMETHOD(GetAnimationNameByIndex)(THIS_ UINT Index, LPCTSTR *ppName);
    STDMETHOD(GetAnimationIndexByName)(THIS_ LPCTSTR pName, UINT *pIndex);

    // SRT
    STDMETHOD(GetSRT)(THIS_
                          DOUBLE PeriodicPosition,   // Position in animation
                          UINT Animation,            // Animation index
                          D3DXVECTOR3 *pScale,       // Returns the scale
                          D3DXQUATERNION *pRotation, // Returns the rotation
                          D3DXVECTOR3 *pTranslation);// Returns the translation

    // Callbacks
    STDMETHOD(GetCallback)(THIS_
                           DOUBLE Position, // Position to start callback search
                           DWORD Flags,               // Callback search flags
                           DOUBLE *pCallbackPosition, // Next callback position
                           LPVOID *ppCallbackData);   // Returns the callback data

  private:
    ULONG               m_nRefCount;      // Reference counter
    LPTSTR              m_strName;        // The name of this animation set
    CAnimationItem     *m_pAnimations;    // An Array of animations
    ULONG               m_nAnimCount;     // Number of animation items.
    D3DXKEY_CALLBACK   *m_pCallbacks;     // List of all callbacks stored
    ULONG               m_nCallbackCount; // Number of callbacks in the above list
    double              m_fLength;        // Total length of this animation set
    double              m_fTicksPerSecond;// The number of source ticks per second
};
```

Let us first examine the class member variables of this class since they will provide a better insight into how we will implement our functionality.

ULONG m_nRefCount
This member will contain the object reference count. When the object is first created, this value will be set to 1 in its constructor. If the application makes a copy of a pointer to the CAnimationSet it should call the CAnimationSet::AddRef method to force the reference count to be incremented. This will make sure that the reference count of our object is always be equal to the number of pointer variables currently pointing to it that have not yet had Release called. The Release method of this class will simply decrease the reference count and cause the object to delete itself from memory if the reference count reaches zero.

When we register the animation set with the D3DX animation controller, the controller will also call the AddRef function of our animation set object and increase the reference count. This is because, until the animation set is un-registered from the controller or the controller is released, the reference count of our object should reflect that the controller has stored a copy of the pointer. Even if our application has called Release on all of its outstanding pointers to a given animation set, the animation set would not be released from memory until the controller no longer needed access to it. In this example, only when the controller was destroyed or the animation set was un-registered, would the controller call the Release method (causing our reference count to hit zero and the object to be deleted from memory).

LPTSTR m_strName
This member is a string that will contain the name of the animation set. In our constructor, this will be extracted from the ID3DXKeyframedAnimationSet that our object is going to replace.

D3DXKEY_CALLBACK *m_pCallbacks
This variable will contain any callback keys that existed in the original ID3DXKeyframedAnimationSet passed into the constructor. The constructor will fetch all the callback keys from the original animation set and allocate this array to store them.

ULONG m_nCallbackCount
This member contains the number of callback keys in the m_pCallbacks array. If this value is set to zero then the animation set has no callback keys defined.

double m_fLength
This member will be set in the constructor to the value of the period of the original ID3DXKeyframedAnimationSet that is being copied. Therefore, this value contains the length of the animation set. We know that this is also the length of the longest running animation in the set (i.e., the highest value timestamp of all keyframes in all animations).

It is this value that will be returned to the animation controller when it calls our CAnimationSet::GetPeriod method. Our animation set also uses this value to calculate a periodic position. If looping is enabled for this animation set, then the periodic position will always be the product of an fmod between the position of the track (passed in by the controller) and the period (length) of the animation set.

double m_fTicksPerSecond
As discussed in the textbook, keyframes do not define their timestamps in seconds but rather using an arbitrary timing system called *ticks*. As our animation set's GetSRT method will always be passed a time value in seconds by the controller, it must be able to convert the seconds value into ticks so that it

can be used to find the two bounding keyframes in each of the S, R and T arrays. This value, which will be copied over in the constructor from the original keyframed animation set, specifies how many of these ticks represent a second. We can convert a value in seconds into a tick value by multiplying by m_fTicksPerSecond.

Callback keys are also defined in ticks, so this member will also be needed to convert between seconds and ticks in the GetCallback method of our class. You will recall that this function is called by the controller to locate the next scheduled callback event. In that case, the controller passes in a current position (in seconds) to begin the search. Using this value, we can convert the initial position and the callback key timestamps into the same timing system for the comparison. GetCallback will return the timestamp of the next scheduled callback key to the controller in seconds not in ticks.

CAnimationItem *m_pAnimations

In the textbook we learned that each animation set contains a number of animations and that an animation is really just a container of keyframe data for a single frame in the hierarchy. If an animation set animates five frames in a hierarchy, it will have five animations defined for it. The name of the frame in the hierarchy will match the name of the animation in the animation set that contains the keyframe data to animate it. This is how the animation controller recognizes the the pairing of hierarchy frames and animations when the set is registered with the controller.

In our implementation of CAnimationSet, we have decided to represent each animation contained in the set as a CAnimationItem object. This is another new class we will introduce in this project. If the animation set has ten animations, then this pointer will point to an array of ten CAnimationItem objects. We will cover the code to the CAnimationItem object after we have discussed CAnimationSet. We can think of a single CAnimationItem object as containing the data of a single Animation data object in an X file.

So CAnimationSet is essentially a CAnimationItem manger. The CAnimationItem object will store the keyframes (SRT Arrays) for a single frame in the hierarchy and be responsible for the keyframe interpolation (via its GetSRT method). The CAnimationSet::GetSRT function will really just act as a wrapper. Its job will be to locate the CAnimationItem that the controller has requested SRT data for, and call its CAnimationItem::GetSRT function. This function will return the SRT data back to the animation set which will in turn return it back to the controller.

ULONG m_nAnimCount

This final member stores the number of animations in the animation set (i.e., the number of elements in the array pointed to by m_pAnimations).

CAnimationSet::CAnimationSet

The constructor takes a single parameter, a pointer to an ID3DXAnimationSet interface. It is this animation set that will have its data extracted and copied by the constructor. We have previously discussed that our CActor will be calling this constructor and will pass in an ID3DXKeyframedAnimationSet so that we can generate a replacement CAnimationSet object which corrects the bug in the GetSRT method. Therefore, this constructor will need to extract the keyframe

data from the passed animation set so that it can make its own copy. However, the base ID3DXAnimationSet interface does not support functions for retrieving the keyframe data so we will first need to query the passed object for an ID3DXKeyframedAnimationSet interface. If the function succeeds then we will have an ID3DXKeyframedAnimationSet interface from which we can extract the data. If the QueryInterface method fails, then the interface we have been passed is attached to an unsupported object which does not expose the ID3DXKeyframedAnimationSet interface. If this is the case, we throw an exception.

```
CAnimationSet::CAnimationSet( ID3DXAnimationSet * pAnimSet )
{
    ULONG   i;
    HRESULT hRet;
    ID3DXKeyframedAnimationSet * pKeySet = NULL;

    // Query to ensure we have a keyframed animation set
    hRet = pAnimSet->QueryInterface( IID_ID3DXKeyframedAnimationSet,
                                     (LPVOID*)&pKeySet );
    if ( FAILED(hRet) || !pKeySet ) throw hRet;
```

If we reach this point, then it means we have a valid interface to a keyframed animation set. The first thing we do is call the ID3DXKeyframedAnimationSet::GetName method to get the name of the keyframed animation set that we are copying. If the animation set has a name, then we use the _tcsdup string duplication function to make a copy of the string and store it in the_strName member variable. We also use the methods of ID3DXKeyframedAnimationSet to copy the period of the animation set and the ticks per second value into member variables of the of the CAnimationSet object.

```
    // Duplicate the name if available
    LPCTSTR strName = pKeySet->GetName( );
    m_strName = (strName) ? _tcsdup( strName ) : NULL;

    // Store total length and ticks per second
    m_fLength           = pKeySet->GetPeriod();
    m_fTicksPerSecond   = pKeySet->GetSourceTicksPerSecond( );
```

Our next task will be to copy over any callback keys that may be contained in the set we are copying. First we call the ID3DXKeyframedAnimationSet::GetNumCallbackKeys and, provided this is greater than zero, allocate the CAnimationSet's callback key array to store this many elements. We then call the ID3DXKeyframedAnimationSet::GetCallbackKeys method and pass in a pointer to this member array. This function will copy all the callback keys in the original animation set into our object's callback keys array.

```
    // Copy callback keys
    m_pCallbacks     = NULL;
    m_nCallbackCount = pKeySet->GetNumCallbackKeys( );
    if ( m_nCallbackCount > 0 )
    {
        // Allocate memory to hold the callback keys
        m_pCallbacks = new D3DXKEY_CALLBACK[ m_nCallbackCount ];
        if ( !m_pCallbacks ) throw E_OUTOFMEMORY;
```

```
        // Copy the callback keys over
        hRet = pKeySet->GetCallbackKeys( m_pCallbacks );
        if ( FAILED(hRet) ) throw hRet;

    } // End if any callback keys
```

The next task will be to find out how many animations exist inside the passed animation set so that we can allocate that many CAnimationItem objects. Remember, a CAnimationItem represents the data for a single animation. Therefore we call the ID3DXKeyframedAnimationSet::GetNumAnimations method and use the returned value to allocate the object's CAnimationItem array to hold this many elements. We then loop through each newly created CAnimationItem in the array and call its BuildItem item method. This method will be discussed when we cover the CAnimationItem code a little later, but as you can see in the following code snippet, we pass in the ID3DXKeyframedAnimationSet interface and the index of the animation we wish to have copied into our CAnimationItem. The CAnimationItem::BuildItem method is a simple function that will fetch the SRT keys for the passed animation and make a copy of them for internal storage. After a call to BuildItem, a CAnimationItem object will contain all the keyframes that existed in the passed animation set for the specified animation index. For example, if we call:

```
m_pAnimations[5].BuildItem( pKeySet , 5 )
```

then the sixth CAnimationItem in our array will contain the SRT keyframes from the sixth animation in the keyframed animation set (pKeySet).

Here we see the code that allocates our CAnimationItem array and populates each item with data from the source animation set:

```
    // Allocate memory for animation items
    m_pAnimations = NULL;
    m_nAnimCount  = pKeySet->GetNumAnimations();
    if ( m_nAnimCount )
    {
        // Allocate memory to hold animation items
        m_pAnimations = new CAnimationItem[ m_nAnimCount ];
        if ( !m_pAnimations ) throw E_OUTOFMEMORY;

        // Build the animation items
        for ( i = 0; i < m_nAnimCount; ++i )
        {
            hRet = m_pAnimations[ i ].BuildItem( pKeySet, i );
            if ( FAILED(hRet) ) throw hRet;

        } // Next animation

    } // End if any animations

    // Release our keyframed friend
    pKeySet->Release();
```

In the code above, you can see that after we have copied the animation data into each of our CAnimationItems, the ID3DXKeyframedAnimationSet interface that we queried for earlier is released.

This is important because every time we call QueryInterface for a COM object, the reference count is incremented just before the requested interface is returned. If we forgot to do this step then the animation set would not be released when the CActor decided it was no longer needed. Remember, after this constructor returns program flow back to CActor, the keyframed animation set that was passed into the function will no longer be needed and it will have its interface released and unregistered from the controller. This will drop the reference count of the original keyframed animation set to zero, causing it to unload itself from memory.

Finally, because we wish our CAnimationSet object to behave like a COM object, we must remember to set the initial reference count of the object to 1 in the constructor.

```
    // ************************************
    // *** VERY IMPORTANT
    // ************************************
    // Set our initial reference count to 1.
    m_nRefCount = 1;
}
```

Once the constructor exits, our object will have been created and populated with the information that was contained in the ID3DXKeyframedAnimationSet passed in by the actor. The reference count of our object will also be 1, which is exactly as it should be. You will see later when we cover the CActor code that this new CAnimationSet will then be registered with the controller, in place of the original.

CAnimationSet::~CAnimationSet

The destructor to this class is nothing special; it just releases any internal memory being used by the animation set. This will be the two arrays that contain the callback keys and the CAnimationItems as well as the memory that was allocated to store the name of the animation set when _tcsdup was called in the constructor. Remember that _tcsdup uses a C alloc style function for its memory allocation, so we must release the memory using the free function.

```
CAnimationSet::~CAnimationSet( )
{
    // Release any memory
    if ( m_pCallbacks  ) delete []m_pCallbacks; m_pCallbacks = NULL;
    if ( m_pAnimations ) delete []m_pAnimations; m_pAnimations = NULL;
    if ( m_strName     ) free( m_strName ); m_strName = NULL;
}
```

What is unique about the destructor for this class is that the application code should never directly invoke it. So we should never ever write code like the following:

```
delete pMyAnimSet;
```

Our object is going to behave like a proper COM object and we never directly delete a COM object. Instead we call the interface's Release method which decrements the reference count of the object. When the reference count drops to zero, the object should delete itself from memory by doing:

```
delete this;
```

This is exactly what happens in our Release method (see next). The destructor is only ever invoked from within the class Release method.

CAnimationSet::Release

When the animation controller is destroyed by the actor, the controller will call Release for each of its registered animation sets. Therefore, our animation set must properly handle this call in COM fashion. This code is almost identical to the Release method of our CActionData class, which also followed the COM protocol.

Release decrements the reference count. When the count reaches zero, the object deletes itself by making the 'delete this' call. When we do a 'delete this', the object destroys itself in the standard way, and the destructor is invoked. When program flow finally returns back to the Release method, the object and all its member variables will have been destroyed. We must make sure that this method never tries to access any member variables or functions after this deletion (even the *this* pointer no longer exists). This is like being stranded in a static function which has no instance associated with it. As you can see, we simply return 0 after the delete.

```
ULONG CAnimationSet::Release( )
{
    // Decrement ref count
    m_nRefCount--;

    // If the reference count has got down to 0, delete us
    if ( m_nRefCount == 0 )
    {
        // Delete us (cast just to be safe, so that any non virtual destructor
        // is called correctly)
        delete (CAnimationSet*)this;

        // WE MUST NOT REFERENCE ANY MEMBER VARIABLES FROM THIS POINT ON!!!
        // For this reason, we must simply return 0 here, rather than dropping
        // out of the if statement, since m_nRefCount references memory which
        // has been released (and would cause a protection fault).
        return 0;

    } // End if ref count == 0

    // Return the reference count
    return m_nRefCount;
}
```

Note that if the object is not actually destroyed, we just decrement the reference count and return the updated value.

CAnimationSet::AddRef

When the actor adds a CAnimationSet object to the animation controller, the animation controller will expect this function to be implemented. This is because it will call the AddRef method when it stores a copy of the animation set's pointer. As you can see, this is a simple one line function that just increments the reference count.

```
ULONG CAnimationSet::AddRef( )
{
    return m_nRefCount++;
}
```

CAnimationSet::QueryInterface

The final IUnknown method we must implement is now familiar to us, given our coverage of the CActionData class. The QueryInterface function is passed an interface GUID and a void pointer and if the passed GUID interface is supported by this object, then on function return the passed void pointer will point to a properly cast version of the object.

If you take a look in CActor.h you will see that the GUID we generated (via GuidGen.exe) for the CAnimationSet interface is defined as follows, along with an IID_CAnimationSet alias:

```
GUID IID_CAnimationSet = {0x5B23B100, 0xE885, 0x4F63, {0xB0, 0x2E, 0x50, 0xFC, 0x99, 0xBA, 0x3, 0xDD}};
```

We will support three interfaces for this object. First, we obviously want to support the top level CAnimationSet interface since this is the actual type of the object. We will also support the casting of our object to an ID3DXAnimationSet interface. Remember, this interface is the base interface for all animation sets that are compatible with the D3DX animation controller. Regardless of the type of animation set registered with a controller (custom or otherwise), the controller will see all animation sets as being of type ID3DXAnimationSet. Therefore, every animation set we register must support this interface. This means of course that all the methods of this interface must be supported also. Our CAnimationSet is derived from ID3DXAnimationSet so we should implement all the methods of this interface in our object also. The third and final interface we must implement functions for is IUnknown. ID3DXAnimationSet is derived from this interface and since our class is derived from ID3DXAnimationSet, we must support the methods of its base class also. In short, the three interfaces we support are IUnknown, ID3DXAnimationSet, and CAnimationSet. Therefore, our QueryInterface implementation should allow the casting of the 'this' pointer to any of these three types.

```
HRESULT CAnimationSet::QueryInterface( REFIID iid, LPVOID *ppv )
{
    // We support three interfaces, the base ID3DXAnimationSet, IUnknown
     // and ourselves.
    // It's important that we cast these items, so that the compiler knows we
    // possibly need to switch to an alternate VTable
    if ( iid == IID_IUnknown )
        *ppv = (LPVOID)((IUnknown*)this);
```

```
    else if ( iid == IID_ID3DXAnimationSet )
        *ppv = (LPVOID)((ID3DXAnimationSet*)this);

    else if ( iid == IID_CAnimationSet )
        *ppv = (LPVOID)((CAnimationSet*)this);

    else
    {
            // The specified interface is not supported!
            *ppv = NULL;
            return E_NOINTERFACE;

    } // End iid switch

    // We're supported!
    AddRef();
    return S_OK;
}
```

Notice the double cast of the 'this' pointer – something we did in the CActionData::QueryInterface method previously. Remember, this aids the compiler in choosing the correct vtable pointer to return if multiple base classes are being derived from.

Having implemented the required IUnknown functions, we must now implement the methods of the other interface from which this object is derived: ID3DXAnimationSet. All such methods must be implemented since they will be used by the animation controller when registering and playing back the animation set. Remember, ID3DXAnimationSet is a pure abstract base class, so all of its functions *must* be implemented in our derived class.

CAnimationSet::GetName

This function is called by the animation controller to fetch the name of an animation set. We simply return a pointer to the string member variable containing the name of the animation set. The name of our animation set was copied from the ID3DXKeyframedAnimationSet passed into the constructor.

```
LPCTSTR CAnimationSet::GetName( )
{
    return m_strName;
}
```

CAnimationSet::GetPeriod

The GetPeriod method should return the length of the animation set (copied from the ID3DXKeyframedAnimationSet interface passed into the constructor). The period of an animation set is defined by its longest running animation. The longest animation is the animation which has the keyframe with the highest timestamp in the set. The period of the animation is the timestamp of this keyframe converted from ticks into seconds.

```
DOUBLE CAnimationSet::GetPeriod( )
{
    return m_fLength;
}
```

If the keyframe with the highest timestamp value had a timestamp of 2400 ticks, the period would be calculated as 2400 * TicksPerSecond. Since this value never changes, it is calculated once when the animation set is first created and then cached. As we are copying the information from an already created ID3DXKeyframedAnimationSet, we can simply extract this value and copy it into our member m_fLength variable. Refer back to our coverage of the constructor to see this value copied from the passed keyframed animation set.

CAnimationSet::GetPeriodicPosition

We discussed the duties of this function many times throughout the textbook since it is one of the most important in the system. GetPeriodicPosition will be called by the animation controller and is passed a position value in seconds. This position is actually the current time of the track to which the animation set is applied. As this position may be well outside the total length of the animation set, this function is responsible for returning a periodic position that represents the behavior of the animation set.

As an example, if the animation set was configured to loop, then the position should be mapped such that the track position should always be converted into the timeframe of the animation. If the period of the animation set was 20 seconds and a track position of 110 seconds was passed in, this would be mapped to a periodic position of 10 seconds (10 seconds into its 6^{th} loop).

Obviously, if the animation set was configured not to loop, then this would return a periodic position of 20 seconds, the last keyframe in the animation set. That is, after the track position passes 20 seconds, the same periodic position for all subsequent track positions would be returned and the same SRT data eventually generated. In this case, it would appear as if the animation set stopped playing after 20 seconds.

In our class we will treat all animation sets as looping animations. Therefore, to map the passed track position to a periodic position (a local animation set time in seconds) we simply perform the modulus of the passed track position and the period (length) of the entire animation set.

```
DOUBLE CAnimationSet::GetPeriodicPosition( DOUBLE Position )
{
    // To map, we'll just loop the position round
    double Pos = fmod( Position, m_fLength );
    if ( Pos < 0 ) Pos += m_fLength;
    return Pos;
}
```

> **Note**: In the GetPeriodicPosition code we are careful to handle the case where the position may be specified as a negative value. For example, if the position was set to -12 for a 10 second animation then this should be treated as a 2 second loop around from the beginning of the animation. If the period of the animation was 10 seconds then -12 mod 10 would be -2. If we add the period of the animation to this (10 seconds) we get 8 seconds.

You are encouraged to add additional mapping modes beyond the simple looping logic we have implemented here. You could implement ping-pong mapping or return a periodic position that is clamped to the period of the animation set. You could also implement your own custom periodic mapping modes as well.

The final periodic position returned from this function is defined in seconds and is used by the animation controller to pass into the animation set's GetSRT method (once for each of its animations). The periodic position will be used to find the two keyframes from each SRT list that bound the time. Once the keyframes that bound the periodic position are found, they can be interpolated using a function of time. We will see this implementation in a moment when we examine the GetSRT method.

CAnimationSet::NumAnimations

This method is declared in the ID3DXAnimationSet interface and is used by the animation controller to determine how many animations are contained in the animation set. The controller must have this information so that it can set up the loop that iterates through every animation in an animation set. For each animation, it calls the GetSRT method to generate its SRT data for the current periodic position. Basically, the value returned from this method tells the controller how many GetSRT calls must be made to update this animation set.

```
UINT CAnimationSet::GetNumAnimations( )
{
    return m_nAnimCount;
}
```

This value was originally extracted from the keyframed animation set passed into the constructor. It describes the number of frames in the hierarchy that are being animated by this animation set.

CAnimationSet::GetAnimationNameByIndex

This method is called by the controller to fetch the name of a given animation in the animation set. It can be used to determine which frame in the hierarchy is being animated by the animation. This works because the name of the animation will always be the same as the name of the frame in the hierarchy which it animates.

```
HRESULT CAnimationSet::GetAnimationNameByIndex ( UINT Index, LPCTSTR *ppName )
{
    // Validate
    if ( !ppName || !*ppName || Index >= m_nAnimCount ) return D3DERR_INVALIDCALL;

    // Copy the selected item's name (it must always exist).
    _tcscpy( (LPTSTR)*ppName, m_pAnimations[ Index ].GetName() );

    return D3D_OK;
}
```

The function will be passed two parameters, the index of the animation in the set that is being inquired about and the address of a string pointer. The function uses the passed index to access its array of animations. (Remember, each animation in our array is actually a CAnimationItem object.) We copy the name of the animation at the specified index using the _tcscpy function, which we know will allocate memory for the string prior to copying it. We then assign the string pointer passed in to point to the name we have just duplicated. When the function returns, the name of the animation at the requested index (assuming it is a valid index) will be pointed to by the pointer passed in.

CAnimationSet::GetAnimationIndexByName

This next method (also from ID3DXAnimationSet) is used by the controller to fetch the index of the animation associated with the passed name. When an animation set is being registered, the animation controller calls the animation set's GetAnimationIndexByName function for each frame in the hierarchy. The controller expects to get back either a valid index via the pIndex output parameter and D3D_OK, or D3DERR_NOTFOUND via the function result.

This function allows the animation indices to be cached by the animation controller, removing the need to look up the index (or name) each time. It also helps the controller know which frames in the hierarchy even have animation data (those which resulted in D3DERR_NOTFOUND obviously do not having a matching CAnimationItem).

Once the animation controller caches the index of each animation in the set, it calls the animations set's AddRef method to increase its reference count. At this point the animation set is considered to be registered with the controller.

As you can probably guess, this is a function that simply loops through each of its animations, fetches the name of each animation and performs a string compare between the animation name and the string passed into the function. If a match is found, the index of the animation is copied into the integer whose address was passed in as the second parameter and the function returns success.

```
HRESULT CAnimationSet::GetAnimationIndexByName ( LPCTSTR pName, UINT *pIndex )
{
    ULONG i;

    // Validate
    if ( !pIndex || !pName ) return D3DERR_INVALIDCALL;

    // Search through our animation sets
    for ( i = 0; i < m_nAnimCount; ++i )
    {
        // Does the name match ?
        if ( _tcsicmp( pName, m_pAnimations[i].GetName() ) == 0 )
        {
            // We found it, store the index and return
            *pIndex = i;
            return D3D_OK;

        } // End if names match
```

```
    } // Next Item

    // We didn't find this item!
    return D3DERR_NOTFOUND;
}
```

If no match is found, we return D3DERR_NOTFOUND to the caller.

CAnimationSet::GetSRT

We have discussed at length the importance of the animation set's GetSRT function and the role it plays in the overall animation system. It is probably not overstating the point to say that this method is the core of the entire animation engine.

GetSRT is called by the controller for each animation in the animation set. Its job is to calculate the SRT data for the current periodic position. The periodic position is passed into the function along with the index of the animation that we wish to generate SRT data for. The method is also passed a scale vector, a rotation quaternion, and a translation vector, which on function return should be filled with the SRT data for the specified time.

While you might expect this function to be large, it is actually just a simple wrapper around the CAnimationItem::GetSRT method, which we will discuss shortly.

```
HRESULT CAnimationSet::GetSRT( DOUBLE PeriodicPosition, UINT Animation,
                               D3DXVECTOR3 *pScale, D3DXQUATERNION *pRotation,
                               D3DXVECTOR3 *pTranslation )
{
    // Validate
    if ( Animation > m_nAnimCount ) return D3DERR_INVALIDCALL;

    // Return the interpolated result
    return m_pAnimations[ Animation ].GetSRT( PeriodicPosition,
                                              pScale,
                                              pRotation,
                                              pTranslation );
}
```

As you can see, the function uses the passed animation index to access the CAnimationItem in its animation array. It then calls its GetSRT method passing in the periodic position and the three structures that will contain the SRT output. Remember, the CAnimationItem class represents the data and members for a single animation in the set. It is a keyframe container that exposes its own GetSRT method which performs the interpolation to generate the SRT data for the passed periodic position for a single animation.

If the animation set contained 50 animations, then we would expect the animation controller to call the CAnimationSet::GetSRT method 50 times in a single update. Each time, the index of a different animation would be passed. This is used to call the GetSRT method of the corresponding CAnimationItem in the array and generate its SRT data. Our function is really nothing more than a function that routes an animation request to the GetSRT method of the correct animation.

CAnimationSet::GetCallback

The final method that we need to implement in our CAnimationSet class is called GetCallback (an ID3DXAnimationSet interface method). As discussed in the textbook, this method is passed a track position by the controller and will perform a search starting from that position to locate the time and data for the next scheduled callback event in the track timeline. Remember, the controller will cache this callback information and will not need to call this method again until the callback has been executed.

The code that follows shows the first section of the function. The function is passed a time (in seconds) by the animation controller describing the track position from which to begin the search for the next callback key. The time value passed in depends on how the function is being called by the animation controller. As explained in the textbook, if the controller is having AdvanceTime called for the first time, or if the global time of the controller has been reset, the callback event cache of the controller will be in an invalid state. When this is the case, the controller will call the GetCallback method of the animation set passing in the current position of the track (i.e., the track time). It will be returned the next scheduled callback event on the track timeline at some point in the future. The animation controller will then cache this information so that it knows it does not have to perform this search again until the position of the track has passed the cached callback key timestamp causing event execution.

If the callback event cache is not invalid, then the controller will call this function passing in the previously cached event time as the position parameter. For example, imagine the first time the AdvanceTime method is called and the controller calls the animation set's GetCallback method, passing in the current track position (0 in this case). The function might return a callback key with a timestamp of 10 seconds. This information will be cached by the controller so that it knows it does not have to do anything else with the callback system until 10 seconds (track time) has been reached. Approximately 10 seconds later, when the AdvanceTime call happens again, the controller would determine that the current track position is now larger than the previously cached callback key timestamp. The callback key is executed (i.e., the callback handler is called) and now it is time to find a new 'next' scheduled callback key. The controller calls the GetCallback method of the animation set again but will not pass in the current track position (which may be larger than 10 seconds). Instead, the previously cached callback time (10 seconds) will be passed in as the position parameter. This will cause the function to begin searching for a new callback key from the position of the previous callback key.

Remember that if the above system was not employed, callback events could be skipped. For example, imagine that we have a scheduled next callback event of 10 seconds, but the next time GetCallback is called, 12 seconds have passed. The 10 second event would be triggered normally because the controller would correctly detect that the position of the track (12 seconds) has passed the currently cached callback time (10 seconds). However, if we were to then perform the search for the next scheduled callback key starting at the current track position (12 seconds), we have risked skipping an event that may have been registered at 11 seconds because we jumped straight from 10 to 12 seconds. Therefore, by always searching for the next scheduled callback event from the position of the previously cached callback key, we make sure that we catch and trigger all callback events, even if the actual track position is several seconds ahead of the callback key processing pipeline.

The second parameter to this function can be a combination of zero or more flags that control how the search is performed.

If the controller passes in the D3DXCALLBACK_SEARCH_EXCLUDING_INITIAL_POSITION flag, then our function should not return a callback key which shares the same timestamp as the initial position passed in. In the textbook we learned that the controller will always pass this flag if a previously cached callback exists. This is because the position passed in will be the time of the previous timestamp and, if we do not ignore the initial position in the search, we will end up returning that same callback key that has already been executed. The exception is when the controller has an invalid cache; in this case, no previous callback exists and the controller is interested in the very first callback key that exists from the passed initial position (including that initial position).

Another flag that can also be combined in this parameter is the D3DXCALLBACK_SEARCH_BEHIND_INITIAL_POSITION flag, which specifies that the call would like the search for the next callback key to be done in the reverse direction (i.e., searching backwards from the passed initial position to find the next 'previous' key). Interestingly, in our laboratory tests, we never seemed to be passed this flag by the D3DXAnimationController, so it is very hard to determine with accuracy when the controller might pass this flag. It may be that it never does and that this is simply a flag that the application can use for its own callback key queries. You might assume that it is used by the controller when an animation set is playing in ping-pong mode and the direction of the animation changes with every odd and even loop. However, this is highly unlikely since the GetPlayBack type method is not a member of the ID3DXAnimationSet base interface and therefore the controller would have no way of accessing whether an animation set was configured to loop or ping-pong. At the time of writing there was no exporting software supporting the ping-pong animation mode, so these are ultimately untested conjectures. So it may be that this search mode is just for an application's benefit. After all, use of the GetCallback method is not restricted to the controller; it can also be a utility function used by your application to search for callback keys. Either way, the ID3DXKeyframedAnimationSet implementation supports the backwards search mode, so our implementation will do so as well.

The final two parameters are output parameters. The controller will pass in the address of a double and the address of a void pointer and on function return, the double should contain the track time (in seconds) of the next scheduled callback key and the void pointer should point to any context data (a CActionData object in our case) that was associated with the callback key when it was registered. This context data will be passed to the callback handler function (covered later) when the callback event is executed.

Here is the first small section of the function that requires some explanation:

```
HRESULT CAnimationSet::GetCallback( DOUBLE Position, DWORD Flags,
                                    DOUBLE *pCallbackPosition,
                                    LPVOID *ppCallbackData )
{
    long                i;   // Must be signed long for the backwards search
    D3DXKEY_CALLBACK    Key;

    // Are there any keys at all?
    if ( m_nCallbackCount == 0 ) return D3DERR_NOTFOUND;

    // Modulate position back into our range (and convert to ticks)
    double fPeriodic = fmod( Position, m_fLength ) * m_fTicksPerSecond;
    double fLoopTime = (Position * m_fTicksPerSecond) - fPeriodic;
```

The first thing the code does is test to see if this animation set even has any callback keys registered. If not, the function can return immediately. Notice that we return the D3DERR_NOTFOUND result expected by the controller when no more callback keys exist on the track timeline.

The next two lines of code might seem a bit confusing, so let us examine the time conversions which must be performed in this function in order to return the next callback key to the controller as a track position.

As we know from our earlier discussions, callback keys, just like SRT keys, are defined in ticks. Along with SRT keys, they help define the period of the animation set. If an animation set has a period of 10 seconds, then we know that any callback keys will have timestamps within this period. However, the controller is not interested in getting back a callback key timestamp as a periodic position because it has no concept of animation set local time. The controller wants to know when the next callback event will occur in track time, and as we know, the two are very different.

Let us imagine that we have a looping animation set with a period of 10 seconds which contains a single callback key at 10 seconds. We know that the track position will continue to increase with calls to AdvanceTime, but the periodic position of the animation set will loop every 10 seconds. If we simply searched for a callback key from the passed track position each time, once the track position exceeded 10 seconds (and continued to increase) we would never find another. The next time the animation set looped, our sound effect (for example) would not play. Therefore, we need to map the passed track position into a periodic position, perform the search for the next callback key starting from that periodic position, and, once found, convert that periodic position back into a future track position and return it to the controller.

With our 10 second animation set example, at a track position of 15 seconds, the callback key (at 10 seconds periodic position) would have been executed once. Now the controller would call the GetCallback method again to find another callback key, passing in a track position of 15 seconds. Our function would convert this into a periodic position of 5 seconds (i.e., 5 seconds into the second loop) and it would start the search and find our callback key at 10 seconds (periodic position).

Of course, we cannot simply return this periodic position of 10 seconds back to the controller because the track position is already at 15 seconds and it wants to know the next (future) time that this callback key needs to be executed in track time. So our function, having been passed a track position of 15 seconds, first maps this to a 5 second periodic position. We calculate that value in the prior code by performing the modulus of the passed track position and the period of the animation. This gives us:

PeriodicPosition = fmod (TrackPosition , Period) * TicksPerSecond
PeriodicPosition = fmod (15 , 10)
PeriodicPosition = 5

This calculation maps the track position to a periodic position. We know that whatever loop we are on, we are currently 5 seconds through it. You can see that in the above code listing, we perform this calculation and store the result in the local variable fPeriodic. This is the periodic position from which we wish to begin our search for callback keys. Notice that when we perform that calculation, we also multiply the result by m_fTicksPerSecond so that the periodic search start position is now specified in

ticks. Since all of our keys are specified with tick timestamps, we now have our start position using the same timing type as the callback keys for the search.

You might think that we now have everything we need, but this is not the case quite yet. While the periodic position certainly allows us to search and find the next scheduled callback key, its timestamp will be a periodic position. The controller will want to get that timestamp back as a track position, so the timestamp of the callback we eventually return must be converted from a periodic position into a track position. The problem is that normally the animation set would not have any idea which iteration of a loop it is on because it does not record how many times it has looped. However, this is precisely why the animation controller passes us a track position and not a periodic position (as it does with the GetSRT method). It is only when we have the track position from which to begin the search do we have the necessary information to turn the periodic timestamp of a key back into a track position.

If you look at the previous code listing you will see that we calculate a value and store it in a local variable called fLoopTime. This uses the passed track position and the previously calculated periodic position to get the number of complete loops the animation has performed.

In our example, we said the function was passed a track position of 15 seconds and the period of the animation set was 10 seconds. At this point we have also calculated the periodic position as being 5 seconds. Therefore, if we subtract the current periodic position from the track position, we have the number of seconds of complete animation loops that have been performed:

LoopTime = TrackPosition – PeriodicPosition
LoopTime = 15 – 5
LoopTime = 10 seconds of completed loops.

This is exactly what we do in the first section of the function code shown previously -- we simply subtract the periodic position from the track position. However, our periodic position is currently in ticks, so we convert the track position to ticks also. What ends up in the fLoopTime local variable is the number of ticks of complete loops that the animation has played out. This can also be thought of as the track position at which the current animation loop began (converted to ticks).

So we now know what we have stored in the two local variables. But why do we need know the total loop time? Well, in our example we said that the callback key was at a periodic position of 10 seconds. Therefore, we would begin our search from 5 seconds into the callback key array and find that the next callback key encountered has a periodic position of 10 seconds. We know that this is a periodic position, but the controller wants this to be a track position. That conversion is now very easy. We simply add the timestamp of the callback key to the total loop time (the track position at which the current loop began) and we have the track position in the future that this key is scheduled for:

FutureTrackPos = LoopTime + TimeStamp
= 10 + 10
= 20 seconds track time this key will be triggered

As you can see, by simply adding the timestamp of the key (which is a periodic position) to the total loop time, we end up with that future periodic position as a track time. The periodic position is

essentially like an offset from the track position when this current animation loop started. And we know that this works out properly. If we have a 10 second long looping animation set which has a single callback key at 10 seconds (periodic position), we know that the callback key should be triggered at 10 seconds, 20 seconds, 30 seconds, etc. (i.e., every time the track position crosses the 10 second boundary of the animation set's period).

That was quite a long discussion to explain two lines of code, but now we know what these local variables contain and how we need to map the resulting timestamp back into a track position. The rest of the function will be easy to understand.

The remainder of the function is mostly divided into two code blocks depending on whether the `D3DXCALLBACK_SEARCH_BEHIND_INITIAL_POSITION` flag has been specified by the controller. You will recall from the textbook that this flag instructs our function to perform the search for the next callback key from the initial position in a backwards direction instead of the more common forward direction.
We will take a look at the code that deals with finding the next callback key in forward search mode first since this is the mode used by the controller all of the time. In other words, this is the code that is executed if the `D3DXCALLBACK_SEARCH_BEHIND_INITIAL_POSITION` flag is not passed by the controller.

```
    // Searching forwards?
    if ( !(Flags & D3DXCALLBACK_SEARCH_BEHIND_INITIAL_POSITION) )
    {
        // Find the first callback equal to, or greater than the periodic position
        for ( i = 0; i < m_nCallbackCount ; ++i )
        {
            if ( m_pCallbacks[i].Time >= fPeriodic ) break;
        }// Next Callback

        // If nothing was found, then this HAS to be the first key
        // (for the next loop)
        if ( i == m_nCallbackCount )
        {
            // Increase the loop time and use the first key
            fLoopTime += (m_fLength * m_fTicksPerSecond);
            i = 0;

        } // End if wrap
```

This code block sets up a loop to iterate through each callback key in the callback key array. Inside the loop, we compare the timestamp of each callback key and break when we find the first callback key that has a timestamp that is either greater than or equal to the search start time. What we are doing here is simply trying to find the first callback key that is not behind the search start time. As this is our forward search mode, we are not interested in any callback keys that are behind the track position passed in, as they will have already been executed.

Once we find a suitable callback key, we break from the for loop. At this point the loop variable 'i' will contain the index of the key in the array that we are potentially interested in. You can see in the above code that once outside the loop, if 'i' is equal to the number of callback keys, then no future callback keys exist. We know then that the search start time was greater than the timestamps of all callback keys in the array. When this is the case, we essentially need to loop around the animation. So we know that the first key in the array is now the key we want as we have executed all keys right up to the end of the

array and it is time to start again from the beginning. However, we cannot just simply set ‘i’ to zero and leave it at that, since we need to account for the fact that we have just performed another loop of animation that we did not account for when we calculated the fLoopTime variable at the start of the function. Since we have searched to the end of the current period and have looped back around to the beginning again, we have just performed an additional animation loop. Therefore, we add onto the fLoopTime variable (which stores the current number of animation loops in ticks) the period of the animation set (in ticks).

For example:

AnimationSet.Period =10 seconds
CallBackKey.Time = 5 seconds
StartSearchTrackPosition = 18 seconds
StartSearchPeriodicPosition = 8 seconds
LoopTime = 10 seconds

The above settings demonstrate how this function might be called for an animation set with a period of 10 seconds that has a single callback key registered at 5 seconds. The function is passed a start search time (as a track position) of 18 seconds. We showed earlier how a modulus of this value with the period of the animation set will convert the search start time into a periodic position of 8 seconds.

Now we know, just by looking at the data described above, that from a track position of 18 seconds, the next callback key should actually be at track position 25 seconds (five seconds into the third loop). So we perform the search for the next callback key from 8 to 10 seconds and we do not find one; this is because the only callback key has a timestamp less than 8 seconds. This means we need to loop. We know that the first callback key is the callback key we are interested in, and we also increment the loop time by the period of the animation set:

LoopTime + = 10
LoopTime = 20 seconds

Now that we have compensated for the additional loop, later in the function we will be able to calculate the track position of the callback key as:

TrackPos = LoopTime + CallBackKey.Time;
= 20 + 5
= 25 seconds.

And there we have it. The addition to the loop time variable in the above code lets us keep a record of the number of animation loops performed. It is used later in the function to convert the timestamp of the callback key back into a future track position.

At this point we now have the index of the callback key stored in loop variable ‘i’. The next section of code (the conclusion of the forward search) fetches this key from the array and then performs several tests for compliance with the input search flags.

```
        // Get the key
        Key = m_pCallbacks[ i ];

        // Do we ignore keys that share the same position?
        bool bExclude = Flags & D3DXCALLBACK_SEARCH_EXCLUDING_INITIAL_POSITION;

        if ( (bExclude && Key.Time == fPeriodic) )
        {
            // If we're going to wrap onto the next loop, increase our loop time
            if ( (i + 1) == m_nCallbackCount )
              fLoopTime += (m_fLength * m_fTicksPerSecond);

            // Get the next key (taking care to loop round where appropriate)
            Key = m_pCallbacks[ (i + 1) % m_nCallbackCount ];

        } // End if skip to the next key

    } // End if searching FORWARDS
```

In the above code, once the callback key data is fetched from the array we test to see if the caller (the animation controller) specified `D3DXCALLBACK_SEARCH_EXCLUDING_INITIAL_POSITION`. If so, then we are not interested in this key if it has a timestamp that is equal to the search position. As you can see, if the flag is set and the key timestamp is equal to the periodic position then we need to ignore this key and fetch the next one in the array -- element i+1. Notice the conditional that states if i+1 is equal to the number of callback keys, then the original key was the last one in the callback array and we need to loop around and fetch the first callback key. If this is the case, we record this loop in the fLoopTime variable so that we always have an accurate record of exactly how many ticks of animation looping has been performed by this animation set. Finally, we fetch the actual key we need. Notice the code we use to index into the correct array element. We use the modulus of i+1 and the number of callback keys in the array. If i+1 is equal to the number of callback keys, zero is returned from the operation and the first callback key in the array is used as required.

We have now covered the code to find the correct callback key when we are in forward searching mode. The next section of code shows essentially the reverse operation being performed. We will not take this code block line by line as it is just a mirror image of the code we have just discussed. Rather than searching forward from the current search position and looping back around to the beginning when necessary, it searches backwards from the passed search position looping back around to the end of the array when necessary.

```
// else we are in backwards search mode
    else
    {
        // Find the first callback equal to, or greater than the periodic position
        for ( i = (signed)m_nCallbackCount - 1; i >= 0; --i )
        {
            if ( m_pCallbacks[i].Time <= fPeriodic ) break;

        } // Next Callback

        // If nothing was found, then this HAS to be the last key
        //(for the next loop)
        if ( i == -1 )
```

```
        {
            // Decrease the loop time and use the last key
            fLoopTime -= (m_fLength * m_fTicksPerSecond);
            i = (signed)m_nCallbackCount - 1;

        } // End if wrap

        // Get the key
        Key = m_pCallbacks[ i ];

        // Do we ignore keys that share the same position?
        bool bExclude = Flags & D3DXCALLBACK_SEARCH_EXCLUDING_INITIAL_POSITION;
        if ( (bExclude && Key.Time == fPeriodic) )
        {
            // If we're going to wrap onto the previous loop,
            // decrease our loop time
            if ( (i - 1) < 0 ) fLoopTime -= (m_fLength * m_fTicksPerSecond);

            // Get the next key (taking care to loop round where appropriate)
            Key = m_pCallbacks[ (i - 1) % (signed)m_nCallbackCount ];

        } // End if skip to the next key

    } // End if searching forwards
```

At this point in the function we have located our callback key. The controller wants us to store the track position of this callback key in the pCallbackPosition output parameter it passed in, so we assign the sum of the loop time and the timestamp of the callback key. Since both the loop time and the callback key timestamp are in ticks, we must divide the result by the TicksPerSecond ratio of the animation set so that it is a track position specified in seconds. We also assign the context data pointer of the callback key (which in our code will actually be a void pointer to a CActionData object) to the ppCallbackData pointer passed in by the contoller. The last section of the code that performs these steps is shown below.

```
    // Return the time, mapped to the track position (converted back to seconds)
    if ( pCallbackPosition )
        *pCallbackPosition = (Key.Time + fLoopTime) / m_fTicksPerSecond;

    // Return the callback data
    if ( ppCallbackData )
        *ppCallbackData = Key.pCallbackData;

    // Success!!
    return D3D_OK;
}
```

So we see that there is nothing magical about the functions that are implemented by ID3DXKeyframedAnimationSet. While we took a black-box view of them in the textbook, now we have had a chance to see exactly how the animation set passes back information to the animation controller in response to a next scheduled callback key search.

This concludes our coverage of the code and methods in our CAnimationSet class. We still have a ways to go yet though with respect to understanding the system functionality. Next we will need to look at the code that generates SRT data using interpolation. The keyframe interpolation code is tucked away in the

CAnimationItem class, so we will look at this class next to wrap up coverage of our custom animation set.

Source Code Walkthrough - CAnimationItem

For every animation in the set, the keyframe data will be stored in a CAnimationItem object. If our animation set contains 10 animations, it will have an array of 10 CAnimationItem objects. Each item in this array will contain the keyframe data for a single frame in the hierarchy and will expose the methods to build SRT data for any periodic position and return it to the animation set. The set then hands the SRT information back the animation controller.

While this class has only a few methods, it does contain one of the most important in our system -- GetSRT. As we saw in our coverage of CAnimationSet::GetSRT, that function acted as a wrapper around a call to the GetSRT method of a CAnimationItem object at the requested animation index.

Let us first look at the class declaration (see CActor.h).

```
class CAnimationItem
{
public:
    //-----------------------------------------------------------------------
    // Constructors & Destructors for This Class.
    //-----------------------------------------------------------------------
     CAnimationItem( );
    ~CAnimationItem( );

    // Public methods for the class
    LPCTSTR GetName     ( ) const;
    HRESULT GetSRT      ( DOUBLE PeriodicPosition, D3DXVECTOR3 *pScale,
                          D3DXQUATERNION *pRotation, D3DXVECTOR3 *pTranslation );
    HRESULT BuildItem   ( ID3DXKeyframedAnimationSet *pAnimSet, ULONG ItemIndex );

private:
    LPTSTR              m_strName;              // The name of this animation
    D3DXKEY_VECTOR3    *m_pScaleKeys;           // The scale keys
    D3DXKEY_VECTOR3    *m_pTranslateKeys;       // The translation keys
    D3DXKEY_QUATERNION *m_pRotateKeys;          // The rotation keys
    ULONG               m_nScaleKeyCount;       // Number of scale keys
    ULONG               m_nTranslateKeyCount;   // Number of translation keys
    ULONG               m_nRotateKeyCount;      // Number of rotation keys
    double              m_fTicksPerSecond;      // Source ticks per second

    ULONG               m_nLastScaleIndex;     // Cache for last 'start' scale key
    ULONG               m_nLastRotateIndex;    // Cache for last 'start' rot key
    ULONG               m_nLastTranslateIndex; // Cache for last 'start' trans key
    double              m_fLastPosRequest;     // Cache for last periodic position
};
```

The CAnimationItem class exposes three methods. The GetName function returns the name of the animation, which will also match the name of the frame in the hierarchy that it animates. The GetSRT method is responsible for generating the SRT data for a given periodic position. The BuildItem method is used by our CAnimationSet class constructor to copy over the keyframe data from the original animation in the ID3DXKeyframedAnimatonSet.

You will recall how the CAnimationSet constructor is passed a pointer to an ID3DXKeyframedAnimationSet which it will essentially clone. The code fetches the number of animations contained in the animation set and then uses this value to allocate a CAnimationItem array of the same size. The code then looped through each CAnimationItem and called its CAnimationItem::BuildItem function. The function is passed the interface of the ID3DXKeyframedAnimationSet and the index of the animation which we would like to copy into this CAnimationItem. As a reminder, here is a small excerpt from the CAnimationSet constructor which we discussed earlier:

```
// Allocate memory for animation items
    m_pAnimations = NULL;
    m_nAnimCount  = pKeySet->GetNumAnimations();
    if ( m_nAnimCount )
    {
        // Allocate memory to hold animation items
        m_pAnimations = new CAnimationItem[ m_nAnimCount ];
        if ( !m_pAnimations ) throw E_OUTOFMEMORY;

        // Build the animation items
        for ( i = 0; i < m_nAnimCount; ++i )
        {
            hRet = m_pAnimations[ i ].BuildItem( pKeySet, i );
            if ( FAILED(hRet) ) throw hRet;

        } // Next animation

    } // End if any animations
```

The BuildItem function is responsible for extracting the keyframe data from the specified animation in the ID3DXKeyframedAnimationSet and copying it into internal SRT arrays. We will see this function in a moment.

Let us now discuss the members of the CAnimationItem class.

LPTSTR m_strName

This member points to a string that contains the name of the animation. There will also be a frame in the hierarchy with a matching name. The name of the frame and the animation essentially form a link for the controller between the animation's keyframe and the frame matrix in the hierarchy it is to animate.

D3DXKEY_VECTOR3 *m_pScaleKeys

If this animation contains any scale keyframes, then this will point to an array of D3DXKEY_VECTOR3 keys. The array will be allocated in the BuildItem method when the scale key

list is copied over from the matching animation in the ID3DXKeyframedAnimationSet. If no scale keyframes are defined for this animation, this member will be set to NULL.

D3DXKEY_VECTOR3 *m_pTranslateKeys
If this animation contains any positional keyframes, then this will point to an array of D3DXKEY_VECTOR3 keys. The array will be allocated in the BuildItem method when the translation key list is copied over from the matching animation in the ID3DXKeyframedAnimationSet. If no translation keyframes are defined for this animation, this member will be set to NULL.

D3DXKEY_QUATERNION *m_pRotateKeys
If this animation contains any rotation keyframes, then this will point to an array of D3DXKEY_QUATERNION keys. The array will be allocated in the BuildItem method when the rotational keyframe list is copied over from the matching animation in the ID3DXKeyframedAnimationSet. If no scale keyframes are defined for this animation, this member will be set to NULL.

The three arrays just described contain the SRT keyframes of the animation. These are the keyframes that will be used for the interpolation and generation of SRT data in the GetSRT function.

ULONG m_nScaleKeyCount
ULONG m_nTranslateKeyCount
ULONG m_nRotateKeyCount
These three members will be set in the BuildItem method. They describe the number of scale keys, translation keys, and rotation keys stored in the m_pScaleKeys, m_pTranslateKeys and m_pRotateKeys arrays respectively.

double m_fTicksPerSecond
This member will store the TicksPerSecond ratio of its parent animation set. We will need to access this value frequently during interpolation in the GetSRT method, so we copy this value from the parent animation set and cache it for ease of access. Remember that this is a per-set property not a per animation property, so all CAnimationItems in the same CAnimationSet will have the same value.

ULONG m_nLastScaleIndex
ULONG m_nLastRotateIndex
ULONG m_nLastTranslateIndex
These three members are used to optimize the GetSRT method. They are stored so that we do not have to loop through all keyframes in all three arrays to find the bounding keyframes for the passed periodic position every time GetSRT is called by the controller. For example, for periodic position A, we might find that the two bounding scale keyframes are at indices m_pScaleKeys[25] and m_pScaleKeys[26]. What we will do at this point is store the index 25 in the m_nLastScaleIndex member. The next time GetSRT is called for this animation for periodic position B, we can assume a forward moving timeline and begin the search for bounding keyframes starting at scale key 25. This optimizes our search for keyframes by ignoring those that are behind the last cached position and reduces loop traversal overhead.

It should be noted that this is an efficient optimization only when the timeline is being advanced in a forward direction (which is almost all of the time). It provides no speed benefit when playing the animation in the reverse direction (e.g., in ping pong mode where every other loop the periodic position is stepping backwards). We must also make sure that we invalidate the cache as soon as the current periodic position wraps around and becomes smaller than the last cached key time. This is all handled in the GetSRT method, which we will look at in a moment.

double m_fLastPosRequest

This final member is used to store the periodic position of a previous call to the GetSRT method. For example, when the GetSRT method is called, the current periodic position is stored in this member. The next time the GetSRT method is called, we can test the new periodic position against the previous one. If the new periodic position is less than the previous position, we know that the animation has looped (or moved backwards) and we can set the three cached indices (m_nLastScaleKey, m_nLastRotateIndex and m_nLastTranslateIndex) to zero. This make sure that when looping occurs, the search for bounding keyframes always begins at keyframe 0 in each array the next time through.

Let us now examine the three methods exposed by this object. Ww will begin with the CAnimationItem::BuildItem method.

CAnimationItem::BuildItem

BuildItem is called by the CAnimationSet constructor for each CAnimationItem created. The job of this function is to populate the CAnimationItem's internal arrays with the SRT data from the ID3DXKeyframedAnimationSet that is in the process of being cloned and replaced. Since a CAnimationItem object represents the data for a single animation in the set, it is passed the interface to the keyframed animation set that needs to be copied and the index of the animation within that set that will be copied.

The function first tests that the index passed in is within the number of animations contained in the source keyframed animation set. It exits if this is not the case. If the animation index is valid, we use the ID3DXKeyframedAnimationSet::GetAnimationNameByIndex method to fetch the name of the animation within the animation set. As you can see in the following code, we call this method passing in the index of the animation within the set that we wish to retrieve the name for, and a pointer to a string that will point to the name of the animation on function return. We use the tcsdup method to duplicate the string so that we can store a copy of the animation name in the CAnimationItem::m_strName member variable. This name should match the name of a frame in the hierarchy and the name of a registered animation output.

```
HRESULT CAnimationItem::BuildItem( ID3DXKeyframedAnimationSet *pAnimSet,
                                   ULONG ItemIndex )
{
    LPCTSTR strName = NULL;

    // Validate
    if ( !pAnimSet || ItemIndex > pAnimSet->GetNumAnimations( ) )
        return D3DERR_INVALIDCALL;
```

```
    // Get the name and duplicate it
    pAnimSet->GetAnimationNameByIndex( ItemIndex, &strName );
    m_strName = _tcsdup( strName );
```

In the next section we retrieve the number of scale, rotation and translation keys that exist for the animation we are currently in the process of copying. We will obviously need these values to allocate the SRT arrays of the CAnimationItem and to loop through the keyframes in the GetSRT method. We also extract the TicksPerSecond ratio from the animation set and store that in a CAnimationItem member variable. This is an animation set value that will be consistent for all animations in the set, and we store a copy of it inside each CAnimationItem so that we can easily access it from GetSRT without having to query into the parent animation set.

```
    // Store any secondary values
    m_fTicksPerSecond    = pAnimSet->GetSourceTicksPerSecond( );
    m_nScaleKeyCount     = pAnimSet->GetNumScaleKeys( ItemIndex );
    m_nRotateKeyCount    = pAnimSet->GetNumRotationKeys( ItemIndex );
    m_nTranslateKeyCount = pAnimSet->GetNumTranslationKeys( ItemIndex );
```

At this point, we know how many keyframes exist for this animation in each of its scale, rotation, and translation arrays. We will need to allocate these arrays in our CAnimationItem if we intend to copy and store this data from the ID3DXKeyframedAnimationSet. In the following code you can see that we use the values just retrieved to allocate the SRT arrays:

```
    // Allocate any memory required
    if ( m_nScaleKeyCount )
        m_pScaleKeys  = new D3DXKEY_VECTOR3[ m_nScaleKeyCount ];

    if ( m_nRotateKeyCount)
        m_pRotateKeys = new D3DXKEY_QUATERNION[ m_nRotateKeyCount ];

    if ( m_nTranslateKeyCount )
        m_pTranslateKeys = new D3DXKEY_VECTOR3[ m_nTranslateKeyCount ];
```

With our arrays now allocated, all that is left to do is copy the keyframe data from the animation in the ID3DXKeyframedAnimationSet into our own SRT arrays. Luckily, ID3DXKeyframedAnimationSet provides an easy means for retrieving this data. We can retrieve the scale, rotation or translation keys simply by calling the GetScaleKeys, GetRotationKeys, and GetTranslationKeys methods. We pass these functions the index of the animation that we wish to retrieve the keyframes for (the first parameter), and a pointer to a pre-allocated array that will receive the copy of the keyframe data (the second parameter). These arrays are the ones we just allocated. The functions will then copy the keyframe data from the ID3DXKeyframedAnimationSet directly into our CAnimationItem SRT arrays.

```
    // Retrieve the keys
    if ( m_pScaleKeys     )
        pAnimSet->GetScaleKeys( ItemIndex, m_pScaleKeys );

    if ( m_pRotateKeys    )
        pAnimSet->GetRotationKeys( ItemIndex, m_pRotateKeys );
```

```
    if ( m_pTranslateKeys )
        pAnimSet->GetTranslationKeys( ItemIndex, m_pTranslateKeys );

    // We're done!
    return D3D_OK;
}
```

At this stage, our CAnimationItem contains all SRT keyframe data for a single frame in the hierarchy. When the CAnimationSet constructor has called this method for each animation, we will have copied all the animation data from the original keyframed animation set. We can then use our CAnimationSet instead of the original ID3DXKeyframedAnimationSet and sidestep the bug in the ID3DXKeyframedAnimationSet::GetSRT method.

CAnimationItem::GetName

The second method of the CAnimationItem class is a utility function which returns the name of the animation item. It is vital that this function be available to our CAnimationSet class. Recall that our CAnimationSet class must provide a function called GetAnimationNameByIndex (part of the ID3DXAnimationSet base interface). The animation controller will expect this function to be present in our animation set so that it can be called to fetch the name of an animation at the specified index. In our implementation, animations are stored in a CAnimationItem array inside the CAnimationSet. The CAnimationSet::GetAnimationNameByIndex can return the name of an animation to the animation controller by using the passed array index to call CAnimationItem::GetName.

```
LPCTSTR CAnimationItem::GetName( ) const
{
    return m_strName;
}
```

CAnimationItem::GetSRT

This method is, in many ways, the backbone of the entire D3DX animation system. It is responsible for generating the SRT animation data for a specified periodic position.

The animation controller will call the GetSRT method of an animation set for each animation in that set. Each time, the animation index will be passed and the function will generate the SRT data for that animation. This information will be returned to the controller and used to rebuild the frame matrix which shares the same name as the animation.

Although the animation controller expects the call to the GetSRT method of the animation set interface to generate the SRT data, we saw earlier that the animation set GetSRT method acts as a wrapper that forwards the request to the correct CAnimationItem:

```
    return m_pAnimations[ AnimationIndex ].GetSRT( PeriodicPosition, pScale,
                                                   pRotation, pTranslation );
```

As the above code snippet demonstrates, the CAnimationSet::GetSRT method uses the controller supplied index (identifying which animation it needs SRT data for) and periodic position to call the GetSRT method of the corresponding CAnimationItem. CAnimationItem::GetSRT performs the keyframe interpolation for the specified time and stores the final scale, rotation, and translation information in the output parameters.

We took a look at how to implement a GetSRT function in the textbook, so the code to this function should look very familiar to you. Since the function is rather large, we will discuss it a section at a time.

The first section is shown below followed by a discussion of the code.

```
HRESULT CAnimationItem::GetSRT( DOUBLE PeriodicPosition, D3DXVECTOR3 *pScale,
                                D3DXQUATERNION *pRotation,
                                D3DXVECTOR3 *pTranslation )
{
    ULONG                i;
    D3DXQUATERNION       q1, q2;
    double               fInterpVal, fTicks;
    LPD3DXKEY_VECTOR3    pKeyVec1 , pKeyVec2;
    LPD3DXKEY_QUATERNION pKeyQuat1, pKeyQuat2;

    // Validate parameters
    if ( !pScale || !pRotation || !pTranslation ) return D3DERR_INVALIDCALL;

    // Clear them out as D3D does for us :)
    *pScale       = D3DXVECTOR3( 0.0f, 0.0f, 0.0f );
    *pTranslation = D3DXVECTOR3( 0.0f, 0.0f, 0.0f );
    D3DXQuaternionIdentity( pRotation );

    // Reset index caching if we've wrapped around
    if ( PeriodicPosition < m_fLastPosRequest )
    {
        m_nLastScaleIndex       = 0;
        m_nLastRotateIndex      = 0;
        m_nLastTranslateIndex   = 0;

    } // End if wrapped / move backwards

    // Store the last requested position
    m_fLastPosRequest = PeriodicPosition;

    // Now calculate the 'TimeStamp' value.
    fTicks = PeriodicPosition * m_fTicksPerSecond;
```

The function is called by CAnimationSet::GetSRT and is passed the periodic position of the parent animation set along with the addresses of two 3D vectors and a quaternion which the function will populate with the interpolated SRT data. If any of these pointers are NULL, then the function returns immediately, reporting an invalid call.

Next, we set the passed scale and translation vectors to zero and set the rotation quaternions to identity. This is done for safety -- the animation might not have S, R, or T arrays defined, so default values will need to be returned.

The next portion of the above code then tests to see if the current periodic position is smaller than the periodic position that was stored in the previous call. If so, then the periodic position has wrapped around (looped or ping-ponged). It is very important for us to trap this occurance because it affects our bounding keyframe search optimization. Recall that we store the first of the two bounding keyframes (from each array) so that the next time the function is called, we do not have to start looping through the keyframes from the first element. For example, if the first time this function was called, we found the two bounding scale keyframes to be at positions 20 and 21 in the scale keyframes array, the value of 20 (the low bounding keyframe) would be stored in the m_nLastScaleIndex member variable. This means that the next time GetSRT is called for this animation, we can begin searching for bounding keyframes from position 20 in the array instead of 0, thereby skipping tests for the first 20 keyframes in the scale keyframe array.

As you can see, we store a ‘last index’ for each of the arrays (scale, rotation and translation). This optimization assumes a forward moving timeline, so it expects the next call to GetSRT to have a greater periodic position than the previous one. However, when the periodic position of the animation set loops around to zero again, this will not be the case.

Imagine that the first time GetSRT is called the periodic position is such that the low bounding scale keyframe used is at index 99 in our scale keyframe array. At the end of this function, we would store this index in the m_nLastScaleIndex member. Now imagine that the periodic position loops around the next time this function is called such that the low bounding keyframe should now be at index 0. If we simply started searching from index 20 to the end of the array we would never find any bounding scale keyframes. Therefore, you can see that we also cache the previous periodic position. If it is larger than the current periodic position passed into the function, it means that the periodic position has either looped around to zero or, in the case of ping-pong mode, the periodic position is moving backwards. When this is the case, we must start searching for bounding keyframes in each of our arrays from position zero again to make sure we test them all. We do this by setting the three previous keyframe index caches to zero.

The implication is that every time the periodic position loops around, we will not benefit from our ‘last cached index’ optimization. It also means that this optimization will provide no benefit for animation sets that are moving backwards. If the current periodic position has not looped around such that it is smaller than the previous position, no action is taken. You will see in a moment how the cached last keyframe indices will be used to efficiently search through the keyframe arrays.

Next we set the current periodic position in the m_fLastPosRequest member so that the next time this function is called, we will be able to detect a periodic position wrap-around (as just discussed).

The final section of the previous code takes the input periodic position and multiplies it by the TicksPerSecond ratio so that we have the periodic position in ticks rather than seconds. This step is important because the keyframe timestamps are defined in ticks and we want to find the two keyframes in each array that bound the periodic position in ticks, not seconds. Because we took the liberty of

storing the TicksPerSecond ratio of the parent animation set in a CAnimatonItem member variable, we can access it easily without having to implement a CAnimationSet accessor function to return this value every time we need it.

The next section of code is responsible for searching for the bounding keyframes in the animation's scale keyframe array. Notice that we do not simply loop from the start of the keyframe array every time, but start at the m_nLastScaleIndex element in the array. As discussed, this index will usually store the low bounding scale keyframe index from a previous call to the function. If the periodic position has looped around however, this value will be set to zero and the scale keyframe array is searched from the beginning. Notice that we also use two D3DXKEY_VECTOR3 pointers to point to the two bounding keyframes that we find.

```
    // ******************************************************************
    // * SCALE KEYS
    // ******************************************************************
    pKeyVec1 = pKeyVec2 = NULL;
    for ( i = m_nLastScaleIndex; i < m_nScaleKeyCount - 1; ++i )
    {
        LPD3DXKEY_VECTOR3 pKey     = &m_pScaleKeys[i];
        LPD3DXKEY_VECTOR3 pNextKey = &m_pScaleKeys[i + 1];

        // Do these keys  bound the requested time ?
        if ( fTicks >= pKey->Time && fTicks <= pNextKey->Time )
        {
            // Update last index
            m_nLastScaleIndex = i;

            // Store the two bounding keys
            pKeyVec1 = pKey;
            pKeyVec2 = pNextKey;
            break;

        } // End if found keys

    } // Next Scale Key
```

In the above code we loop and fetch the current scale keyframe and the one that follows it in the array. We then compare the periodic position in ticks (fTicks) to see if it is greater than or equal to the current keyframe's timestamp and less than or equal to the next keyframe's timestamp. If this condition is true, then we have found the two keyframes in the array that bound the current periodic position. When this is the case, we store the index of the current keyframe 'i' in the m_nLastScaleIndex member so that the next time this function is called, we can begin searching from this index. We then assign the local variables pKeyVec1 and pKeyVec2 to point to these two scale keyframes. Our search is complete and we have found the two bounding scale keyframes, so we exit the loop. The next step will be to interpolate between these two keyframes to generate a single scale vector that can be returned back to the controller and contribute to the building of the associated frame matrix.

As discussed in the textbook, we can use the current periodic position (in ticks) to perform a linear interpolation (or 'lerp' for short) between the two vectors. First we subtract the periodic position from the timestamp of the low bounding keyframe. Then we divide this value by the difference between the

two timestamps of the keyframes. This will result in a value between 0.0 and 1.0 which describes, as a percentage, the periodic position between these two keyframes. If a value of 0.25 was generated, it would mean that actual periodic position is ¼ of the way between timestamp one and timestamp two.

We feed this value into the D3DXVec3Lerp function which will return a vector that is a weighted interpolation of the two vectors. Using our 0.25 example, D3DXVec3Lerp would return a scale vector that is comprised of ¾ of keyframe one and ¼ of keyframe two. The basic formula for a lerp is ***Vector1 + t(Vector2 – Vector2)*** where **t** is our interpolation value between zero and one. The resulting interpolated scale vector is stored in the pScale vector that was passed in as a parameter by the animation controller. Below we see the code that performs this task:

```
    // Make sure we found keys
    if ( pKeyVec1 && pKeyVec2 )
    {
        // Calculate interpolation
        fInterpVal  = fTicks - pKeyVec1->Time;
        fInterpVal /= (pKeyVec2->Time - pKeyVec1->Time);

        // Interpolate!
        D3DXVec3Lerp( pScale,
                      &pKeyVec1->Value,
                      &pKeyVec2->Value,
                      (float)fInterpVal );
    } // End if keys were found
    else
    {
        // Scale is the same as the last scale key found
        if ( m_nScaleKeyCount )
          *pScale = m_pScaleKeys[ m_nScaleKeyCount - 1 ].Value;

        // Inform cache that it should no longer
        // search unless cache is invalidated
        m_nLastScaleIndex = m_nScaleKeyCount - 1;

    } // End if no keys found
```

If pKeyVec1 or pKeyVec2 are NULL then the two bounding keyframes could not be found in the scale array. For example, this might happen if the periodic position is outside the range of defined scale keys. When this is the case the ‘else’ block of the above code is executed. In this code block we first test if any scale keys even exist in this object and if so, then we assume that the periodic position is larger than the last defined scale keyframe and we just copy the last scale vector defined in the SRT array into pScale. Essentially this amounts to freezing the scaling animation at the last keyframe. Any periodic positions past this timestamp will generate the same final scale vector. We then set the last scale keyframe index to the final keyframe in the scale array so that the next time the function is called, we will not waste time looping and testing any scale keys -- we will just return the final scale key. We are basically stating that this animation appears to be over so we will just return the last scale keyframe unless the periodic position wraps around. If the periodic position does loop around, then we know that the last index caches are cleared and the entire keyframe array is used for bounding keyframe searches again.

In the next section of the code, we perform nearly an identical search and interpolation to generate the rotation quaternion. We search the rotation keyframe array for the two bounding keyframes and once found, perform a spherical linear interpolation (or 'slerp' for short) using the periodic position. This generates a final quaternion that is stored in the pRotation output parameter passed into the function by the animation controller. Here is the code that searches the quaternion array for the two bounding keyframes:

```
    // ******************************************************************
    // * ROTATION KEYS
    // ******************************************************************
    pKeyQuat1 = pKeyQuat2 = NULL;
    for ( i = m_nLastRotateIndex; i < m_nRotateKeyCount- 1; ++i )
    {
        LPD3DXKEY_QUATERNION pKey     = &m_pRotateKeys[i];
        LPD3DXKEY_QUATERNION pNextKey = &m_pRotateKeys[i + 1];

        // Do these keys bound the requested time ?
        if ( fTicks >= pKey->Time && fTicks <= pNextKey->Time )
        {
            // Update last index
            m_nLastRotateIndex = i;

            // Store the two bounding keys
            pKeyQuat1 = pKey;
            pKeyQuat2 = pNextKey;
            break;

        } // End if found keys

    } // Next Rotation Key
```

Now that we have our two keyframes we perform a slerp between them. But first we flip the axes of our quaternion keyframes so that they are left-handed to match our coordinate system. The D3DXQuaternionConjugate function is used for that purpose. It takes the quaternion (x,y,z,w) and returns the quaternion conjugate (-x,-y,-z, w). We can now generate our fInterpVal value by mapping the periodic position with respect to the two keyframe timestamps into the 0.0 to 1.0 range and feed this value into the slerp function to generate the final rotation quaternion that the animation controller needs.

```
    // Make sure we found keys
    if ( pKeyQuat1 && pKeyQuat2 )
    {
        // Reverse 'winding' of these values
        D3DXQuaternionConjugate( &q1, &pKeyQuat1->Value );
        D3DXQuaternionConjugate( &q2, &pKeyQuat2->Value );

        // Calculate interpolation
        fInterpVal  = fTicks - pKeyQuat1->Time;
        fInterpVal /= (pKeyQuat2->Time - pKeyQuat1->Time);

        // Interpolate!
        D3DXQuaternionSlerp( pRotation, &q1, &q2, (float)fInterpVal );

    } // End if keys were found
```

```
    else
    {
        // Rotation is the same as the last key found
        if ( m_nRotateKeyCount )
        D3DXQuaternionConjugate(pRotation,
                                &m_pRotateKeys[ m_nRotateKeyCount - 1 ].Value );

        // Inform cache it should no longer search unless cache is invalidated
        m_nLastRotateIndex = m_nRotateKeyCount - 1;

    } // End if no keys found
```

As was the case with the scale array, we also have an ‘else’ code block that is executed if no bounding rotation keyframes are found. When this is the case the same optimization logic is applied. We simply return the conjugate of the last rotation keyframe in the array and set the m_nLastRotateIndex to point at the last element in the array. Subsequent calls to the function will no longer need to search for bounding quaternion keyframes and can simply return the final quaternion in the array. Only when the periodic position is reversed or looped will the last index cache be invalidated and searches through the quaternion array re-enabled.

The final section of the code searches for the two bounding translation keyframes and returns the interpolated position vector. This code is almost identical to the code that finds and interpolates between scale keyframes (they are both D3DXKEY_VECTOR3 arrays) so we should now fully understand the following code without discussion.

```
    // ******************************************************************
    // * TRANSLATION KEYS
    // ******************************************************************
    pKeyVec1 = pKeyVec2 = NULL;
    for ( i = m_nLastTranslateIndex; i < m_nTranslateKeyCount - 1; ++i )
    {
        LPD3DXKEY_VECTOR3 pKey     = &m_pTranslateKeys[i];
        LPD3DXKEY_VECTOR3 pNextKey = &m_pTranslateKeys[i + 1];

        // Do these keys bound the requested time ?
        if ( fTicks >= pKey->Time && fTicks <= pNextKey->Time )
        {
            // Update last index
            m_nLastTranslateIndex = i;

            // Store the two bounding keys
            pKeyVec1 = pKey;
            pKeyVec2 = pNextKey;
            break;

        } // End if found keys

    } // Next Translation Key

    // Make sure we found keys
    if ( pKeyVec1 && pKeyVec2 )
    {
        // Calculate interpolation
```

```
        fInterpVal  = fTicks - pKeyVec1->Time;
        fInterpVal /= (pKeyVec2->Time - pKeyVec1->Time);

        // Interpolate!
        D3DXVec3Lerp( pTranslation,
                      &pKeyVec1->Value,
                      &pKeyVec2->Value,
                      (float)fInterpVal );

    } // End if keys were found
    else
    {
        // Rotation is the same as the last key found
        if ( m_nTranslateKeyCount )
             *pTranslation = m_pTranslateKeys[ m_nTranslateKeyCount - 1 ].Value;

        // Inform cache it should no longer search unless cache is invalidated
        m_nLastTranslateIndex = m_nTranslateKeyCount - 1;

    } // End if no keys found

    // We're done
    return D3D_OK;
}
```

We have now implemented all the components of our custom animation set. We examined how to build the CAnimationSet class which will be registered with the animation controller and we also discussed the CAnimationItem class that will be used by CAnimationSet to store, manage and interpolate keyframe data. CAnimationSet will be used in many of our demos from this point onwards, so be sure that you understand how it all works. Although the implementation of our ID3DXAnimationSet derived object may not have been something you thought we would have to do, the ID3DXKeyframedAnimationSet bug left us little choice. However, this has proven to be a beneficial aside as it has allowed us to get a much deeper insight into how the D3DX animation system works under the hood. It also provides you with some foundation material should you choose to implement other forms of custom animations that use application generated data.

Now that we have our drop-in replacement for the ID3DXKeyframedAnimationSet, let us return to our discussions concerning adding animation support to our CActor class. These features will be used in Lab Project 10.1 to play back an animated X file.

Source Code Walkthrough - CActor

Adding animation support to CActor will be a trivial task for the most part. While many functions will be added to the class in this lab project, virtually all of them will be simple wrappers around calls to the animation controller. Since these methods wrap the animation controller methods discussed in detail in the textbook, they will not require extensive coverage. Most are functions that set or retrieve properties from the actor's animation controller. This allows an application using our CActor class to access all the methods of its underlying animation controller via the CActor interface.

Below we see an excerpt from CActor.h which shows the new member variables that have been added in this lab project. For the sake of readability, we have not listed method declarations because we will cover the methods later. For now, just observe the new member variables which have been highlighted in bold.

```
class CActor
{
public:
        //---------------- Member Functions Go Here( Not Shown ) ---------------
private:
    LPD3DXFRAME                 m_pFrameRoot;               // Root 'frame'
    LPD3DXANIMATIONCONTROLLER   m_pAnimController;          // controller
    LPDIRECT3DDEVICE9           m_pD3DDevice;               // Direct3D Device .
    CALLBACK_FUNC               m_CallBack[CALLBACK_COUNT]; // callbacks
    TCHAR                       m_strActorName[MAX_PATH];   // Actor Filename

    D3DXMATRIX                  m_mtxWorld;      // Currently active world matrix.
    ULONG                       m_nOptions;      // The requested mesh options.

    // Limits of the Animation Mixer
    ULONG                       m_nMaxTracks;
    ULONG                       m_nMaxAnimSets;
    ULONG                       m_nMaxAnimOutputs;
    ULONG                       m_nMaxEvents;
    ULONG                       m_nMaxCallbackKeys;
};
```

Not surprisingly, we have now added an ID3DXAnimationController pointer to our CActor. It will be assigned to the animation controller returned from the D3DXLoadMeshHierachyFromX function (see LoadActorFromX).

Four of the five new members at the bottom of the listing contain the limits of the animation controller currently being used by the actor. Note that m_nMaxCallbackKeys is not a limit of the animation controller; it is used by the application to tell the actor the maximum number of callback keys that it will register with a single animation set. Earlier, we talked about how this value will be used when the actor is loading an X file. It indicates the size of the temporary array of callback keys that will be passed to the callback key callback function. This is the array that the application will fill with callback key data and return to the actor. We will see this all happening in a moment.

We know from earlier discussion that the animation controller limits must be defined at creation time. Such limits define the maximum number of tracks that can be used on the animation mixer, the maximum number of animation sets that can be simultaneously registered with the controller, the number of matrices/frames that can be manipulated by the controller, and the maximum number of sequencer events that can be registered on the global timeline. In the textbook we also discussed that when we use D3DXLoadMeshHierarchyFromX to load an animated X file, D3DX will create the animation controller for us. This means that setting these controller properties at creation time is out of our hands in that case. The maximum limits will all be specified automatically when the X file is loaded.

When D3DXLoadMeshHierarchyFromX is used to load an X file, an animation controller will be returned and stored by the actor if animation data was contained in the file. The maximum number of

tracks on the controller will always be set to two. Having only two tracks to use for blending (i.e., only two animation sets can be simultaneously played and blended at any one time) might prove to be too limiting in certain cases. You will see in a moment that the CActor will expose a method to allow us to ratchet up these limits either before or after the X file has been loaded and the animation controller has been created. Behind the scenes, the CActor will clone the old animation controller (if one previously exists) to create a new one with the desired maximum limits, while maintaining the integrity of the original controller's animation data. Ultimately this means that the application is not restricted to the default limits of the animation controller created by D3DXLoadMeshHierarchyFromX.

While there are many new functions which are simple one-line wrappers around animation controller interface calls, a number of significant changes have taken place in functions that previously existed (e.g., LoadActorFromX and some of its new helper functions). These methods have been upgraded from the previous lab project to create, store, and potentially clone the animation controller if the limits of the controller are not as desired. Thus, we will cover the code changes to these methods as well.

An intuitive place to start examining the changes to CActor is in its constructor.

CActor::CActor()

By default, we set the animation controller pointer to NULL as this will not receive a meaningful assignment until the X file is loaded. This will happen when the application calls the CActor::LoadActorFromX method.

We also set the default maximum limits for the animation controller. For consistency, we set them to the same defaults used by the D3DXLoadMeshHierarchyFromX function. You will see in a moment how these variables can be changed by the application.

By default, we set the maximum number of animation sets the controller will support to 1, although this will be assigned a proper value as soon as the X file is loaded.

```
CActor::CActor()
{
    // Reset / Clear all required values
    m_pFrameRoot      = NULL;
    m_pAnimController = NULL;
    m_pD3DDevice      = NULL;
    m_nOptions        = 0;

    // Setup the defaults for the maximum controller properties
    // (Defaults to the same defaults D3DX provides).
    m_nMaxAnimSets      = 1;
    m_nMaxAnimOutputs   = 1;
    m_nMaxTracks        = 2;
    m_nMaxEvents        = 30;
    m_nMaxCallbackKeys  = 1024;

    ZeroMemory( m_strActorName, MAX_PATH * sizeof(TCHAR) );
    D3DXMatrixIdentity( &m_mtxWorld );

    // Clear structures
```

```
    for ( ULONG i = 0; i < CALLBACK_COUNT; ++i )
        ZeroMemory( &m_CallBack[i], sizeof(CALLBACK_FUNC) );
}
```

Notice that we also set the maximum number of callback keys that can be registered with an animation set to 1024. This will probably be enough for most cases, but if this is not the case, we will be able to change this setting using the SetActorLimits method which we will discuss shortly. Just as we did in the previous lab project, we also set the world matrix of the actor to an identity matrix and zero out the name of the actor.

Finally, we loop through the actor's callback function array and set all elements to zero. This array previously contained only the callback functions for texture and materials, but we now have four elements in this array, with the fourth element reserved for registration of the callback key collection callback function. The actor defines the following enumeration for callback functions. It tells us the number of possible callbacks as well as the array indices for the callback function pointers.

```
enum CALLBACK_TYPE { CALLBACK_TEXTURE = 0,
                     CALLBACK_EFFECT = 1,
                     CALLBACK_ATTRIBUTEID = 2,
                     CALLBACK_CALLBACKKEYS = 3,
                     CALLBACK_COUNT = 4 };
```

The fourth array element stores a function pointer (and context data pointer) to an application defined callback function that will fill the callback key array for a given animation set. This callback function was discussed earlier in this workbook. As before, these callbacks are registered using the actor's RegisterCallback function which is unchanged from the previous lab project.

CActor::Release()

As in our previous lab project, the actor's Release method is called by the destructor to release all memory allocated by the actor. It may also be called by the application or from other actor methods when the data currently managed by the actor needs to be cleaned out or reset. It releases the frame hierarchy, the animation controller, and the device interface that it has stored. The two new function calls that have been added to this function are shown below in bold.

```
void CActor::Release()
{
    CAllocateHierarchy Allocator( this );

    // Release any active callback data
    ReleaseCallbackData( );

    // Release objects (notice the specific method for releasing the root frame)
    if ( m_pFrameRoot      ) D3DXFrameDestroy( m_pFrameRoot, &Allocator );
    if ( m_pAnimController ) m_pAnimController->Release();
    if ( m_pD3DDevice      ) m_pD3DDevice->Release();

    // Reset / Clear all required values
    m_pFrameRoot      = NULL;
```

```
    m_pAnimController = NULL;
    m_pD3DDevice      = NULL;
    m_nOptions        = 0;

    ZeroMemory( m_strActorName, MAX_PATH * sizeof(TCHAR) );

    // Since 'Release' is called just prior to loading, we should not
    // clear ANYTHING which is designed to be setup and stored prior
    // to the user making that load call. This includes things like
    // the world matrix, and the callbacks.
}
```

Releasing the animation controller interface is of course a logical thing to do when the actor is destroyed. Its release will, in turn, destroy all of its animation sets. However, before this is done, we must make sure that the callback data we have assigned to our animation sets is released. Remember, each callback key in our lab project will have a CActionData object assigned to its context data pointer. When the animation controller releases the animation sets it manages, it will simply release the callback array contained inside that animation set. Since this is the only place the CActionData pointers are stored, we will lose any ability after that point to de-allocate the memory containing the CActionData objects that were allocated in the callback key callback function at load time. Therefore, before we release the controller, the Release method makes a call to a new member function called ReleaseCallbackData. This function (covered next) will release the memory for each CActionData object referenced by callback keys in the callback array of each registered animation set.

It should be noted that while the CActor destructor simply wraps a call to the Release method, this method is also called from other places. For example, it is called by the actor prior to loading an X file to make sure that all existing data is released prior to the new data being loaded.

CActor::ReleaseCallbackData

There are two versions of this function in CActor (i.e., it is overloaded). This version of the ReleaseCallbackData method takes no parameters and is called from the CActor::Release method discussed above. It loops through each animation set currently registered with the controller and fetches an interface to that animation set using the ID3DXAnimationController::GetAnimationSet method. Once we have a pointer to the animation set interface, we call the overloaded version of this function ReleaseCallbackData, passing in the animation set interface as a parameter. This overloaded version of the function (which we will discuss in a moment) does the work of releasing the callback key context data contained in the animation set. The code to the version of the function that is called by CActor::Release is shown below.

```
void CActor::ReleaseCallbackData( )
{
    HRESULT             hRet;
    ULONG               i, SetCount;
    ID3DXAnimationSet * pSet = NULL;

    if ( !m_pAnimController ) return;

    // For each animation set, release the callback data.
```

```
    for (i=0,SetCount=m_pAnimController->GetNumAnimationSets(); i<SetCount; ++i )
    {
        // Retrieve the animation set
        hRet = m_pAnimController->GetAnimationSet( i, &pSet );

        if ( FAILED(hRet) ) continue;

        // Release them for this set
        ReleaseCallbackData( pSet );

        // release the anim set interface
        pSet->Release();

    } // Next Animation Set
}
```

After we have passed the animation set interface into the overloaded version of the function, we can assume that any callback key context data associated with the current animation set has been released. As such, the animation set interface can now safely be released. We do this for all animation sets registered with the animation controller so that on function return all callback context data associated with the actor has been cleaned up.

Keep in mind that this function does not release any animation sets from memory. The animation sets are unregistered later in the CActor::Release method when the animation controller is destroyed. All we are doing here is giving the actor a chance to remove CActionData objects associated with callback keys from memory.

CActor::ReleaseCallbackData (Overloaded Method)

This version of the method is called by the function previously discussed. It is passed the interface of an ID3DXAnimationSet derived class which, in our lab project, is a CAnimationSet interface since we replaced all ID3DXKeyframedAnimationSets with our own implementation. This function will release callback data using only the methods of the ID3DXAnimationSet interface, so it will work correctly with any animation set derived from that interface.

This function is tasked with looping through each callback key registered with the passed animation set and releasing its context data (if it exists). The actor is not concerned with what the context data pointer of a callback key is pointing at, only that it is pointing at some object derived from IUnknown. Since the actor makes this assumption, it can simply loop through each callback key in the array and, if the context data pointer of the current key is non-NULL, cast the void pointer to an IUnknown interface and call its Release method.

We discussed the implementation of our CActionData class earlier and saw how its release method decremented the internal reference count and deleted the object (itself) from memory when the count hit zero. We also examined how the CActionData object is created in the callback key callback function and that when the CActionData object is returned to the actor by the callback function, the actor does not increment its reference count. Our application does not store any copies of this CActionData interface or increment its reference count anywhere else in the application. Each CActionData object will have a

reference count of 1 when first registered with the actor. Thus, when the actor calls the release method for each of its CActionData objects, the objects will delete themselves from memory.

This method works properly with any context data that is an IUnknown derived class. Therefore, you do not have to use our CActionData class; you can use your own context data objects and custom classes if you wish. Just make sure that they are derived from IUnknown and that you correctly implement the methods of the IUnknown interface.

Here is the code to the function that releases all context data for the callback keys registered with a single animation set.

```
void CActor::ReleaseCallbackData( ID3DXAnimationSet * pSet )
{
    double     Position  = 0.0;
    ULONG      Flags     = 0;
    IUnknown * pCallback = NULL;

    // Keep searching until we run out of callbacks
    for ( ;SUCCEEDED( pSet->GetCallback( Position,
                                         Flags,
                                         &Position,
                                         (void**)&pCallback )) ; )
    {
        // Ensure we only get the first available (GetCallback will loop forever).
        if ( Position >= pSet->GetPeriod() ) break;

        // Release the callback (it is required that this be an
        // instance of an IUnknown derived class)
        if ( pCallback ) pCallback->Release();

        // Exclude this position from now on
        Flags = D3DXCALLBACK_SEARCH_EXCLUDING_INITIAL_POSITION;

    } // Next Callback
}
```

The function loops through each callback key in the animation sets callback key array using the ID3DXAnimationSet::GetCallback method. The first time this method is called we include the initial position in the search (position 0.0). The function returns the track position and callback key context pointer for the next scheduled callback key.

When we covered the GetCallback method earlier, we learned that it will continue to loop when searching for keys. For example, if the period of the animation set was 10 seconds and the last callback key returned was the one at 10 seconds, the next time the function is called it would wrap around to the beginning of the array and return the first callback key again. We do not want this behavior in this case because we only need a single pass through the callback key array to release the context data. Thus we break from the loop as soon as the position variable is greater than the period of the animation. You can see that this position variable starts at zero, and is passed into each call to GetCallback method so that its value is overwritten by the position of the next callback key that is scheduled. As soon as this position reaches the length of the animation set (remember that the function returns a position analogous to a

non-looping track time), we know that we have processed all the keys and released any context data that needs releasing.

If we have not yet reached the period of the animation set, then we have a context data pointer returned for the next key in the list. If this is not NULL then it means that it must point to an object derived from IUnknown (our CActionData object for example). We simply cast this void pointer to an IUnknown interface pointer and call its release method. This will decrement the object reference count and cause it to delete itself from memory (unless you have incremented its reference count and stored pointers to these objects somewhere else in your application).

Finally, notice that after the first call to GetCallback is issued, for all future calls we pass in the `D3DXCALLBACK_SEARCH_EXCLUDING_INITIAL_POSITION` flag so that we do not get back the callback data we have just processed.

CActor::SetActorLimits

The application should have the ability to change the maximum limits of the actor's underlying controller both before and after the animation data has been loaded from an X file. This allows it to load an X file and then increase properties like the available mixer tracks from 2 (the default) to however many are desired.

Since this function can be called prior to or after the application has called the CActor::LoadActorFromX function, it works differently depending on whether or not the actor's animation controller already exists. If the controller already exists, then the new requested maximums are stored in the actor's member variables and are compared against the limits of the current controller. If any of the requested maximums are greater than what the current controller can handle, then this function will clone the animation controller into one that can support *at least* the requested maximums. The words 'at least' are important here because this function will only increase the limits of its internal animation controller; it will never decrease them.

If the application passes in zero for any of the properties, the maximum extents of the current controller for that property will be inherited from the previous controller by the clone. For example, if we pass in a MaxTracks parameter of zero but the controller already supports two, the cloned controller will support two tracks also. What is important is the fact that the while passed maximum extents are stored in the actor's member variables, the controller will only need to be cloned if one or more of the requested extents is greater than what is currently supported by the actor's animation controller.

The other mode of this function handles the case when the controller does not currently exist. This can happen if the application has called this function prior to calling LoadActorFromX. When this is the case, the maximum extents will simply be stored in the actor's member variables and the function will return. When the application later calls LoadActorFromX, the function will clone the animation controller automatically if the animation controller returned to the actor from the D3DXLoadMeshHierarchyFromX function does not support the previously set maximum extents the application desires.

The exception to the parameter list is the final parameter, MaxCallbackKeys. This value has nothing to do with the animation controller; it sets the size of the temporary callback key buffer that will be allocated in LoadActorFromX and passed to the application-defined callback key callback function. MaxCallbackKeys should be at least as large as the maximum number of callback keys your application intends to register with a single animation set. The default value is 1024, which was set in the constructor.

Let us now have a look at this function a section at a time.

```
HRESULT CActor::SetActorLimits(     ULONG MaxAnimSets /*= 0*/,
                                    ULONG MaxTracks /* = 0*/,
                                    ULONG MaxAnimOutputs /* = 0 */,
                                    ULONG MaxEvents /* = 0 */,
                                    ULONG MaxCallbackKeys /* = 0 */ )
{
    HRESULT hRet;
    bool    bCloneController = false;
    ULONG   Value;

    // Cache the current details
    if ( MaxAnimSets     > 0 ) m_nMaxAnimSets     = MaxAnimSets;
    if ( MaxTracks       > 0 ) m_nMaxTracks       = MaxTracks;
    if ( MaxAnimOutputs  > 0 ) m_nMaxAnimOutputs  = MaxAnimOutputs;
    if ( MaxEvents       > 0 ) m_nMaxEvents       = MaxEvents;
    if ( MaxCallbackKeys > 0 ) m_nMaxCallbackKeys = MaxCallbackKeys;

    // If we have no controller yet, we'll take this no further
    if ( !m_pAnimController ) return D3D_OK;
```

In this first section we test the passed parameters and if any are larger than zero, we take this as a request that the caller wants to change this property. Therefore, any parameter that is larger than zero is stored directly in the actor's member variables. If the controller is not yet created, then our work is done and we simply return. This will typically be all this function does when it is called from the application prior to the X file being loaded into the actor (or if the X file has no animation data, in which case, no controller will exist for the actor anyway).

If the controller is already created then we need to find out if we need to clone it. The first thing we do is copy the current maximum extents of the actor stored in its member variables into some local variables that we can resize later in the function. We reuse the parameter created variables for this purpose since the values passed in have either been stored in the actor (in which case we are just copying them straight back over again), or were zero (in which case we are copying over the previous limit the actor had set for that property). After this copy, we have the exact desired limits that this actor should be able to support in local variables that we can manipulate.

```
    // Store back in our temp variables for defaults
    MaxAnimSets     = m_nMaxAnimSets;
    MaxTracks       = m_nMaxTracks;
    MaxAnimOutputs  = m_nMaxAnimOutputs;
    MaxEvents       = m_nMaxEvents;
    MaxCallbackKeys = m_nMaxCallbackKeys; // Should never be zero
```

When we clone the animation controller, we must pass all the limits of the new controller into the cloning function; not just the ones we wish to change. This makes sure that all limits are inherited by the cloned controller. If the actor has a controller that was previously limited to two mixing tracks, we might call this method and simply pass in zero as this limit. This states that we are quite happy with the current limit and wish it to survive the clone. The local variables in the above code now contain the limits for each controller property that we would like in our cloned controller.

However, as mentioned earlier in this workbook, we only wish to clone the controller if the desired limits exceed those of the pre-existing controller. If the current controller already has limits that are equal to or exceed the requested limits, no clone takes place. The current controller will be able to handle the applications requirements in that case.

The next section of code extracts each limit from the current controller and tests to see if it is smaller than the requested limit. If it is, then the controller will need to be cloned, so we set the bCloneController Boolean to true. If the requested limit is less than or equal to the current limit of the controller, we simply set the local limit variable to the current limit of the controller.

```
    // Otherwise we must clone if any of the details are below our thresholds
    Value = m_pAnimController->GetMaxNumAnimationOutputs();

    if ( Value < MaxAnimOutputs )
        bCloneController = true; else MaxAnimOutputs = Value;

    Value = m_pAnimController->GetMaxNumAnimationSets();

    if ( Value < MaxAnimSets )
        bCloneController = true; else MaxAnimSets = Value;

    Value = m_pAnimController->GetMaxNumTracks();
    if ( Value < MaxTracks )
         bCloneController = true; else MaxTracks = Value;

    Value = m_pAnimController->GetMaxNumEvents();
    if ( Value < MaxEvents )
        bCloneController = true; else MaxEvents = Value;
```

To understand why this code is necessary, let us imagine that we have a controller that is currently capable of managing 100 animation outputs. Let us also imagine that the application calls this method and specifies an animation output limit of 80. In this case, the controller does not need to be cloned because we only wish to expand the limits of the controller, not contract them. We made this design decision to prevent the application from accidentally breaking the animation data loaded from the X file. In this example, the actor's requested limit (80) would be compared against the current limit of the controller (100) and the Boolean is not set to true. Instead we simply upgrade the requested limit (MaxAnimOutputs=80) to the current limit of the controller (MaxAnimOutputs=100).

While this might seem like a strange thing to do, remember that while this particular limit might not cause the controller to be cloned, one of the other limits of the controller may be lower than requested, causing the controller to be cloned anyway. By upgrading the local variable limits so that they are at least as large as the current controller, that limit will be inherited by the clone. If the MaxAnimSets

member contained a value of 10 but the current controller only supported 2 tracks, the controller would be cloned. However, when we pass the MaxAnimOutputs local variable into the clone function, we are specifying that the controller be created with 100 animation outputs (the original maximum) instead of 80 animation outputs (the requested amount). So this code is necessary because we want to make sure that the limits of the original controller that will not change survive in the cloned controller. If we did not have this safeguard, and we cloned the animation controller with 80 animation outputs instead of 100, the animation data for 20 frames in the hierarchy would be lost in the clone. This is almost always something that the application would not intend to happen.

At this point in the code, our Boolean variable will indicate that the controller either does or does not need cloning. If it does then we pass our local variables as the limits to the ID3DXAnimationController::CloneAnimationController method to create a new controller with the desired limits. All animation data that existed in the original controller will now be present in the clone (even our context data pointers).

Once the clone has been performed, we release the original controller's interface and assign the actor's m_pAnimController pointer to the newly cloned interface. The remaining section of the code that performs the clone is shown below.

```
    // Clone our animation controller if there are not enough set slots available
    if ( bCloneController )
    {
        LPD3DXANIMATIONCONTROLLER pNewController = NULL;

        // Clone the animation controller
        hRet = m_pAnimController->CloneAnimationController( MaxAnimOutputs,
                                                            MaxAnimSets,
                                                            MaxTracks,
                                                             MaxEvents,
                                                           &pNewController );
        if ( FAILED(hRet) ) return hRet;

        // Release our old controller
        m_pAnimController->Release();

        // Store the new controller
        m_pAnimController = pNewController;

    } // End if requires clone

    // Success
    return D3D_OK;
}
```

CActor::LoadActorFromX

The LoadActorFromX function is another method that existed in the previous lab project but has now been upgraded to facilitate the incorporation of animation data. The code that has been added is highlighted in bold. The changes may look trivial but this is because the method performs most of the new functionality in new member functions of the actor. Let us look at it a bit at a time.

```
HRESULT CActor::LoadActorFromX( LPCTSTR FileName, ULONG Options,
                                LPDIRECT3DDEVICE9 pD3DDevice,
                                  bool bApplyCustomSets /* = true */ )
{
    HRESULT hRet;
    CAllocateHierarchy Allocator( this );

    // Validate parameters
    if ( !FileName || !pD3DDevice ) return D3DERR_INVALIDCALL;

    // Release previous data!
    Release();

    // Store the D3D Device here
    m_pD3DDevice = pD3DDevice;
    m_pD3DDevice->AddRef();

    // Store options
    m_nOptions = Options;

    // Load the mesh heirarchy and the animation data etc.
    hRet = D3DXLoadMeshHierarchyFromX( FileName, Options, pD3DDevice, &Allocator,
                                       NULL, &m_pFrameRoot, &m_pAnimController );
    if ( FAILED(hRet) ) return hRet;

    // Copy the filename over
    _tcscpy( m_strActorName, FileName );
```

This first section of the code is almost entirely unchanged. It simply increases the reference count of the passed Direct3D device and stores its pointer in a member variable. It then uses the D3DXLoadMeshHierarchyFromX function to load the frame hierarchy. The only update here is that we now pass the address of an ID3DXAnimationController interface pointer to the loading function. If the X file contains animation data then an animation controller will be created for us along with its animation sets and it will be returned to us via this pointer. At this point, we will have a pointer to the animation controller interface for our hierarchy stored in the actor's m_pAnimationController member variable.

We then copy the name of the X file from which the actor was loaded into the m_strActorName member variable. We saw in the previous lab project that the application uses the actor's name when processing X file references inside an IWF file. If an X file has already been loaded, then an actor with the same name as the X file will already exist in the scene. The application can then choose to instance that actor instead. Now however, the actor name also plays another role. We discussed earlier that the application defined callback function for feeding in callback keys to the actor will also be passed the name of the

actor. This allows the application defined callback to test whether this is an X file it wishes to define callback keys for.

The next section of code is new. The first thing the actor does once it knows it has a valid controller is call the CActor::SetActorLimits method:

```
    // Apply our derived animation sets
    if ( m_pAnimController )
    {
        // Apply our default limits if they were set before we loaded
        SetActorLimits( );
```

This time, the function is passed no parameters, indicating that the parameters passed into the function will all be zero by default. When we discussed this function earlier we learned that when a given limit is zero, the current value for that limit stored in the actor's member variables is used. If the application has used the SetActorLimits method to set its desired limits for the controller prior to calling the LoadActorFromX function, the clone will be performed if the controller created for us by D3DX is not capable of fulfilling our application requirements.

The next line of code is very important. It tests to see if a callback key callback function has been registered with this actor by the application. If it has, then the pFunction pointer of the CALLBACK_FUNC structure in the fourth element (CALLBACK_CALLBACKKEYS = 4) of the actor's callback function array will not be NULL. If this is the case, a new method, which we have not yet discussed, is called. This method is called ApplyCallbacks and will be discussed next.

The ApplyCallbacks function will loop through every animation set currently registered with the controller, and for each one, will call the application defined callback function. The callback function will be passed a temporary array of D3DXKEY_CALLBACK structures. The application can then store callback keys and context data in this array before returning it back to the ApplyCallback method. This method will then replace the current animation set with a new copy of the animation set that has the callback keys registered with it. Remember, we have to do this because we have no way of registering callback keys with an animation set after it has been created.

```
        // If there is a callback key function registered, collect the callbacks
        if ( m_CallBack[CALLBACK_CALLBACKKEYS].pFunction != NULL )
             ApplyCallbacks();
```

We will look at the ApplyCallbacks method in a moment, but just note that when it returns, our animation controller may now contain animation sets that have callback keys registered with them.

The final section of the function code uses another new CActor method called ApplyCustomSets. As discussed earlier in this workbook, at the time of writing, a bug existed in the ID3DXKeyframedAnimationSet::GetSRT method. Because of this, we constructed a way around the problem by replacing all ID3DXKeyframedAnimationSets registered with our controller with CAnimationSet copies. That is what the ApplyCustomSets method does (we will cover the code to this method in a moment). It loops through every animation set currently registered with the controller and creates a replacement CAnimationSet object for each. It then copies over all the animation data from the

original keyframed animation set into our own CAnimationSet. Once we have a copy of each animation set, we release the original keyframed animation sets and register our CAnimationSet objects in their place. We covered all of the code for CAnimationSet earlier in this workbook.

```
        // Apply the custom animation set classes if we are requested to do so.
        if ( bApplyCustomSets == true )
        {
            hRet = ApplyCustomSets();
            if ( FAILED(hRet) ) return hRet;

        } // End if swap sets

    } // End if any animation data

    // Success!!
    return D3D_OK;
}
```

Notice that the LoadActorFromX method accepts a Boolean parameter called bApplyCustomSets. Only if this value is set to true will the ApplyCustomSets method be called and our own CAnimationSet implementations replace the ID3DXKeyframedAnimationSets registered with the controller. This parameter allows us to quickly unplug our CAnimationSet objects from the system when the bug in ID3DXKeyframedAnimationSet is fixed in the future.

While only a small amount of code was added to LoadActorFromX, there were calls made to two new methods which we will look at next. These two new methods do contain significant amounts of code.

CActor::ApplyCallbacks

The ApplyCallbacks method is called by LoadActorFromX after the actor has been loaded and already has an animation controller. The purpose of this function is to provide the application with a means of registering callback keys for animation sets registered with the animation controller. Keys cannot be registered with an animation set after it has been created, so we provide this functionality by making new copies of the animation sets for which the application has specified callback keys. We can register these new callback keys as we create the new animation set copies and then release the original animation sets and register the new ones (with the callback keys) in their place.

The first section of this function is shown next. It checks that the animation controller of the actor is valid and that it already has registered animation sets. If not, then the function simply returns. Next, we store (in the SetCount local variable) the number of animation sets currently registered with the animation controller. We will need to loop through each animation set and call the application defined callback function (if it has been registered) to give the application a chance to specify callback keys for each animation set.

Once we have recorded the number of sets in the animation controller, we allocate a temporary array of D3DXKEY_CALLBACK structures. For each animation set processed, we will pass this array into the application defined callback function. The callback function can then fill this array with callback data as we saw earlier in this workbook. Notice that the size of this temporary array is determined by the actor limit m_nMaxCallbackKeys, which can be changed using the SetActorLimits method. This is initially

set to 1024, which means the callback function will have enough room to register 1024 callback keys in this array for a single animation set. Remember, this is a per-set limit since the temporary buffer will be reused for each animation set processed by this function. The m_nMaxCallbackKeys member variable allows us to control the temporary memory overhead used by this function.

```
HRESULT CActor::ApplyCallbacks( )
{
    ULONG   i, j;
    HRESULT hRet;
    ID3DXKeyframedAnimationSet * pNewAnimSet = NULL, **ppSetList = NULL,
                               * pKeySet = NULL;
    ID3DXAnimationSet          * pAnimSet    = NULL;
    D3DXKEY_CALLBACK           * pCallbacks  = NULL;

    // Validate
    if ( !m_pAnimController || !m_pAnimController->GetNumAnimationSets( ) )
         return D3DERR_INVALIDCALL;

    // Store set count
    ULONG SetCount = m_pAnimController->GetNumAnimationSets( );

    // Allocate our temporary key buffer
    pCallbacks = new D3DXKEY_CALLBACK[ m_nMaxCallbackKeys ];
    if ( !pCallbacks ) return E_OUTOFMEMORY;

    // Allocate temporary storage for our new animation sets here
    ppSetList = new ID3DXKeyAnimationSet*[ SetCount ];

    if ( !ppSetList ) { delete pCallbacks; return E_OUTOFMEMORY; }
```

Once we have allocated the callback key array, we allocate an array of ID3DXKeyAnimationSet interface pointers. The size of this array is equal to the number of animation sets currently registered with the controller.

We have several things we must consider when implementing this function. First, we will need to unregister any animation sets that need to be replaced. These will only be animation sets that have a callback key count greater than zero. For any others we will let them remain registered with the controller. Second, we may have a situation where the controller has some animation sets that are not of the ID3DXKeyframedAnimationSet type (e.g., custom sets, compressed animation sets, etc.). Since we can only register callback keys with keyframed animation sets, we will want to also leave these others alone, registered with the controller. To ease this process, we have decided to implement this in three passes/loops. This makes the code slightly longer but easier to understand and maintain.

In the first loop, we will fetch each animation set from the animation controller and store a copy of its interface pointer in the temporary ID3DXAnimationSet array we have just allocated. In the loop, we will call ID3DXAnimationController::GetAnimationSet to fetch each set. As this function returns a pointer to the base interface, this is ideal. We simply store pointers to all the animation sets (keyframed or otherwise) in our temporary animation set array and then remove that set from the controller. What we will have at the end of this first pass is an empty animation controller, with pointers to each animation set it used to have registered in our temporary array. We can then work directly with this array, rejecting

or replacing animation sets we no longer want and leaving the ones we do want unaltered. At the end of the function, we can loop through this array and register all the animation sets back with the controller. Some of these animation sets will have been replaced by copies containing callback key data.

Here is the code that performs this first un-register pass.

```
for ( i = 0; i < SetCount; ++i )
    {
        // Keep retrieving index 0 (remember we unregister each time)
        hRet = m_pAnimController->GetAnimationSet( 0, &pAnimSet );
        if ( FAILED( hRet ) ) continue;

        // Store this set in our list, and AddRef
        ppSetList[ i ] = pAnimSet;
        pAnimSet->AddRef();

        // Unregister the old animation sets first otherwise we won't have enough
        // 'slots' for the new ones.
        m_pAnimController->UnregisterAnimationSet( pAnimSet );

        // Release this set, leaving only the item in the set list.
        pAnimSet->Release();

    } // Next Set
```

Notice that when we copy the interface pointer for each animation set, we increase its reference count. If you study the previous code, you will realize that prior to the GetAnimationSet call, the animation controller is the only object that has an interface to each animation set, so the reference count of the animation set would be 1. When we call GetAnimationSet, the controller returns an interface to our application, automatically increasing the reference count before returning the pointer. The reference count of the animation set at this point is 2. We then copy this interface pointer into our array and increase the reference count again, so the reference count is 3. This is correct since there are three pointers to this interface currently in use. The animation controller has its own pointer to it, the pAnimSet local variable currently has a reference to it, and our interface pointer array has the third. We then call the animation controller's UnregisterAnimatonSet method so that the animation set releases its pointer to the interface, taking the reference count down to 2. Next we release the temporary pAnimSet pointer which decrements the reference count to 1. This is now exactly how we want it -- the only reference to this animation set is now in our local ID3DXAnimationSet array.

The next pass through the animation sets is where all the work is done. We loop through each animation set in our temporary array and query its interface. If it is not an ID3DXKeyframedAnimationSet interface, we will skip to the next iteration of the loop. We are essentially leaving this animation set alone and will re-add it to the controller later in the function. It will be unaltered from its initial state. If it is a keyframed animation set, then the QueryInterface method will return us a pointer to that interface:

```
    // Loop through each animation set and rebuild a new one containing the
    // callbacks.
    for ( i = 0; i < SetCount; ++i )
    {
```

```
        // Skip if we didn't manage to retrieve
        if ( ppSetList[i] == NULL ) continue;

        // Retrieve the set we're working on
        pAnimSet = ppSetList[i];

        // Query the interface to get a keyframed animation set
        hRet = pAnimSet->QueryInterface( IID_ID3DXKeyframedAnimationSet,
                                         (void**)&pKeySet );
        if ( FAILED(hRet) ) continue;
```

If we get this far in this iteration, we have a keyframed animation set which the application may wish to register callback keys for. We now have to call the application defined callback function to see if that is the case.

In the following code we see a technique we have used many times before when calling callback functions. If the application has registered a callback key callback function with the actor, its function pointer will exist in the fourth element in the actor's callback function array. If you examine CActor.h you will see that we have defined a type called COLLECTCALLBACKS which describes a pointer to this method:

```
typedef ULONG (*COLLECTCALLBACKS )( LPVOID pContext,
                                    LPCTSTR strActorFile,
                                    LPD3DXKEYFRAMEDANIMATIONSET pAnimSet,
                                    D3DXKEY_CALLBACK pKeys[] );
```

As you can see, any variables we declare with this type will be pointers to functions with the exact function signature of our application defined callback function (dictated by the actor). Your callback function *must* use this exact signature.

In the following code we create a pointer of this type called CollectCallbacks and assign it the value of the pFunction member of the fourth element in the actor's callback array. If the application has registered a callback function of this type with the actor (using the CActor::RegisterCallback method), then we will now have a pointer to the function that we can call. Otherwise, this element will be set to NULL, indicating the application has expressed no desire to register any callback keys with this actor's animation sets.

> **Note**: It is important to remember that the application must register any callback functions with the actor prior to calling LoadActorFromX because these functions are called in the middle of the loading process. This was also true of the texture and material callback functions that were covered in the previous lab projects.

In the next section of code, we fetch the function pointer and use it to invoke the callback function, passing any context data that was registered (the CScene object instance in our project). We also pass the function the name of the actor so that the callback function can determine which actor is making the call and, therefore, what callback data that actor should receive. We also pass in a pointer to the animation set interface so the callback function can extract information about which set it is being called for. In the example callback function we showed earlier, the animation set's interface was used to extract the name of the set. This allowed the callback function to determine what callback data should be

registered (if any) with the current animation set being processed. Finally, we pass in a pointer to our temporary D3DXKEY_CALLBACK array so that the application can fill it with callback data for the current animation set.

When the callback function returns, it will return an integer describing how many keys were placed in the array by the callback function. If the function returns zero, then we do not have to alter this animation set; we can simply continue to the next iteration of the loop and leave this animation set alone. This animation set will be re-registered with the animation controller later in the function. Here is the code that shows the process just described.

```
        // Retrieve our application's registered function pointer
        COLLECTCALLBACKS CollectCallbacks
            = (COLLECTCALLBACKS)m_CallBack[ CALLBACK_CALLBACKKEYS ].pFunction;

        // Request that our key buffer be filled
        ULONG KeyCount
           = CollectCallbacks( m_CallBack[ CALLBACK_CALLBACKKEYS ].pContext,
                               m_strActorName, pKeySet, pCallbacks );

        // If no keys are to be added, leave the existing one alone.
        if ( KeyCount == 0 ) { pKeySet->Release(); continue; }
```

If we get this far, then the current animation set we are processing is one that the application has supplied us with callback keys for. Therefore, as callback keys can only be registered with an animation set at creation time, we need to create a new copy of this animation set which will eventually be used to replace it. In the next section of code we create a new animation set that has the same name, source ticks per second, playback type, and number of animation as the animation set we are copying.

```
        // Create a new animation set for us to copy data into
        hRet = D3DXCreateKeyframedAnimationSet( pKeySet->GetName(),
                                                pKeySet->GetSourceTicksPerSecond(),
                                                pKeySet->GetPlaybackType(),
                                                pKeySet->GetNumAnimations(),
                                                KeyCount,
                                                pCallbacks,
                                                &pNewAnimSet );

        if ( FAILED(hRet) ) { pKeySet->Release(); continue; }
```

We now have a new animation set which has the same parameters as the original animation set, with one big difference. Notice that when we call the D3DXCreateKeyframedAnimationSet method, now we also pass in the number of callback keys (returned by the callback function) and a pointer to the array containing those keys (populated by the callback function). As result, the new animation set created will contain the callback key data supplied by the callback function.

Of course our job is not yet done. Although our new animation set shares the same properties as the original set and now includes callback data, it still contains no animation data. Although our new animation set has had space reserved for the correct number of animations, these animations have no data. We will have to manually extract the SRT keyframes from each animation in the original set and assign them to matching animations in the new set.

The following code performs the copying of the SRT data for each animation. It sets up a loop to iterate through each animation in the original set. For each animation, it first fetches the number of scale, rotate, and translate keys registered with that animation. These three values are then used to allocate temporary arrays to store copies of the SRT data for this animation. We then copy the scale, rotation and translation keys from the original animation into these three arrays.

```
        // Copy over the data from the old animation set
        //(we've already stored the keys)
        for ( j = 0; j < pKeySet->GetNumAnimations(); ++j )
        {
            LPCTSTR               strName = NULL;
            ULONG                 ScaleKeyCount, RotateKeyCount,
                                  TranslateKeyCount;
            D3DXKEY_VECTOR3     * pScaleKeys = NULL, * pTranslateKeys = NULL;
            D3DXKEY_QUATERNION  * pRotateKeys = NULL;

            // Get the old animation sets details
            ScaleKeyCount     = pKeySet->GetNumScaleKeys( j );
            RotateKeyCount    = pKeySet->GetNumRotationKeys( j );
            TranslateKeyCount = pKeySet->GetNumTranslationKeys( j );

            pKeySet->GetAnimationNameByIndex( j, &strName );

            // Allocate any memory required
            if ( ScaleKeyCount     )
                pScaleKeys     = new D3DXKEY_VECTOR3[ ScaleKeyCount ];

            if ( RotateKeyCount    )
               pRotateKeys    = new D3DXKEY_QUATERNION[ RotateKeyCount ];

            if ( TranslateKeyCount )
               pTranslateKeys = new D3DXKEY_VECTOR3[ TranslateKeyCount ];
            // Retrieve the keys
            if ( pScaleKeys     ) pKeySet->GetScaleKeys( j, pScaleKeys );
            if ( pRotateKeys    ) pKeySet->GetRotationKeys( j, pRotateKeys );
            if ( pTranslateKeys ) pKeySet->GetTranslationKeys( j, pTranslateKeys );
```

We now have the SRT data for the current animation we are copying over. Our next task is to register these SRT keys with the matching animation in the new animation set using the ID3DXKeyframedAnimationSet::RegisterAnimationSRTKeys method. When this function returns, D3DX will have copied the SRT data into the animation in the new set. These temporary SRT arrays are no longer needed and can be deleted.

```
            hRet = pNewAnimSet->RegisterAnimationSRTKeys(  strName,
                                                           ScaleKeyCount,
                                                           RotateKeyCount,
                                                           TranslateKeyCount,
                                                           pScaleKeys,
                                                           pRotateKeys,
                                                           pTranslateKeys, NULL );
            // Delete the temporary key buffers
            if ( pScaleKeys     ) delete []pScaleKeys;
            if ( pRotateKeys    ) delete []pRotateKeys;
```

```
            if ( pTranslateKeys ) delete []pTranslateKeys;

            // If we failed, break out
            if ( FAILED(hRet) ) break;

        } // Next Animation 'item'
```

If for some reason we got this far but were forced to break out of the above loop before each animation had been copied, then it means something went wrong during the copy procedure. The next section of code shows that if this is the case, we will release the new animation set and leave the original animation as is. We just continue to the next iteration of the loop to process the next animation set. This is a safe way to try to continue the process in the event of some unforeseen error.

```
        // If we didn't reach the end, this is a failure
        if ( j != pKeySet->GetNumAnimations() )
        {
            // Release new set, and reference to old
            pKeySet->Release();
            pNewAnimSet->Release();
            continue;

        } // End if failed
```

At this point we have copied over all the animation data from the original animation set into the new animation. The original animation set can now be released from memory as it will no longer be needed. Notice how we perform two releases to free the original animation set. The pKeySet pointer is the ID3DXKeyframedAnimationSet interface to the original animation set that we retrieved with the QueryInterface call. We then release the original animation set interface pointer stored in thre array and replace it with our new copy.

```
        // Release our duplicated set pointer
        pKeySet->Release();

        // Release the actual animation set, memory will now be freed
        pSetList[I]->Release();

        // Store the new animation set in our temporary array
        ppSetList[i] = pNewAnimSet;

    } // Next Set
```

Now every animation set has been processed. Some may have been replaced with copies, while others may have been left in their original state. Either way, at this point, the ppSetList array contains all the animation sets we wish to register with the animation controller. In the third pass we do exactly that. We loop through each animation set in this array and register it with the animation controller. We then release the interface pointer stored in the array since we no longer need it. This will not cause the animation set to be freed from memory because the animation controller has a pointer to it now and will have incremented its reference count when the set was registered.

```
    // third pass, register all new animation sets
```

```
    for ( i = 0; i < SetCount; ++i )
    {
        // Nothing stored here?
        if ( !ppSetList[i] ) continue;

        // Register our brand new set. (AddRef is called)
        m_pAnimController->RegisterAnimationSet( ppSetList[i] );

        // Release our hold on the custom animation set
        ppSetList[i]->Release();

    } // Next Set
```

The last section of the function frees the temporary animation set array and callback key array from memory. It also assigns the controller's first animation set to track zero by default. If we did not do this then no animation set would be assigned to any track. Remember, although the D3DXLoadMeshHierarchyFromX function automatically assigns an animation set to track zero on our behalf, we have unregistered all of those animation sets and undone this mapping.

```
    // Free up any temporary memory
    delete []ppSetList;
    delete []pCallbacks;

    // Set the first animation set into the first track, otherwise
    // nothing will play, since all previous tracks have potentially been
    //  unregistered.
    SetTrackAnimationSetByIndex( 0, 0 );

    // We're all done
    return D3D_OK;
}
```

That was a sizable function but ultimately very straightforward. We are essentially just cloning animation sets manually so that we can add additional data to them.

CActor::ApplyCustomSets

One of the last methods to be called from the LoadActorFromX method is CActor::ApplyCustomSets. This function gives us a chance to replace all ID3DXKeyframedAnimationSets with our own CAnimationSet objects. You will recall from our earlier discussion that this allows us to sidestep a bug in the ID3DXKeyframedAnimationSet::GetSRT method that existed at the time of this writing.

This method follows, for the most part, the same logic as the CActor::ApplyCallbacks method just discussed. In fact, it executes using the same three pass apporach. First it copies all the animation sets from the controller into a locally allocated array. Each animation set is then un-registered with the controller. In the second pass we loop through each animation set in the array. For each ID3DXKeyframedAnimationSet we find, we copy its information into a new CAnimationSet object. Luckily, the CAnimationSet constructor takes care of the actual copying of the keyframe data from the passed ID3DXKeyframedAnimationSet, so this code is a lot shorter than the previous function. For each

set we clone, we release the original. As before, if we find any compressed or custom animation sets we leave them alone in the array for re-registration later in the function. At the end of the second pass, we will have an array of animation sets where each keyframed animation set has been replaced by a CAnimationSet object. In the third pass, we simply register every animation set in this array with the animation controller.

Note however that this method is called by CActor::LoadActorFromX after the ApplyCallbacks method has been called. Therefore, the animation sets currently registered with the controller may well have callback keys defined for them. As we saw when we covered the CAnimationSet constructor, the callback keys of the animation set are also copied over into the new CAnimationSet copy.

The first pass of this function should look familiar. It allocates an array of ID3DXAnimationSet interfaces large enough to store a copy of each animation set currently registered with the controller.

```
HRESULT CActor::ApplyCustomSets( )
{
    ULONG   i;
    HRESULT hRet;
    CAnimationSet       * pNewAnimSet = NULL;
    ID3DXAnimationSet   * pAnimSet    = NULL, ** ppSetList = NULL;

    // Validate
    if ( !m_pAnimController || !m_pAnimController->GetNumAnimationSets( ) )
        return D3DERR_INVALIDCALL;

    // Store set count
    ULONG SetCount = m_pAnimController->GetNumAnimationSets( );

    // Allocate array to hold animation sets
    ppSetList = new ID3DXAnimationSet*[ SetCount ];
    if ( !ppSetList ) return E_OUTOFMEMORY;

    // Clear the array
    ZeroMemory( ppSetList, SetCount * sizeof(ID3DXAnimationSet*) );
```

We now loop and fetch each animation set from the animation controller and store the retrieved base interface pointer in our local animation set array. As we copy over each animation set interface, we release that animation set from the controller so that the only reference to the animation set interface is now in our array.

```
    // Loop through each animation set and copy into our set list array
    for ( i = 0; i < SetCount; ++i )
    {
        // Keep retrieving index 0 (remember we unregister each time)
        hRet = m_pAnimController->GetAnimationSet( 0, &pAnimSet );
        if ( FAILED( hRet ) ) continue;

        // Store this set in our list, and AddRef
        ppSetList[ i ] = pAnimSet;
        pAnimSet->AddRef();
```

```
        // Unregister the old animation sets first otherwise we won't have enough
        // 'slots' for the new ones.
        m_pAnimController->UnregisterAnimationSet( pAnimSet );

        // Release this set, leaving only the item in the set list.
        pAnimSet->Release();

    } // Next Set
```

The second pass is where we copy over the data from the original animation set into a new CAnimationSet. We do this by allocating a new CAnimationSet object and passing into the constructor the ID3DXAnimationSet base interface of the set we intend to clone. The constructor will take care of copying over all the keyframe data and storing it in the CAnimationSet's internal variables (if it is an ID3DXKeyframedAnimationSet that is passed in). Because this copying is happening in the constructor we have no way of returning success or failure, so we use exceptions. If an exception is thrown from inside the constructor, the catch block will simply delete the CAnimationSet we just allocated. When this happens, the original animation set's pointer is left in our array and will be re-registered with the controller later on.

```
    // Loop through each animation set and rebuild a new custom one.
    for ( i = 0; i < SetCount; ++i )
    {
        // Skip if we didn't retrieve anything
        if ( ppSetList[i] == NULL ) continue;

        // Allocate a new animation set, duplicating the one we just retreived
        // Note : Because this is done in the constructor, we catch the
        // exceptions because no return value is available.
        try
        {
            // Duplicate
            pNewAnimSet = new CAnimationSet( ppSetList[i] );

        } // End Try Block
        catch ( HRESULT & e )
        {
            // Release the new animation set
            delete pNewAnimSet;

            // Just skip this animation set (leave it in the array)
            continue;

        } // End Catch block
        catch ( ... )
        {
            // Just skip this animation set (leave it in the array)
            continue;

        } // Catch all other errors (inc. out of memory)
```

If we get this far without incident, then the animation set has been successfully copied into a new CAnimationSet object. The original animation set can then be released and a pointer to our new CAnimationSet stored in the array in its place.

```
        // Release this set, memory will now be freed
        ppSetList[i]->Release();

        // Store the new animation set in our temporary array
        ppSetList[i] = pNewAnimSet;

    } // Next Set
```

Finally, in the third pass we loop through each animation set in the array and register it with the controller. We then delete the temporary array and bind the first animation set to the first track of the controller.

```
    // third pass, register all new animation sets
    for ( i = 0; i < SetCount; ++i )
    {
        // Register our brand new set. (AddRef is called)
        m_pAnimController->RegisterAnimationSet( ppSetList[i] );

        // Release our hold on the custom animation set
        ppSetList[i]->Release();

    } // Next Set

    // Free up any temporary memory
    delete []ppSetList;

    // Set the first animation set into the first track, otherwise
    // nothing will play, since all previous tracks have been unregistered.
    SetTrackAnimationSetByIndex( 0, 0 );

    // We're all done
    return D3D_OK;

}
```

When this function returns back to LoadActorFromX, all ID3DXKeyframedAnimationSets will have been replaced with our CAnimationSets.

We have now covered all the new methods involved with loading and initializing the actor for animation. The remaining functions exposed by the actor are used by the application to play animations and configure the playback settings.

CActor::AdvanceTime

The new AdvanceTime method is the heartbeat of our actor. The application will call this method periodically to update the animation system's internal clock. This is really just a wrapper function around a call to the ID3DXAnimationController::AdvanceTime method, which updates the animation system and generates the new relative frame matrices for the hierarchy.

The first thing you will often want to do after updating the frame matrices is traverse the hierarchy and build the absolute matrices for each frame. You will recall from the previous lab project that we did this, during each iteration of our game loop, using the CActor::UpdateFrameMatrices method. This method traverses the frame hierarchy and combines all relative matrices to generate the world matrices for each frame in the hierarchy. It makes sense that we would want to perform this task *after* animating the local frame matrices because this step would invalidate the previous world matrices.

For convenience, we have added a Boolean parameter called UpdateFrames to this function (set to true by default). When set to true, the function will automatically call CActor::UpdateFrameMatrices before returning. This allows the actor to update the animation and rebuild the absolute matrices for each frame with a single call to CActor::AdvanceTime. The UpdateFrameMatrices method is unchanged from the previous lab project so will not be covered again here.

There may be times when you do not wish the world matrices of each frame to be calculated immediately after an animation update has taken place. In this case you can pass false as this parameter. You might do this because the application intends to make some manual adjustments to the relative frame matrices prior to the world matrix rebuilding. If the application does pass false to the UpdateFrames parameter, it must make sure that it calls CActor::UpdateFrameMatrices prior to rendering the actor. If it does not, the animations applied to the relative frame matrices will not be reflected in their world space counterparts used for the mesh transformations.

The CActor::AdvanceTime method is shown below.

```
void CActor::AdvanceTime(     double fTimeElapsed,
                              bool UpdateFrames /* = true */,
                              LPD3DXANIMATIONCALLBACKHANDLER pCallbackHandler)
{
    if ( !IsLoaded() ) return;

    // Set the current time if applicable
    if ( m_pAnimController )
        m_pAnimController->AdvanceTime( fTimeElapsed, pCallbackHandler );

    // Update the frame matrices
    if ( UpdateFrames ) UpdateFrameMatrices( m_pFrameRoot, &m_mtxWorld );
```

The application passes the amount of elapsed time since the previous call to the function, which is then routed to the ID3DXAnimationController::AdvanceTime method. As discussed earlier, when the ID3DXAnimationController::AdvanceTime method returns program flow back to our function, the relative hierarchy frame matrices will have been updated to represent their new positions. Finally, we call the UpdateFrameMatrices method which uses the updated relative matrices to build the

absolute/world matrices for each frame that will be used for transformation and rendering of any meshes in the hierarchy.

As the third parameter to the CActor::AdvanceTime method, the application can pass a pointer to a ID3DXAnimationCallbackHandler derived class. This base abstract interface exposes only one function which we must implement if we wish our callback keys to be used. When the controller executes a callback key, it will call the ID3DXAnimationCallbackHandler::HandleCallback method. Obviously this will only happen if we have passed into the controller the pointer to an object that is derived from this interface.

If you take a look in the d3dx9anim.h header file which ships with the SDK, you can see that the ID3DXAnimationCallbackHandler interface is declared as:

```
DECLARE_INTERFACE(ID3DXAnimationCallbackHandler)
{
    STDMETHOD(HandleCallback)(THIS_ UINT Track, LPVOID pCallbackData) PURE;
};
```

This is a pure virtual base class rather than an interface; it is not even derived from IUnknown. What does this mean for us? Well, all we have to do is derive our own class from this base class and implement its single method: HandleCallback. We can then pass a pointer to our object into the CActor::AdvanceTime method, where it will passed to the ID3DXAnimationController::AdvanceTime method. From there, the controller will call its HandleCallback method whenever a callback key is executed.

When this method is called by the controller, it is passed two parameters. The first is the track number for which the callback key was triggered. Your callback function might use this to determine if it wishes to take any action with respect to the current track. The second parameter is the callback key context data pointer. Remember, this will contain either NULL or the address of a CActionData object. Recall from our earlier discussion that our actor enforces the rule that callback key context pointers should point to an IUnknown derived class so that the actor can clean it up properly. In our application, we use the CActionData object for storing data that we would like passed to our callback method. In Lab Project 10.1, each CActionData object will contain the name of a wave file sound effect that the callback function can play when the key is triggered.

If you look in CScene.h you will see that we have derived our own class from ID3DXAnimationCallbackHandler like so:

```
class CActionHandler : public ID3DXAnimationCallbackHandler
{
public:
     STDMETHOD(HandleCallback)(THIS_ UINT Track, LPVOID pCallbackData);
};
```

Note that we have added nothing to this class and used a straight implementation of the interface laid out by the base class. It is a pointer to a CActionHandler class that we will pass into the

CActor::AdvanceTime method. Its HandleCallback method will be called by the controller whenever a callback key needs to be processed.

The CActionHandler::HandleCallback method is implemented in CScene.cpp (see below). Our callback function is very simple and does not use the track number passed by the controller for any purpose. It is only interested in the second parameter, which contains a pointer to our CActionData object (containing the name of a sound file that will need to be played).

The first thing we do is cast the void context data to an IUnknown interface. We know that whatever object may be pointed at by this void pointer has to be either NULL or one derived from IUnknown since our CActor class insists on it. Once we have cast it to IUnknown, we had better make sure that this is a CActionData object since it is what our callback handler is interested in handling. Therefore, we call IUnknown::QueryInterface to check that it is indeed one of our CActionData objects. If it is not, then we return immediately since this callback function does not know how to handle any other data type. If it is a CActionData object, then we are returned a CActionData interface which we can then use to extract the wave filename.

```
HRESULT CActionHandler::HandleCallback( UINT Track, LPVOID pCallbackData )
{
    IUnknown    * pData   = (IUnknown*)pCallbackData;
    CActionData * pAction = NULL;

    // Determine if this is in a format we're aware of
    if ( FAILED( pData->QueryInterface( IID_CActionData, (void**)&pAction ) ) )
         return D3D_OK; // Just return unhandled.
```

Now that we have an interface to our CActionData object, we check its m_Action member variable. This can currently only be set to ACTION_NONE or ACTION_PLAYSOUND, but you may decide to add different types of actions to this class yourself. Our callback function only handles sound effect callback keys at the moment, so we have to make sure that we only work with CActionData objects that are in ACTION_PLAYSOUND mode.

```
    // This is our type, lets handle it
    switch ( pAction->m_Action )
    {
        case CActionData::ACTION_PLAYSOUND:

            // Play the sound if available
            if ( pAction->m_pString != NULL )
                 sndPlaySound( pAction->m_pString, SND_ASYNC | SND_NODEFAULT );
            break;

    } // End Switch Action Type

    // Release the action we queried.
    pAction->Release();

    // We're all done
    return D3D_OK;
}
```

If this is an ACTION_PLAYSOUND mode CActionData object, we fetch the filename from its m_pString member and pass it into a Win32 function (sndPlaySound) which loads and plays the specified wave file. We then release the interface to the CActionData object and return from the function.

In our lab project we register two callback keys of type ACTION_PLAYSOUND. Thus, this callback function will be called twice by the controller in a given loop of animation. Since the animation is set to loop, these same two callback keys will cause this function to be called over and over again so that the sounds play during every loop of the animation.

sndPlaySound

To keep things simple, we are using the Win32 function sndPlaySound to play our sound effects. This function takes two parameters. The first is the name of the wave file we wish to play and as you can see, we pass in the name of the wave file stored inside the CActionData object. The second parameter is a combination of one or more of the following flags:

Value	Meaning
SND_ASYNC	The sound is played asynchronously and the function returns immediately after beginning to play the sound. To terminate an asynchronously played sound, call **sndPlaySound** with *lpszSoundName* set to NULL. We use this option so that we can start a long sound playing and continue with our application processing.
SND_LOOP	The sound plays repeatedly until **sndPlaySound** is called again with the *lpszSoundName* parameter set to NULL. You must also specify the SND_ASYNC flag to loop sounds.
SND_MEMORY	If this flag is specified, then the first parameter should not point to a string containing the filename of the wave file but should instead point to an image of a waveform sound in memory.
SND_NODEFAULT	If the sound cannot be found, the function returns silently without playing the default sound. We use this option so that in the event that the sound file is missing, we do not end up playing some default sound instead that might be out of context with our scene.
SND_NOSTOP	If a sound is currently playing, the function immediately returns FALSE, without playing the requested sound. If you specify this flag and a sound is already playing, no action will be taken. Without this flag, the currently playing sound would be cut short and the new sound played immediately.
SND_SYNC	The sound is played synchronously and the function does not return until the sound ends. We do not want to use this flag because our animation would freeze and our application would receive no frame updates until the sound had finished playing.

This is certainly not a function that you would use in a commercial game project (that is what DirectXSound is for), especially since it can only play one sound at a time. However, the purpose of this exercise is to demonstrate the callback mechanism, so this works nicely for us.

Note: In order to use the sndPlaySound function, you must make sure that you are linking to the winmm.lib library (part of the platform SDK). This library includes all the Win32 multimedia functionality.

Advancing our Actor

Let us look at an example of how the actor is updated in our application. You should be fairly comfortable by now with our application framework and the fact that we usually handle any scene based animation updates in the CScene::AnimateObjects method. This method is called for every iteration of our game loop by the CGameApp::FrameAdvance method, giving the scene a chance to update the positions of any objects prior to rendering. The function is passed the application CTimer object so that it can retrieve the elapsed time since the last frame update and forward this time to the CActor::AdvanceTime method.

Note: This is not the exact CScene::AnimateObjects call found in Lab Project 10.1, but it is very close. We have to discuss some additional topics before we are ready to look at the full version of this function. However, we will see all but a few lines of the code and show the important points for this discussion.

```
void CScene::AnimateObjects( CTimer & Timer )
{
    static CActionHandler Handler;

    // Process each object
    for ( ULONG i = 0; i < m_nObjectCount; ++i )
    {
        // Increase actor's reference time if this stores an actor
        if ( m_pObject[i]->m_pActor )
         m_pObject[i]->m_pActor->AdvanceTime( Timer.GetTimeElapsed(),
                                              false,
                                              &Handler );

    } // Next Object
}
```

The function starts by declaring a variable of type CActionHandler. This object contains the callback function that we wish the controller to use to process callback keys. Since we will need to use this object every frame, we make it a static variable rather than a stack variable that has to be repeatedly created and destroyed. We did not make this a member of the CScene class because the only time this object is ever used is in this function. So we decided to keep its scope safely limited to this function. By making it static we can have the best of both worlds -- a global variable that is created once with a safe scope limited to this one function.

We then loop through each CObject in the scene's object array. You will recall from the previous lab project that our scene may consist of single mesh objects and objects with actors attached and still behave properly. In this function however, we are only interested in objects which are actors. So for each object that has an actor attached, we call the actor's AdvanceTime method, passing in the elapsed time retrieved from the timer along with a pointer to our callback handler. At the end of this loop, each actor in the scene will have had its frame hierarchy animated. In Lab Project 10.1 we only have a single actor which will contain all of the objects in the scene and their associated animations.

Why are we passing in false as the second parameter? Recall from our earlier discussion that if it is set to true, then the actor will automatically traverse the hierarchy and build the absolute matrices for each frame. You might imagine that this is surely something we want to have done, right?

While it is true that we need to update the absolute matrices after animation has been applied, we certainly do not wish to perform multiple traversals if we can avoid it. You will recall from the previous lab project that before rendering an actor we must also set its world matrix so that we can position it in the world at an arbitrary location and orientation. (The application can move and position the actor in the scene by applying transformations to the matrix stored in the parent CObject to which the actor is attached.) In the CScene::Render method, prior to rendering the actor's subsets, we call CActor::SetWorldMatrix and pass in the parent CObject matrix as the root node matrix:

```
pActor->SetWorldMatrix( &m_pObject[i]->m_mtxWorld, true );
```

As we learned in the previous workbook, this function is passed the world matrix of the actor as its first parameter and it caches this matrix internally. It is by manipulating the CObject::m_mtxWorld matrix that the application can move the entire actor about in the scene. If true is passed as the second parameter, then the passed matrix is combined with the root node matrix and all changes are filtered down through the hierarchy. Since this call happens in the render function (after the AnimateObjects method), it would be wasteful for us to pass true to the CActor::AdvanceTime method. The result would be a redundant and pointless hierarchy traversal. If we passed true to CActor::AdvanceTime, the hierarchy frames would be generated and the absolute world matrices for each frame constructed and stored. However, when CScene::Render calls CActor::SetWorldMatrix, the absolute matrices we just generated would be obsolete because we have just re-positioned the root node of the actor. Thus, all absolute frame matrices would need to be rebuilt again. Many of the actor methods expose this UpdateFrames Boolean option, but you only want to pass true to the final one called before rendering.

To summarize, using our actor class requires the following steps (some of which are optional):

1. Create a CActor object.
2. Use CActor::RegisterCallback method to register any callback functions for callback key registration and texture and material parsing. (OPTIONAL).
3. Set the desired maximum extents of the actor using the CActor::SetActorLimits method. (OPTIONAL)
4. Load the X file into the actor using CActor::LoadActorFromX.
5. During every iteration of your game loop:
    a. Increment the actor's internal clock using CActor::AdvanceTime (will update the actor's frame matrices).
    b. Set the world matrix for the actor using CActor::SetWorldMatrix.
    c. Render the actor by looping through each subset and calling CActor::DrawSubset.

CActor Utility Functions

We have already discussed the core functions of the actor and saw how easy it is to operate via its interface. However, the actor must also expose many utility functions to allow the application to get and set the properties of the underlying animation controller. For example, the application will want the ability to assign different animation sets to different tracks and to control the global time of the controller. The application will also want to be able to register sequencer events and change the properties of a mixer track to control how animation sets are blended. These are all methods exposed by the ID3DXAnimationController interface which are now (for the most part) wrapped by CActor. Let us take a look at them now.

CActor::ResetTime

CActor::ResetTime can be called to reset the global clock of the animation controller to zero. The reason an application might want to do this is related to the fact that with each call to CActor::AdvanceTime, the global time of the controller gets higher and higher. If the application was left running for a very long time, this global time would eventually reach a very high number. If left long enough, it might loop round to zero by itself, causing jumps in the animation. Furthermore, as sequencer events are registered on the global timeline, this is our only means for returning the global clock of the controller back to zero so that those sequencer events can be triggered again.

This function wraps the ID3DXAnimationController::ResetTime method. The reset time method is a little more complicated than it might first seem. Not only does it reset the global timer of the controller back to zero, but it also wraps around each of the track timers. It does not simply set them to zero since this would cause jumps in the animation. Instead it wraps them around such that the track timer is as close to zero as possible without altering the periodic position of the animation set currently being played. This function is designed to reset the global time to 0.0 while retaining the current periodic position for all playing tracks.

```
void CActor::ResetTime( bool UpdateFrames /* = false */ )
{
    if ( !IsLoaded() ) return;

    // Set the current time if applicable
    if ( m_pAnimController ) m_pAnimController->ResetTime( );

    // Update the frame matrices
    if ( UpdateFrames ) UpdateFrameMatrices( m_pFrameRoot, &m_mtxWorld );
}
```

Notice how this function also has the UpdateFrames Boolean so that the application can force an immediate rebuild of the hierarchy's absolute frame matrices. For example, if this is the last CActor method you are calling prior to rendering the actor's subset you might decide to do this. Normally, you will pass false as this parameter (the default).

CActor::GetTime

This method wraps the ID3DXAnimationController::GetTime method. It returns the current accumulated global time of the animation controller.

```
double CActor::GetTime( ) const
{
    if ( !m_pAnimController) return 0.0f;
    return m_pAnimController->GetTime();
}
```

The GetTime method is useful if an animation wants to perform its own looping logic. For example, imagine that a given animation plays out for 25 seconds and that the track the animation set is assigned to has several sequencer events registered within that time frame. Because sequencer events are on the global timeline, even if the animation set was configured to loop, each sequencer event would only be triggered once. Once the global time of the controller increased past 25 seconds, it would continue to grow and the events would never be triggered again. However, if the application wants these sequencer events to loop with the animation set, it could retrieve the global time of the actor using CActor::GetTime and, if it has climbed over a certain threshold, reset back to zero. This would cause the time to reset every 25 seconds in our example. Thus, the animation set would loop and the sequencer events on the global timeline would be triggered each time.

CActor::GetMaxNumTracks

This function returns the number of tracks currently available on the animation controller. It is a wrapper around the ID3DXAnimationController::GetMaxNumTracks method. For example, the application might use this method to query the current number of tracks available on the mixer and if not enough, the application could call the CActor::SetActorLimits method to extend this numer.

```
ULONG CActor::GetMaxNumTracks( ) const
{
    if ( !m_pAnimController ) return 0;
    return m_pAnimController->GetMaxNumTracks();
}
```

Assigning Animation Sets to Mixer Tracks

The application will often need the ability to assign different animation sets to tracks on the animation mixer. For example, imagine the actor is a game character. When the actor is in a walking state, the application would probably just assign a walking animation set to a mixer track and play that track on its own. But if the character were to suddenly fire its weapon, the application would also want to assign a firing animation set to another track and blend the two animations together so that the character appears to continue walking and fire his weapon. The ID3DXAnimationController interface exposes a single method for this purpose called ID3DXAnimationController::SetTrackAnimationSet. This function

accepts a track number and a pointer to the animation set interface you wish to assign to that track. This must be an animation set that has been previously registered with the animation controller.

Setting a track in this way can sometimes seem a rather clunky approach. Often, our application may not have a pointer to the interface of the animation set, which means it must be retrieved from the controller first (performing a search by name or by index). It would be much nicer if our actor also allowed the application to specify the name of an animation set or its index as well. For example, if we know that we have an animation set called 'Fire' which we wish to assign to track 1, we would first have to retrieve an interface pointer by calling ID3DXAnimationSet::GetAnimationSetByName, and then pass the returned animation set interface into the SetTrackAnimationSet interface. To remove this burden from the application, our CActor actually exposes three methods (SetTrackAnimationSet, SetTrackAnimationSetByName, and SetTrackAnimationSetByIndex) that can be used to assign animation sets to mixer tracks in a variety of different ways.

These methods allow the application to bind an animation set to a mixer track using either its interface, its numerical index within the controller or by using the name of the animation set. They are shown below with a brief discussion of each.

CActor::SetTrackAnimationSet

This method is a wrapper around its ID3DXAnimationController counterpart. The application must pass two parameters; the first should be the zero based index of the mixer track that the specified animation set should be assigned to and the second should be the ID3DXAnimationSet interface pointer we wish to set.

```
HRESULT CActor::SetTrackAnimationSet(ULONG TrackIndex,
                                     LPD3DXANIMATIONSET pAnimSet )
{
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Set anim set
    return m_pAnimController->SetTrackAnimationSet( TrackIndex, pAnimSet );
}
```

This function forwards the parameters to the ID3DXAnimationController::SetTrackAnimationSet method. In order to use this method, the application must already have an interface to the animation set it wishes to assign to a track. We can use the CActor::GetAnimationSet method (discussed in a moment) for this purpose.

CActor::SetTrackAnimationSetByIndex

We implemented this function to make the assignment of animation sets to mixer tracks a one line call within the application code. If the application knows the zero based index of the animation set it wishes to assign, then this function is the one to use. The application passes the track to assign the animation set to and the index of the animation set.

```
HRESULT CActor::SetTrackAnimationSetByIndex( ULONG TrackIndex, ULONG SetIndex )
{
    HRESULT hRet;
    LPD3DXANIMATIONSET pAnimSet = NULL;

    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Retrieve animation set by index
    hRet = m_pAnimController->GetAnimationSet( SetIndex, &pAnimSet );
    if ( FAILED(hRet) ) return hRet;

    // Set anim set
    hRet = m_pAnimController->SetTrackAnimationSet( TrackIndex, pAnimSet );

    // Release the one we retrieved
    pAnimSet->Release();

    // Return result
    return hRet;
}
```

This method automates some of the work the application would usually have to do. It calls the ID3DXAnimationController::GetAnimationSet method to retrieve an interface to the animation set at the specified index. As discussed in the textbook, this method accepts an index and the address of an ID3DXAnimationSet interface pointer. If a valid animation set exists in the controller at the specified index, its interface will be returned in the second parameter. We then pass this interface into the ID3DXAnimationController::SetTrackAnimationSet method, along with the track index, to perform the actual track assignment. Notice that we release the interface that was returned from ID3DXAnimationController::GetAnimationSet so the object's reference count is correctly maintained.

CActor::SetTrackAnimationSetByName

This final track setting method is almost identical to the previous function in way that it behaves. This time, the function should be passed a track index and a string containing the name of the animation set we wish to assign to the specified mixer track.

The function uses the ID3DXAnimationController::GetAnimationSetByName method, which is passed the name of the animation set and the address of an ID3DXAnimationSet interface pointer. If an animation set with the specified name exists within the animation controller, on function return, the pointer passed as the second parameter will point to the interface of this animation set. Once the animation set interface has been retrieved, we can bind it to the desired track using the ID3DXAnimationController::SetTrackAnimationSet method as we have done in the previous two methods.

```
HRESULT CActor::SetTrackAnimationSetByName( ULONG TrackIndex, LPCTSTR SetName )
{
    HRESULT hRet;
    LPD3DXANIMATIONSET pAnimSet = NULL;
```

```
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Retrieve animation set by name
    hRet = m_pAnimController->GetAnimationSetByName( SetName, &pAnimSet );
    if ( FAILED(hRet) ) return hRet;

    // Set anim set
    hRet = m_pAnimController->SetTrackAnimationSet( TrackIndex, pAnimSet );

    // Release the one we retrieved
    pAnimSet->Release();

    // Return result
    return hRet;
}
```

Using CActor to Alter Mixer Track Properties

As discussed in the textbook, the animation controller will have an internal multi-track animation mixer available for use. Much like an audio mixing desk, each track has a number of properties that can be altered to change the way the animation set is played and combined into the final result. We can enable or disable a track midway through an animation, alter the track position to adjust the timeline of a single animation set, change the speed at which the track position is incremented with respect to the global timer, and change the weight of a track so that the SRT data contributes more or less to the final matrix generated for that frame.

The ID3DXAnimationController provides methods to allow our application to perform all of these tasks, and so too will our CActor. In the next section, we will look at a series of small wrapper functions around the corresponding animation controller methods that manage the animation mixer properties and behavior.

CActor::SetTrackPosition

This method allows the application to alter the timer of a single track on the mixer. We pass in the index of the track we wish to alter and the new position we would like to set the track's timer to. Remember that this is track time (not periodic animation set time) that we are setting here. Since the track position is mapped to a periodic position, altering the track position allows us to manually jump, skip, or pause an animation. For example, if we called this function in our game loop passing in the same track position each time, the animation would appear frozen. This is because the same track position would be mapped to the same periodic position resulting in identical SRT data. Of course, if the animation set was also being blended with other tracks, only its contribution would be frozen. The other tracks would continue to play out as expected.

```
HRESULT CActor::SetTrackPosition( ULONG TrackIndex, DOUBLE Position )
{
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;
```

```
    // Set the position within the track.
    return m_pAnimController->SetTrackPosition( TrackIndex, Position );
}
```

CActor::SetTrackEnable

This function is passed a track index and a Boolean variable. If the Boolean is set to true, the track will be enabled and any animation set assigned to that track will play out as expected. The track will remain enabled until it is disabled. If false is passed, the specified track will be disabled and will remain so until it is re-enabled by the application. When a track is disabled, it will be ignored by the animation controller. Any animation set assigned to that track will not contribute to the frame hierarchy the next time AdvanceTime is called.

```
HRESULT CActor::SetTrackEnable( ULONG TrackIndex, BOOL Enable )
{
    // Validate
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Set the details
    return m_pAnimController->SetTrackEnable( TrackIndex, Enable );
}
```

CActor::SetTrackPriority

In the textbook we learned that each track on the mixer can be assigned to one of two priority blend groups. The fact that these groups are referred to as high and low priority is perhaps a bit misleading as the blend ratio between these two groups can be altered such that the low priority group could contribute more to the frame hierarchy than the high priority group.

This method allows us to assign a track to one of the two priority groups. We specify the priority group using the D3DXPRIORITY_TYPE enumeration shown below:

```
typedef enum _D3DXPRIORITY_TYPE
{
    D3DXPRIORITY_LOW = 0,
    D3DXPRIORITY_HIGH = 1,
    D3DXEDT_FORCE_DWORD = 0x7fffffff
} D3DXPRIORITY_TYPE;
```

```
HRESULT CActor::SetTrackPriority( ULONG TrackIndex, D3DXPRIORITY_TYPE Priority )
{
    // Validate
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Set the details
    return m_pAnimController->SetTrackPriority( TrackIndex, Priority );
}
```

CActor::SetTrackSpeed

We discussed in the textbook that each track has its own independant position and its own speed (set to 1.0 by default). Using this method we can speed up/slow down the rate at which a single animation set is playing without affecting animation sets assigned to any other tracks on the mixer. The application passes this function the index of the track and the new speed.

```
HRESULT CActor::SetTrackSpeed( ULONG TrackIndex, float Speed )
{
    // Validate
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Set the details
    return m_pAnimController->SetTrackSpeed( TrackIndex, Speed );
}
```

The track speed is changed internally by the controller. It uses the track speed property to scale the elapsed time passed into the AdvanceTime method before adding the result to the track position. As a simple example, let us imagine we pass in an elapsed time of 5 seconds. Five seconds would be added to the global clock of the animation controller. Now the controller needs to add this elapsed time to the position of each track to update the track timelines also. However, before it does this, it scales elapsed time by the track speed. If we imagine that the track speed was set to 3.0 and that the current track position was 20.0, the track position would be updated like so:

TrackPosition =20
ElapsedTime = 5
Track Speed = 3.0

NewTrackPosition = TrackPosition + (ElapsedTime * TrackSpeed)
= 20 + (5 * 3)
= 20 + 15
= 35

If we imagine that another currently active mixer track also has a track position of 20 but only has a track speed of 0.5 we can see that the track position for this track would be updated much less during thr same advance time call:

TrackPosition = 20
ElapsedTime = 5
Track Speed = 0.5

NewTrackPosition = TrackPosition + (ElapsedTime * TrackSpeed)
= 20 + (5 * 0.5)
= 20 + 2.5
= 22.5

As you can see, the first animation set will appear to play much quicker than the second one in a single update. In the first case, with an elapsed time of 5 seconds, the timeline of the track was actually updated 15 seconds to a new track position of 35 seconds. The second animation set was advanced only by 2.5 seconds to a new track position of 22.5 seconds.

CActor::SetTrackWeight

The weight of a track controls how strongly the SRT data generated by its assigned animation set contributes to the overall hierarchy. It also controls the weight at which it is blended with other animation sets/tracks assigned to the same priority group.

```
HRESULT CActor::SetTrackWeight( ULONG TrackIndex, float Weight )
{
    // Validate
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Set the details
    return m_pAnimController->SetTrackWeight( TrackIndex, Weight );
}
```

The default weight for each track is 1.0. This means that the SRT data generated by the animations of the animation set will not be scaled and will influence the hierarchy at full strength. If the weight of track A is set to 0.5 and the weight assign to track B is 1.0 and they both belong to the same priority group, the animation set assigned to track B will influence the hierarchy more strongly than track A. Setting track weights is very important as it allows you to find the right balance when multiple animations are being blended and played. We will see many examples of multi-track animation blending as we progress through the course.

CActor::SetTrackDesc

The actor also exposes a function that allows the application to set all the track properties with a single function call. This function is a wrapper around ID3DXAnimationController::SetTrackDesc. It accepts a track index and a pointer to a D3DXTRACK_DESC structure which contains the new properties for the track

```
HRESULT CActor::SetTrackDesc( ULONG TrackIndex, D3DXTRACK_DESC * pDesc )
{
    // Validate
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Set the details
    return m_pAnimController->SetTrackDesc( TrackIndex, pDesc );
}
```

Here we see the D3DXTRACK_DESC structure as a reminder:

```
typedef struct _D3DXTRACK_DESC {
    D3DXPRIORITY_TYPE Priority;
    FLOAT Weight;
    FLOAT Speed;
    DOUBLE Position;
    BOOL Enable;
} D3DXTRACK_DESC, *LPD3DXTRACK_DESC;
```

Retrieving the Properties of a Mixer Track

Just as an application using our actor will need the ability to set track properties on the animation mixer, it will also need a means for retrieving the current values being used by those mixer tracks. The ID3DXAnimationController exposes two methods that allow the application to retrieve the properties of the mixer.

CActor::GetTrackDesc

CActor::GetTrackDesc is the exact opposite of the method previously discussed. The application passes in the track number it wishes to retrieve properties for and the address of a D3DXTRACK_DESC structure. On function return, this structure will be filled with the properties of the specified mixer track.

```
HRESULT CActor::GetTrackDesc( ULONG TrackIndex, D3DXTRACK_DESC * pDesc ) const
{
    // Validate
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Get the details
    return m_pAnimController->GetTrackDesc( TrackIndex, pDesc );
}
```

CActor::GetTrackAnimationSet

The second method exposed by the animation controller to communicate track properties to the application is ID3DXAnimationController::GetTrackAnimationSet. This allows an application to retrieve an interface to the animation set currently assigned to a mixer track.

This function is passed only a track index and returns a pointer to an ID3DXAnimationSet interface for that animation set assigned to the track.

```
LPD3DXANIMATIONSET CActor::GetTrackAnimationSet( ULONG TrackIndex ) const
{
    LPD3DXANIMATIONSET pAnimSet;

    // Validate
    if ( !m_pAnimController ) return NULL;

    // Get the track details (calls AddRef) and return it
    if ( FAILED(m_pAnimController->GetTrackAnimationSet( TrackIndex, &pAnimSet )))
        return NULL;
    return pAnimSet;
}
```

Setting the Priorty Blend Weight of the Controller

The animation controller has a global property for all tracks called the priority blend weight. It is a single scalar value (usually between 0.0 and 1.0) which determines how the high and low priority track groups on the mixer will be combined during the final blending stage. Setting this value to 0.5 for example, will blend the SRT data generated from both blend groups using a 50/50 mix.

Our actor wraps the ID3DXAnimationController methods for setting and retrieving this blend weight. CActor::SetPriorityBlend and CActor::GetPriortyBlend are two methods exposed to the application for this purpose:

```
HRESULT CActor::SetPriorityBlend( float BlendWeight )
{
    // Validate
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Set the details
    return m_pAnimController->SetPriorityBlend( BlendWeight );

}
```

```
float CActor::GetPriorityBlend( ) const
{
    // Validate
    if ( !m_pAnimController ) return 0.0f;

    // Get the details
    return m_pAnimController->GetPriorityBlend( );
}
```

Querying the Controller's Animation Sets

The ID3DXAnimationController interface exposes methods to allow the application to fetch interfaces for registered animation sets. Unlike the ID3DXAnimationController::GetTrackAnimationSet method, we can use these methods to fetch interfaces for animation sets that are not currently assigned to any track on the animation mixer. Obviously we need to be able to fetch animation sets which are not currently assigned to mixer tracks so that we can assign them to tracks on the mixer. The controller also exposes methods that allow the application to query the number of animation sets currently registered with the controller as well as the maximum number supported.

This collection of functionality is covered by four different actor methods. The first method allows the application to query the maximum number of animation sets that can be registered with the animation controller simultaneously:

```
ULONG CActor::GetMaxNumAnimationSets( ) const
{
    if ( !m_pAnimController ) return 0;
    return m_pAnimController->GetMaxNumAnimationSets( );
}
```

The second method allows the application to query the number of animation sets that are currently registered with the animation controller:

```
ULONG CActor::GetAnimationSetCount( ) const
{
    // Validate
    if ( !m_pAnimController ) return 0;

    // Return the count
    return m_pAnimController->GetNumAnimationSets( );
}
```

The next two methods allow us to fetch interfaces to animation sets that are currently registered with the controller. The first method allows us to fetch the animation set interface using an index. This is the zero based index of the animation set within the controllers's array of registered animation sets:

```
LPD3DXANIMATIONSET CActor::GetAnimationSet( ULONG Index ) const
{
    LPD3DXANIMATIONSET pAnimSet;

    // Validate
    if ( !m_pAnimController ) return 0;

    // Get the animation set and return it
    if ( FAILED( m_pAnimController->GetAnimationSet( Index, &pAnimSet ) ))
        return NULL;
    return pAnimSet;
}
```

Your application may not always know the index of an animation set it wishes to fetch, but may know the name of the animation. This second function allows us to pass in a string containing the name of the animation set we wish to retrieve an interface for. As with the above function, this one wraps the call to its ID3DXAnimationController counterpart. If an animation set is registered with the animation controller which matches the name passed into the function, an ID3DXAnimationSet interface to that animation set will be returned:

```
LPD3DXANIMATIONSET CActor::GetAnimationSetByName( LPCTSTR strName ) const
{
    LPD3DXANIMATIONSET pAnimSet;

    // Validate
    if ( !m_pAnimController ) return 0;

    // Get the animation set and return it
    if ( FAILED( m_pAnimController->GetAnimationSetByName( strName, &pAnimSet ) ))
```

```
        return NULL;
    return pAnimSet;
}
```

Registering Track Events with the Animation Sequencer

As discussed in the textbook, the animation controller includes an event sequencer that allows an application to schedule track property changes for a specific global time. Just as each property of a mixer track can be set with a call to one of the SetTrackXX methods discussed ealier, each track property also has a method in the ID3DXAnimationController for scheduling that track property change to occur at a specific time. Our CActor has wrapped these methods and the source code to these functions will be dicussed in this section. Since these are simply wrapper functions around the methods of the animation controller (discussed in the main course text), these functions will requite little explanation.

> **Note:** When using these sequencer functions, remember that events are specified in global time. That is, the global time of the controller is incremented with each AdvanceTime call. Global time does not loop unless the timer is specifically reset using CActor::ResetTime. Also remember that the global time of the controller may be very different from the time of a specific track. This will be true if the track position has been manipulated by the application (see CActor::SetTrackPosition) or if the speed of a track is not the default. If the global time is never reset and continues to increment, a registered sequencer event will only ever occur once. This is true even if the animation set assigned to that track is configured to loop.

CActor::KeyTrackEnable

This method can be used by the application to schedule a track to be enabled or disabled at a specific global time. The application should pass in the track index as the first parameter and the second parameter should be set to true or false indicating whether the track should be enabled or disabled by this event. The third parameter is the global time at which this event should occur.

```
D3DXEVENTHANDLE CActor::KeyTrackEnable( ULONG TrackIndex, BOOL NewEnable,
                                        double StartTime )
{
    // Validate
    if ( !m_pAnimController ) return NULL;

    // Send the details
    return m_pAnimController->KeyTrackEnable( TrackIndex, NewEnable, StartTime );
}
```

Our method simply forwards the request on to the animation controller. This method is a sequencer version of the CActor::SetTrackEnable method discussed previously.

CActor::KeyTrackPosition

This method allows the application to schedule a track position manipulation at a specified global time. Essentially it allow us to manipulate track time at a specified global time. It is important that we distinguish between the two different timelines being used here. As the first paramater the track index is passed for which the position will be changed. As the second parameter we pass in the new track position that we would like this track to be set to at the time when this event is triggered.

The 'NewPosition' is specified in track time, not global time and not as a periodic position. We might for example set this NewPosition to 20 seconds for example. If the animation had a period of 10 seconds, then this would essentially cause the animation to jump to the beginning of its 3rd iteration (if looping is enabled for this animation set). This is because a track position of 20 seconds would be mapped to a periodic position of 0 seconds for a looping animation with a 10 second period.

The third parameter is the time at which we would like this track position change event to occur. Unlike the second parameter, this is not specified in track time but is instead specified in global time which might be quite different. As mentioned, the sequencer events are registered on the global time line.

```
D3DXEVENTHANDLE CActor::KeyTrackPosition( ULONG TrackIndex, double NewPosition,
                                          double StartTime )
{
    // Validate
    if ( !m_pAnimController ) return NULL;

    // Send the details
    return m_pAnimController->KeyTrackPosition(TrackIndex,NewPosition,StartTime);
}
```

This method is the sequencer version of the CActor::SetTrackPosition method discussed previously.

CActor::KeyTrackSpeed

This method allows the application to schedule a track speed property change to occur at a specified global time. We pass in the track index and the new speed we would like this track to be set to when the event is triggered. The third parameter is the global time at which we would like this event to be triggered. The fourth parameter is the event duration (in seconds). The duration describes how many seconds we would like it to take, after the event has been triggered, to transition the current speed to the new speed. This feature (along with the next parameter) allows us to schedule smoother transitions.

```
D3DXEVENTHANDLE CActor::KeyTrackSpeed( ULONG TrackIndex, float NewSpeed,
                                       double StartTime, double Duration,
                                       D3DXTRANSITION_TYPE Transition )
{
    if ( !m_pAnimController ) return NULL;

    // Send the details
    return m_pAnimController->KeyTrackSpeed( TrackIndex, NewSpeed,
                                             StartTime, Duration, Transition );
}
```

The fifth parameter is a member of the D3DXTRANSITION_TYPE enumeration which describes how we would like the change from the current speed to the new speed to occur over the specified duration. The two choices are linear interpolation and spline based interpolation.

```
typedef enum _D3DXTRANSITION_TYPE {
    D3DXTRANSITION_LINEAR = 0x000,
    D3DXTRANSITION_EASEINEASEOUT = 0x001,
    D3DXEDT_FORCE_DWORD = 0x7fffffff
} D3DXTRANSITION_TYPE;
```

Whichever transition type we use, the change from the old speed to the new speed will still be performed within the specified duration. If linear is being used then the current speed will linearly ramp up/down from the old speed to the new speed over the duration. If ease-in ease-out is used, the speed change will start off slowly, gradually increase until some maximum, level off, and then, when near the end of the specified duration, the speed change will decrease until the final target is reached. As the member of the enumerated type suggests, this changes the speed in a more natural way, speeding up and slowing down at the outer ends of the duration.

This method is the sequencer version of the SetTrackSpeed method discussed previously.

CActor::KeyTrackWeight

This method allows the application to schedule a weight change for a specified track at a specified global time. By sequencing weight change events, we can essentially script the strength at which an animation set influences the frame hierarchy over a period of time.

```
D3DXEVENTHANDLE CActor::KeyTrackWeight( ULONG TrackIndex, float NewWeight,
                                        double StartTime, double Duration,
                                        D3DXTRANSITION_TYPE Transition )
{
    // Validate
    if ( !m_pAnimController ) return NULL;

    // Send the details
    return m_pAnimController->KeyTrackWeight( TrackIndex, NewWeight, StartTime,
                                              Duration, Transition );
}
```

This function, like the previous one, also accepts a duration and transition type parameter. This allows the weight of the track to be changed from its current weight (at the time the event is triggered) to its new weight, over a specified time in seconds (the Duration parameter). The transition type once again controls whether we wish the change from the current weight to the new weight of the track to be interpolated linearly or using a spline based approach.

This method is the sequencer version of the CActor::SetTrackWeight method discussed previously.

Registering Priorty Blend Changes with the Sequencer

The animation controller has a global property called the *priority blend*. This value is usually set between zero and one and is used to weight the contributions of the high and low priority groups that are blended together in the final mixing stage.

As discussed in the textbook, mixer tracks can be assigned to one of two priority groups (high or low). When AdvanceTime is called, the SRT data for each animation set is generated. Once we have the SRT data generated from each track, all SRT data belong to tracks in the same priority groups are blended together using their track weights to weight their contribution in the mix. This is done for both the high and low priority groups. At this point, the animation controller has two groups of SRT data: the output from the low priority mixing phase and the output from the high priority mixing phase. Once this is output is prepared, the SRT data in these two groups is blended together. The priority blend value of the controller is used to weight the contribution of the two groups in the final mix. The output of this final stage is a single set of SRT data used to rebuild the relative matrix of the attached animated frame.

```
D3DXEVENTHANDLE CActor::KeyPriorityBlend( float NewBlendWeight, double StartTime,
                                          double Duration,
                                            D3DXTRANSITION_TYPE Transition )
{
    // Validate
    if ( !m_pAnimController ) return NULL;

    // Send the details
    return m_pAnimController->KeyPriorityBlend( NewBlendWeight,
                                                StartTime, Duration, Transition );
}
```

Just like the track speed and weight changes, when we schedule an event to change the priority blend weight, we can also specify a duration and transition type. This allows us to slowly change the priority blend weight from its old value to the new one.

This method is the sequencer version of the CActor::SetPriorityBlend method discussed previously.

Removing Sequencer Events from the Global Timeline

There may be times when you need to un-register a sequencer event. Perhaps your application has reset the global time of the controller but does not wish a certain event to be triggered again the second time through. This next series of methods allow the application to unregister sequencer events in a variety of different ways.

CActor::UnkeyEvent

The ID3DXAnimationController has an UnkeyEvent method that we have wrapped in CActor::UnkeyEvent. The method is passed the event handle of the event you wish to unregister. All

event registration functions return a D3DXEVENTHANDLE, which is a unique ID for that sequencer event. If you wish to perform some action on that event later (e.g., remove it), this is the handle that you can use to identify this specific event to the D3DX animation system.

If the passed D3DXEVENTHANDLE matches the handle of an event currently registered on the global timeline, this method will remove it. This method can be used to unregister all event types (weight, speed, position, etc). The animation controller will automatically know which type of event it is and which track that event has to be removed from based on the passed event handle.

```
HRESULT CActor::UnkeyEvent( D3DXEVENTHANDLE hEvent )
{
    // Validate
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Send the details
    return m_pAnimController->UnkeyEvent( hEvent );
}
```

CActor::UnkeyAllTrackEvents

This method removes all events that currently exist for a given track. The application simply passes in the index of the track and the controller will remove any events that have been registered for that track.

```
HRESULT CActor::UnkeyAllTrackEvents( ULONG TrackIndex )
{
    // Validate
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Send the details
    return m_pAnimController->UnkeyAllTrackEvents( TrackIndex );
}
```

Events that have been registered for other mixer tracks are not affected by this method. Note as well that priority blend events are *not* removed by this method. This is because priority blend events are not specific to a given track but instead alter the priority blend weight of the animation controller, which is used by all tracks. Any tracks events that were previously registered with the track index passed into the function will no longer be valid when the function returns.

CActor::UnkeyAllPriorityBlends

Priority blend events are unlike all other event types because they are not track specific. Instead, they alter a global property of the controller. Because of this, the CActor::UnkeyAllTrackEvents method cannot be used to unregister events of this type. The CActor::UnkeyAllPriorityBlends method should be used to clear all priority blend events from the global timeline.

```
HRESULT CActor::UnkeyAllPriorityBlends( )
{
    // Validate
```

```
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Send the details
    return m_pAnimController->UnkeyAllPriorityBlends( );
}
```

Validating Events

The CActor::ValidateEvent function can be used to test if an event is still valid. Valid events are events which have not yet been executed (because the global time is smaller than the timestamp of the event) or events that are currently being executed. The method accepts a single parameter, the D3DXEVENTHANDLE of the event you wish to validate. Any event whose timestamp is less than the global time of the controller is considered invalid.

```
HRESULT CActor::ValidateEvent( D3DXEVENTHANDLE hEvent )
{
    // Validate
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Send the details
    return m_pAnimController->ValidateEvent( hEvent );
}
```

When the global time of the controller is reset, all events that were previously considered invalid become valid again. The exception of course, is if you pass in the handle of an event that your application has since un-registered.

Fetching the Details for an Upcoming Event

It is often useful for an application to know when a sequencer event is currently being executed so that the application can perform some action when the event is triggered. This is much like how an application might respond to a callback function. However, a callback method is not used for this purpose. Instead, the application can poll for an event type on a specific track or poll for a currently executing priority blend event using this next series of functions. If an event is currently being executed that fits the specified criteria, the handle of the event will be returned. The CActor::GetEventDesc method can then be used to fetch the event details of this event using the passed event handle.

CActor::GetCurrentTrackEvent

This method is used to test if an event is currently being executed on a given track. The function accepts two parameters. For the first parameter, the application should pass the index of the track for which it is requesting event information. For the second parameter, the application should pass a member of the D3DXEVENT_TYPE enumeration specifying the type of events it is interested in being informed about.

This method just wraps the corresponding ID3DXAnimationController method. If an event of the specified type is currently being executed on the specified track, the handle of the event will be returned from the method.

```
D3DXEVENTHANDLE CActor::GetCurrentTrackEvent( ULONG TrackIndex,
                                              D3DXEVENT_TYPE EventType ) const
{
    // Validate
    if ( !m_pAnimController ) return NULL;

    // Send the details
    return m_pAnimController->GetCurrentTrackEvent( TrackIndex, EventType );
}
```

The D3DXEVENT_TYPE enumeration is defined as follows in the DirectX header files.

```
typedef enum _D3DXEVENT_TYPE {
    D3DXEVENT_TRACKSPEED = 0,
    D3DXEVENT_TRACKWEIGHT = 1,
    D3DXEVENT_TRACKPOSITION = 2,
    D3DXEVENT_TRACKENABLE = 3,
    D3DXEVENT_PRIORITYBLEND = 4,
    D3DXEDT_FORCE_DWORD = 0x7fffffff
} D3DXEVENT_TYPE;
```

Passing D3DXEVENT_PRIORITYBLEND into this method will never return a valid handle since priority blend events are not track events.

CActor::GetCurrentPriorityBlend

This method accepts no parameters and will return the handle of the currently executing priority blend event. If no priority blend event is being executed then the function will return NULL.

```
D3DXEVENTHANDLE CActor::GetCurrentPriorityBlend( ) const
{
    // Validate
    if ( !m_pAnimController ) return NULL;

    // Send the details
    return m_pAnimController->GetCurrentPriorityBlend( );
}
```

CActor::GetEventDesc

This method can be used to fetch the details of any sequencer event registered on the global timeline. It accepts two parameters. The first parameter is the handle of the event for which information is to be retrieved (via parameter two). This could be the handle returned from either the CActor::GetCurrentPriorityBlend or CActor::GetCurrentTrackEvent if you wish to retrieve information

about an event that is currently being executed. The method simply wraps its ID3DXAnimationController counterpart.

```
HRESULT CActor::GetEventDesc( D3DXEVENTHANDLE hEvent, LPD3DXEVENT_DESC pDesc )
const
{
    // Validate
    if ( !m_pAnimController ) return D3DERR_INVALIDCALL;

    // Send the details
    return m_pAnimController->GetEventDesc( hEvent, pDesc );
}
```

CActor Utility Functions

The final two methods of the CActor interface fall into the category of utility functions. These are methods that you are not likely to use very often when integrating CActor into your day-to-day projects, but they do come in handy when using the CActor class as part of a tool. The first method is simply an upgrade from Lab Project 9.1.

CActor::SaveActorToX

This method is used to save the actor out to an X file. Unlike the previous version of this function, we now pass the D3DXSaveMeshHierarchyToFile function the address of the animation controller interface. This will ensure that D3DX will save the frame and mesh data to the X file as well as the animation data. This single change to this function is highlighted in bold in the listing below.

```
HRESULT CActor::SaveActorToX( LPCTSTR FileName, ULONG Format )
{
    HRESULT hRet;

    // Validate parameters
    if ( !FileName ) return D3DERR_INVALIDCALL;

    // If we are NOT managing our own attributes, fail
    if ( GetCallback( CActor::CALLBACK_ATTRIBUTEID ).pFunction != NULL )
         return D3DERR_INVALIDCALL;

    // Save the hierarchy back out to file
    hRet = D3DXSaveMeshHierarchyToFile( FileName, Format,
                                        m_pFrameRoot, m_pAnimController,
                                        NULL );
    if ( FAILED(hRet) ) return hRet;

    // Success!!
    return D3D_OK;
}
```

CActor::ApplySplitDefinitions

This next function is a large one, but the code does not use any techniques we have not yet encountered. Before examining the code, let us first discuss the service this method is intended to provide and why an application would be interested in such a service.

As discussed in the textbook, some X file exporters only support saving animated X files with a single animation set. The Deep Exploration™ plugin for 3D Studio Max™ supports multiple animation set export and is a really excellent X file exporter. If you can afford both 3D Studio and this plugin, you would be hard pressed to find a better and easier solution. However, most students just getting started in their game programming studies simply cannot afford such professional tools. So a workaround for this problem is often needed.

One way to get around this problem requires artist participation. The artist can store all the animation sequences for a given object directly after each other on a single timeline. For example, if an artist was building animation data for a game character, he might use the first 10 seconds of the timeline to store the walking animation, the next 10 seconds to store the idle animation, the next 10 seconds for the death animation, and so on. If this character's animation was played back in this arrangement, it would essentially cycle through all possible animations that the character is capable of as the timeline is traversed from start to finish.

In Lab Project 10.2 we use an X file called 'Boney.x' that has been constructed in this way. Because all the animation sequences are stored on the same timeline and are essentially part of the same animation set (as far as the modeling application is concerned), this X file can be exported by applications that support saving only a single animation set. All the animation data we need will be saved in the X file.

The problem is that all of these sequences will exist in a single animation set and this is far from ideal. Normally, we would like these animations to be stored in separate animation sets so that each individual sequence can be played back by the animation controller in isolation. We would also like the ability to blend, for example, a walking animation sequence with a firing animation sequence. We know that in order to accomplish this, we must have those two sequences in different animation sets so that they can be assigned to different tracks on the animation mixer. But having been supplied with this X file which contains all the animation data in a single set, what are we to do?

Our answer was to implement a new method for CActor called ApplySplitDefinitions, which allows us to correct this problem after the X file has been loaded. This method will allow the application to pass in an array of split definition structures. Each structure will describe how we would like a section of the current 'single' animation set to be copied into a new animation set. For example, if we had a single animation set with five sequences stored in it, this function could be used to break it into five separate animation sets. Each split definition structure that we pass in would contain the start and end positions on the original 'combined' timeline where the new animation set will start and end. It would also contain the name that we would like to call this new animation set. Once the method returns, the original animation set would have been released and we would now have five separate animation sets in its place.

This approach does require that the artist let us know the start and end positions of each sequence in the set so that our code can correctly fill in the split definition structures before passing them to the ApplySplitDefinitions function. However, this can also prove to be a limitation, especially if the artist is not available for us to question. So we have designed something that negates the need for even that requirement.

In Lab Project 10.2 we will develop the source code for a tool called The Animation Splitter. It is a simple dialog box driven GUI tool wrapped around the CActor::ApplySplitDefinitions method. The Splitter will allow us to graphically set markers on the combined timeline and apply the splits into separate sets. Behind the scenes this tool will call the CActor::ApplySplitDefinitions method to split the animation set into multiple animation sets based on the markers you set via the user interface. Then you can save the actor back out to an X file with its newly separated animation sets.

Whether you use this tool to split up your combined animations as a pre-process or use the CActor::ApplySplitDefinitions method in your main code after loading the X file is up to you. Bear in mind that after you have applied the splits, you can always use the CActor::SaveActorToX method to save the data back out to file in its new form. This GUI tool is just a user-friendly way to configure the call to CActor::ApplySplitDefinitions. So let us have a look at this final CActor method which will be used by the animation splitter in the next project to do all the heavy lifting.
The CActor::ApplySplitDefinitions method accepts an array of AnimSplitDefinition structures This structure (defined in CActor.h) is shown below.

```
typedef struct _AnimSplitDefinition // Split definition structure
{
    TCHAR   SetName[128];       // The name of the new animation set
    ULONG   SourceSet;          // The set from which we're sourcing the data
    double  StartTicks;         // Ticks at which this new set starts
    double  EndTicks;           // Ticks at which this new set ends
    LPVOID  Reserved;           // Reserved for use internally, do not use.

} AnimSplitDefinition;
```

Each stucture of this type that we pass into the function will describe a new animation set that we wish to create from a segment of an existing one. The members are described below:

TCHAR SetName[128]
This member is where supply the name of the new animation set we wish to be created.

ULONG SourceSet
In this member we supply the index of the animation set currently registered with the controller that we would like the data for this new animation set to be extracted from. In the case of a single combined animation set, this will always be set to zero since the controller will only have one set. However, the function will handle splitting from multiple sources. This is essentially the source information for this definition. It is the set which will have a section of its keyframe data copied into a new animation set. This set will be released after the splits have been applied.

double StartTicks
This is the starting marker on the source set's animation timeline indicating where the section of animation data we wish to copy into a new set begins. For example, if we were supplied a single animation set and informed that the walking sequence for this animation began at tick 400 and ended at tick 800, we would set both the StartTicks and EndTicks members of this structure to 400 and 800 respectively. Any animation data in the source animation set between these two tick positions will be copied into the new set.

double EndTicks
This member describes the end marker for the section of animation data we wish to copy into the new animation set from the source animation set.

LPVOID Reserved
This member is reserved and should not be used.

Let us first look at an example of how an application might use the CActor::ApplySplitDefinitions function, before we cover the code. Continuing our previously discussed example, let us imagine we have loaded an X file into our actor which contains two animation sequences that we would like to divide into two separate animations sets called 'Walk' and 'Run' respectively. Let us also imagine that we are informed by our artist that the walking sequence is contained in the animation timeline between ticks 0 and 400 and the running sequence is contained in the original animation set between ticks 400 and 800. To perform this action, we would write the following code:

```
// Allocate an array for two definitions
AnimSplitDefinition    AnimDefs[2];
UINT                   NumberOfAnimDefs=2;

// Set up definition 1 called 'Walk'
_tcscpy( AnimDefs[0].SetName, _T("Walk") );
AnimDefs[0].SourceSet   =     0
AnimDefs[0].StartTicks  =     0
AnimDefs[0].EndTicks    =     400

// Set up defnition 2 called 'Run'
_tcscpy( AnimDefs[1].SetName, _T("Run") );
AnimDefs[0].SourceSet   =     0
AnimDefs[0].StartTicks  =     400
AnimDefs[0].EndTicks    =     800

// Create the two new animation sets and release the original ( set 0 )
pActor->ApplySplitDefinitions( AnimDefsCount , AnimDefs );
```

That is all there is to the process. The animation controller of the actor now has two separate animation sets called 'Walk' and 'Run' where previously only a single animation set (set 0) exisited. The original animation set will have been unregistered from the controller and freed from memory when the CActor::ApplySplitDefinitions function returns.

Let us now study the code. This is going to be quite a large function so we will need to cover it a step at a time. Fortunately, there is hardly anything here that we have not studied and implemented already, so for the most part it will be easy going.

The first section of the function has the job of cloning the actor's animation controller if it cannot support the number of animation sets passed in the nDefCount parameter. Remember, each split definition in this array is describing a new animation set we would like to create and register with the animation controller. If the animation controller is currently limited to only having two animation sets registered with it, but the application has passed in an array of 10 split definitions, we know we must have an animation controller that is capable of having the 10 new animation sets we are about to create registered with it.

```
HRESULT CActor::ApplySplitDefinitions( ULONG nDefCount,
                                       AnimSplitDefinition pDefList[] )
{
    HRESULT                     hRet;
    LPCTSTR                     strName;
    ULONG                       i, j, k;
    LPD3DXANIMATIONSET          pAnimSet;
    LPD3DXKEYFRAMEDANIMATIONSET pSourceAnimSet, pDestAnimSet;

    D3DXKEY_VECTOR3            *ScaleKeys     = NULL, *NewScaleKeys = NULL;
    D3DXKEY_VECTOR3            *TranslateKeys = NULL, *NewTranslateKeys = NULL;
    D3DXKEY_QUATERNION         *RotateKeys    = NULL, *NewRotateKeys = NULL;

    ULONG                       ScaleKeyCount, RotationKeyCount,
                                TranslationKeyCount, AnimationCount;

    ULONG                       NewScaleKeyCount,
                                NewRotationKeyCount,
                                NewTranslationKeyCount;

    D3DXVECTOR3                 StartScale, EndScale,
                                StartTranslate, EndTranslate;

    D3DXQUATERNION              StartRotate, EndRotate;

    // Validate pre-requisites
    if ( !m_pAnimController || !IsLoaded() || nDefCount == 0 )
        return D3DERR_INVALIDCALL;

    // Clone our animation controller if there are not enough set slots available
    if ( m_pAnimController->GetMaxNumAnimationSets() < nDefCount )
    {
        LPD3DXANIMATIONCONTROLLER pNewController = NULL;

        // Clone the animation controller
        m_pAnimController->CloneAnimationController(
                                  m_pAnimController->GetMaxNumAnimationOutputs(),
                                  nDefCount,
                                  m_pAnimController->GetMaxNumTracks(),
                                  m_pAnimController->GetMaxNumEvents(),
                                 &pNewController );
```

```
        // Release our old controller
        m_pAnimController->Release();

        // Store the new controller
        m_pAnimController = pNewController;

    } // End if too small!
```

Notice in the above code that when we clone the animation controller we feed in all the same controller limits as the current controller, with the exception of the second parameter. This is where we pass in the number of animation sets we will need this new controller to handle. Therefore, the new controller will inherit all the limits of the original controller but with an increase in the number of animation sets that can be registered. The original controller is then released and the actor's controller member pointer assigned the address of our cloned controller.

We will now set up a loop to process each split definition in the passed array. For each one, we will fetch the index of the source set it references. This is the index of the animation set from which the keyframe data will be extracted. If this is not an ID3DXKeyframedAnimationSet then we will skip this definition. Provided it is a keyframed animation set, we create a new ID3DXKeyframedAnimationSet. The name of this set is the name that was specified by the application and passed in the split definition.

```
    // We're now going to start building for each definition
    for ( i = 0; i < nDefCount; ++i )
    {
        // First retrieve the animation set
        if ( FAILED(m_pAnimController->GetAnimationSet( pDefList[i].SourceSet,
                                                        &pAnimSet )) ) continue;

        // We have to query this to determine if it's keyframed
        if ( FAILED( pAnimSet->QueryInterface( IID_ID3DXKeyframedAnimationSet,
                                               (LPVOID*)&pSourceAnimSet ) ) )
        {
            // Release animation set and continue
            pAnimSet->Release();
            continue;

        } // End if failed to retrieve keyframed set

        // We can release the original animation set now, we've 'queried' it
        pAnimSet->Release();

        // Create a new 'destination' keyframed animation set
        D3DXCreateKeyframedAnimationSet(pDefList[i].SetName,
                                        pSourceAnimSet->GetSourceTicksPerSecond(),
                                        pSourceAnimSet->GetPlaybackType(),
                                        pSourceAnimSet->GetNumAnimations(),
                                        0,
                                        NULL,
                                        &pDestAnimSet );
```

Look at the call to the D3DXCreateKeyframedAnimationSet function above. With the exception of the first parameter, where we pass in a new name, we inherit all other properties from the source set (playback type, number of animations, and source ticks per second ratio).

With our new animation set created, our next task is to loop through each animation in the source animation set and extract the scale, rotation, and translation keys into temporary arrays. The following code fetches the SRT key counts for the animation currently being processed. It then allocates SRT arrays to store a copy of the source SRT data. Then, it stores a copy of the SRT key data in the temporary SRT arrays so that we have a complete copy of the keyframe data to work with. Notice that one of the first things we do is fetch the name of the animation we are processing. We will need this later when we wish to register the copy of the animation with the new animation set. We need to make sure that the animation names remain intact since this provides the mapping between the animation data and the frame in the hierarchy it animates.

```
        // Loop through the animations stored in the set
        AnimationCount = pSourceAnimSet->GetNumAnimations();
        for ( j = 0; j < AnimationCount; ++j )
        {
            // Get name
            pSourceAnimSet->GetAnimationNameByIndex( j, &strName );

            // Retrieve all the key counts etc
            ScaleKeyCount           = pSourceAnimSet->GetNumScaleKeys( j );
            RotationKeyCount        = pSourceAnimSet->GetNumRotationKeys( j );
            TranslationKeyCount     = pSourceAnimSet->GetNumTranslationKeys( j );
            NewScaleKeyCount        = 0;
            NewRotationKeyCount     = 0;
            NewTranslationKeyCount  = 0;

            // Allocate enough memory for the keys
            if ( ScaleKeyCount )
                ScaleKeys = new D3DXKEY_VECTOR3[ ScaleKeyCount ];

            if ( TranslationKeyCount )
                TranslateKeys = new D3DXKEY_VECTOR3[ TranslationKeyCount ];

           if ( RotationKeyCount )
                RotateKeys = new D3DXKEY_QUATERNION[ RotationKeyCount ];

            // Allocate enough memory (total) for our new keys,
            // + 2 for potential start and end keys
            if ( ScaleKeyCount )
                  NewScaleKeys = new D3DXKEY_VECTOR3[ ScaleKeyCount + 2 ];

           if ( TranslationKeyCount )
                  NewTranslateKeys = new D3DXKEY_VECTOR3[TranslationKeyCount+ 2 ];

           if ( RotationKeyCount )
                  NewRotateKeys = new D3DXKEY_QUATERNION[ RotationKeyCount + 2 ];

            // Retrieve the physical keys
            if ( ScaleKeyCount )
               pSourceAnimSet->GetScaleKeys( j, ScaleKeys );
```

```
            if ( TranslationKeyCount )
               pSourceAnimSet->GetTranslationKeys( j, TranslateKeys );

            if ( RotationKeyCount )
                 pSourceAnimSet->GetRotationKeys( j, RotateKeys );
```

The inner loop is concerned with copying the keyframe data for a single animation in the source set into a single animation in the destination set. Further, we will only copy over keyframes that fall within the start and end markers specified in the definition. What we must consider however is that the definition may have a start or end marker set between two keyframes in the source set. For example, imagine an animation has two translation keys at 0 and 10 seconds respectively. It is possible that we have placed a start and end marker at 3 and 8 seconds, respectively. Since the only two keyframes that exist fall outside these two markers, we would end up not copying anything into the new animation set. This is certainly not the way it should work.

In such a case, if the start and end markers do not fall on pre-existing keyframe positions, we must generate them ourselves and insert them into the new animation set. In the current example, this means we would need to generate a start and an end keyframe to be inserted at 3 and 8 seconds and. These are the two keyframes that the final animation would contain.

So it seems that we might have a situation where the start or end marker is not situated on pre-existing keyframe positions, and when this is the case we may need to insert a new start or end keyframe (or both, if both markers are between existing keyframes). But how do we generate a scale, rotation and translation key for these ‘in-between’ times?

When you think about this problem, you realize that we are asking a question we have already answered numerous times before. The ID3DXKeyframedAnimationSet::GetSRT method does just that. All we have to do is pass it the start marker position and it will interpolate the correct scale, rotation and translation keys for those in-between times. In the next section of code, we call the GetSRT method twice to generate SRT keys for the StartTicks and EndTicks positions specified in the current definition. Because the GetSRT method expects a time in seconds and we have our split definition marker values in ticks, we must pass in the Start and End marker positions divided by the source ticks per second value of the animation set.

```
            // Get the SRT data at the start and end ticks
            // (just in case we need to insert them)
            pSourceAnimSet->GetSRT( (double)pDefList[i].StartTicks /
                                     pSourceAnimSet->GetSourceTicksPerSecond(), j,
                                    &StartScale, &StartRotate, &StartTranslate );

            pSourceAnimSet->GetSRT( (double)pDefList[i].EndTicks /
                                     pSourceAnimSet->GetSourceTicksPerSecond(), j,
                                    &EndScale, &EndRotate, &EndTranslate );

            // Swap 'winding', we're adding these directly backto the anim
            // controller, not using directly.
            D3DXQuaternionConjugate( &StartRotate, &StartRotate );
            D3DXQuaternionConjugate( &EndRotate, &EndRotate );
```

We may not actually need the two sets of SRT keys we have just generated. If the start and end markers fall on existing keyframe positions then we can simply copy them over into the new animation. However, if this is not the case, then we require the above step to interpolate the keys for the start and end markers. Notice that we swap the handedness of the quaternions returned so they are left-handed.

Now it is time to start copying over the relevant data from the source animation into the new animation. We will do this in three passes.

In this first pass we copy over the scale keys. In this first section of the scale key pass, we loop through each scale key in the array and skip any keys which have timestamps prior to the StartTicks position specified in the current split definition being processed. If a key has a smaller timestamp we simply continue the next iteration of the loop to process the next scale key. If the timestamp of the current scale key is larger than the EndTicks time (also supplied in the split definition structure) then it means that we have processed all scale keys between the start and end marker positions and we are not interesting in copying any keys after this point. When this is the case, we break from the loop and our job is done.

```
            // ******************************************************************
            // * SCALE KEYS
            // ******************************************************************
            for ( k = 0; k < ScaleKeyCount; ++k )
            {
                D3DXKEY_VECTOR3 * pScale = &ScaleKeys[k];

                // Skip all keys prior to the start time
                if ( pScale->Time < pDefList[i].StartTicks ) continue;

                // Have we hit a key past our last time?
                if ( pScale->Time > pDefList[i].EndTicks ) break;
```

If we get here then we have a key that needs to be copied. However, if we have not yet added any scale keys then this is the first. Also, if the timestamp of this first key we are about to add is not exactly the same as the StartTicks marker position stored in the definition, it means that the first keyframe we are about to copy occurs after the start tick position. We need a keyframe to be inserted at the start marker position so we insert the start scale key we calculated above using the GetSRT method. This will make this start key the first in the array (now definitively located at the start marker position). We then copy over the current key we are processing.

```
                // If we got here we're within range.
                //If this is the first key, we may need to add one
                if(NewScaleKeyCount==0 && pScale->Time != pDefList[i].StartTicks )
                {
                    // Insert the interpolated start key
                    NewScaleKeys[ NewScaleKeyCount ].Time  = 0.0f;
                    NewScaleKeys[ NewScaleKeyCount ].Value = StartScale;
                    NewScaleKeyCount++;

                } // End if insert of interpolated key is required

                // Copy over the key and subtract start time
                NewScaleKeys[ NewScaleKeyCount ] = *pScale;
```

```
            NewScaleKeys[ NewScaleKeyCount ].Time -= pDefList[i].StartTicks;
            NewScaleKeyCount++;
        } // Next Key
```

At the end of this loop we will have copied over all scale keys that existed in the original animation between the start and end marker positions. Further, we may have inserted a new start key at the beginning of the array if the first key we intended to copy had a greater timestamp than the starting marker position. We must always have keyframes on the start and end marker positions.

Now we must test to see if the last scale key we added in the above loop has a timestamp equal to the EndTicks position. If so, then all is well because the last key we copied is exactly where this animation set's timeline should end. However, if this is not the case, then it means the last scale key we copied occurred before the EndTicks position. In that case, we must insert an additional key at the end marker position. We calculated that end key ealier using GetSRT, so we add it to the end of the array.

```
        // Last key matched end time?
        if ( NewScaleKeys[NewScaleKeyCount - 1].Time !=
             pDefList[i].EndTicks - pDefList[i].StartTicks )
        {
            // Insert the interpolated end key
            NewScaleKeys[ NewScaleKeyCount ].Time  = pDefList[i].EndTicks –
                                                     pDefList[i].StartTicks;
            NewScaleKeys[ NewScaleKeyCount ].Value = EndScale;
            NewScaleKeyCount++;

        } // End if insert of interpolated key is required
```

That is the end of the first pass. We now have a temporary array called NewScaleKeys which contains all scaling information between the two markers specified by the split definition for the current animation being copied.

In the second pass we will do exactly the same thing, only this time we will be copying over translation keys instead. The code is nearly identical.

```
        // ******************************************************************
        // * TRANSLATION KEYS
        // ******************************************************************
        for ( k = 0; k < TranslationKeyCount; ++k )
        {
            D3DXKEY_VECTOR3 * pTranslate = &TranslateKeys[k];

            // Skip all keys prior to the start time
            if ( pTranslate->Time < pDefList[i].StartTicks ) continue;

            // Have we hit a key past our last time?
            if ( pTranslate->Time > pDefList[i].EndTicks ) break;

            // If we got here we're within range.
            // If this is the first key, we may need to add one
            if (NewTranslationKeyCount==0 &&
               pTranslate->Time!= pDefList[i].StartTicks )
```

```
                {
                    // Insert the interpolated start key
                   NewTranslateKeys[NewTranslationKeyCount].Time  = 0.0f;
                   NewTranslateKeys[NewTranslationKeyCount].Value =
                                                              StartTranslate;
                   NewTranslationKeyCount++;
                } // End if insert of interpolated key is required

                // Copy over the key and subtract start time
              NewTranslateKeys[NewTranslationKeyCount] = *pTranslate;
              NewTranslateKeys[NewTranslationKeyCount].Time -=
                                                    pDefList[i].StartTicks;
              NewTranslationKeyCount++;

            } // Next Key

            // Last key matched end time?
            if ( NewTranslateKeys[NewTranslationKeyCount - 1].Time !=
                 pDefList[i].EndTicks - pDefList[i].StartTicks )
            {
                // Insert the interpolated end key
                NewTranslateKeys[ NewTranslationKeyCount ].Time =
                              pDefList[i].EndTicks - pDefList[i].StartTicks;

              NewTranslateKeys[ NewTranslationKeyCount ].Value = EndTranslate;
                NewTranslationKeyCount++;

            } // End if insert of interpolated key is required
```

Once again, the code shows that if there are no keyframes existing in the source animation set on the start and end marker positions, we insert the start and end keys interpolated using GetSRT prior to the copy process.

At this point, two of the three copy passes are complete. We have two arrays that contain scale keys and translation keys that existed either on or between the two markers. In the final pass, we copy over the rotation information using the same strategy. Once again, we insert the start and end quaternion keys we interpolated earlier if it is necessary to use them.

```
            // ******************************************************************
            // * ROTATION KEYS
            // ******************************************************************
            for ( k = 0; k < RotationKeyCount; ++k )
            {
                D3DXKEY_QUATERNION * pRotate = &RotateKeys[k];

                // Skip all keys prior to the start time
                if ( pRotate->Time < pDefList[i].StartTicks ) continue;

                // Have we hit a key past our last time?
                if ( pRotate->Time > pDefList[i].EndTicks ) break;

                if ( NewRotationKeyCount == 0 &&
                   pRotate->Time != pDefList[i].StartTicks )
                {
```

```
                // Insert the interpolated start key
                NewRotateKeys[ NewRotationKeyCount ].Time  = 0.0f;
                NewRotateKeys[ NewRotationKeyCount ].Value = StartRotate;
                NewRotationKeyCount++;

            } // End if insert of interpolated key is required

            // Copy over the key and subtract start time
            NewRotateKeys[ NewRotationKeyCount ] = *pRotate;
            NewRotateKeys[ NewRotationKeyCount ].Time -=
                                                pDefList[i].StartTicks;
            NewRotationKeyCount++;

        } // Next Key

        // Last key matched end time?
        if ( NewRotateKeys[NewRotationKeyCount - 1].Time !=
           pDefList[i].EndTicks - pDefList[i].StartTicks )
        {
            // Insert the interpolated end key
            NewRotateKeys[ NewRotationKeyCount ].Time  =
                                pDefList[i].EndTicks - pDefList[i].StartTicks;

            NewRotateKeys[ NewRotationKeyCount ].Value = EndRotate;
            NewRotationKeyCount++;

        } // End if insert of interpolated key is required
```

With the copy process complete, we now have three arrays that describe the SRT data for one of the animations in our newly created animation set. Next we will register that SRT data with our new animation set. Notice that we supply the same name for the animation we are adding to the new animation set as the animation we are copying from. We retrieved this information previously at the start of the animation loop. We must make sure that when we register this new animation copy with our new animation set that we give it the same name as the animation it was copied from. This name provides the mapping between the SRT data contained in the animation and the hierarchy frame which it animates. Once we have added the new animation to our new animation set, we can release the temporary arrays we allocated for the copy process.

```
        // Register this with our destination set
        pDestAnimSet->RegisterAnimationSRTKeys(strName,
                                               NewScaleKeyCount,
                                               NewRotationKeyCount,
                                               NewTranslationKeyCount,
                                               NewScaleKeys,
                                               NewRotateKeys,
                                               NewTranslateKeys, NULL );

        // Clean up
        if ( ScaleKeys )   delete []ScaleKeys; ScaleKeys = NULL;
        if ( TranslateKeys )    delete []TranslateKeys; TranslateKeys = NULL;
        if ( RotateKeys )       delete []RotateKeys; RotateKeys = NULL;
        if ( NewScaleKeys )     delete []NewScaleKeys; NewScaleKeys = NULL;
```

```
            if ( NewRotateKeys )    delete []NewRotateKeys; NewRotateKeys = NULL;
            if ( NewTranslateKeys )
               delete []NewTranslateKeys; NewTranslateKeys = NULL;

        } // Next Animation
```

The animation copy loop we have just examined is executed for every animation in the source set. This creates corresponding (albeit edited) versions of those same animations in the new set. Once we have exited the inner loop, we have copied over all required animation data and have successfully dealt with the current split definition being processed. We have created a new animation set for it and have populated it with updated animation data.

Before moving on to processing the next split definition in the array, we release the interface to the original animation set. This does not delete it from memory since the controller is currently still using it. Our new animation sets will not be added to the controller until later, so for the time being, the controller still contains the original sets. In fact, the last thing we would want to do at this point is actually remove the source animation set from memory. Remember, we may have more split definitions to process and some of them may (and probably will) use the same source animation set for the copying process. So we will still need access to it. This will certainly be the case when the X file contains a single animation set containing all the animation sequences. We are only releasing the copy of the interface pointer that we were returned from pAnimationController->GetAnimationSet( ) at the start of the split definitions loop. The outer loop (i.e., the split definition loop) closes like so:

```
        // We're done with the source 'keyframed' animation set
        pSourceAnimSet->Release();

        // Store the dest animation set for use later
        pDefList[i].Reserved = (LPVOID)pDestAnimSet;

    } // Next Definition
```

Notice that this function uses the reserved member of the split definition structure it has just processed to store a temporary pointer to the new animation set it just created. Now we see why this member was reserved -- it gives the function a temporary place to store the animation sets created for each split definition until we register them with the controller later on.

At this point in the function, we have processed all split definitions and have created a new animation set for each. We will now need to register these animation sets with the controller. But before we do, we first need to remove any existing sets. We no longer need these old animation sets as they were merely the source data containers for the new animation sets we have created.

```
    // Release all animation sets from the animation controller
    // (Note: be careful because the GetNumAnimationSets result,
    // and the values passed in to GetAnimationSet alter ;)
    for ( ; m_pAnimController->GetNumAnimationSets() > 0; )
    {
        // Retrieve the animation set we want to remove
        m_pAnimController->GetAnimationSet( 0, &pAnimSet );
        // Unregister it (this will release inside anim controller)
        m_pAnimController->UnregisterAnimationSet( pAnimSet );
```

```
        // Now release the last known copy
        pAnimSet->Release();

    } // Next Animation Set
```

We now have an empty animation controller and it is time to register our new animation sets. Remember that the Reserved member of each split definition structure was used to store an interface pointer to the animation set that we created for that definition. So all we have to do now is loop through each split definition and register the animation sets stored there with the controller.

```
    // Now add all the new animation sets back into the controller
    for ( i = 0; i < nDefCount; ++i )
    {
        // Retrieve back from the structure
        pDestAnimSet = (LPD3DXKEYFRAMEDANIMATIONSET)pDefList[i].Reserved;
        if ( !pDestAnimSet ) continue;

        // Register with the controller (addrefs internally)
        m_pAnimController->RegisterAnimationSet( pDestAnimSet );

        // Release our local copy and clear the list item just in case
        pDestAnimSet->Release();
        pDefList[i].Reserved = NULL;

    } // Next Definition
```

Now we have an animation controller with new animation sets defined by the split definition array we passed in. Since we have removed all the old animation sets, there will not currently be an animaton set assigned to any track. Therefore, this function will perform a default assignment of the first set to track 0 on the mixer.

```
    // Set the first set in track 0 for default
    m_pAnimController->GetAnimationSet( 0, &pAnimSet );
    m_pAnimController->SetTrackAnimationSet( 0, pAnimSet );
    pAnimSet->Release();

    // Success!!
    return D3D_OK;
}
```

That was a fairly large function and one you will probably not call directly very often. As discussed, Lab Project 10.2 is a splitter tool which is essentially built entirely around this one function call. It provides a nice way around a problem for people who have their animation data combined in the X file and wish to divide it into separate sets. ApplySplitDefinitions is a utility function and should not be used in a time critical portion of your code. Also note that if you intend to save the actor back out to an X file, then you must make sure that the actor is created in managed mode. Finally, if you wish to use this function, you will want to disable the call to ApplyCustomSets in CActor::LoadActorFromX since this function expects to work with the data extracted from the X file. It has no concept of callback keys (as they are never specified in an X file) and it has no concept of our CAnimationSet object either.

Supporting CActor Instancing

Although we have finished adding animation support to the CActor class, we will use this lab project to add some much needed support to our applications for the correct instancing of animated actors. As we know from previous lessons, the ability to have several objects in our scene that have unique positions but share the same mesh data is vitally important. Instancing allows us to avoid storing multiple copies of identical geometry (and other properties) in memory. Indeed, we have used mesh instancing going back all the way to some of the first projects we have done together. This of course is why our CScene class represents objects using the CObject class. The CObject class contains a world matrix that describes the position of the object in the world. It also has a pointer to a separate mesh or actor which points to the actual model space data of the object's associated mesh(s).

In the case of a simple mesh, instancing is easy. If we have a mesh of a street lamp that we wish to place at multiple locations in the scene, we can load the street lamp mesh once and then have several CObject's reference that mesh. Each CObject contains its own world matrix that can be used to position the mesh in the correct place in the scene. In the case of simple static meshes like this, all we have to do before we render an object is set its world matrix on the device and then render the mesh it points to. Even if several CObject's point to the same mesh, as long as we set each object's world matrix prior to rendering its associated mesh, the pipeline will correctly transform and render the mesh in the correct position in the scene. Since this is how we render non-instanced objects as well, our application does not care whether it is the only object referencing that mesh data or not. It all works the same way.

When dealing with actors, instancing support is not quite so automatic or free from CPU overhead. An actor contains a hierarchy of matrices which must all be updated to position the actor in the scene using the associated object's world matrix. Unlike a single mesh object where we can just set the object's matrix as the current world matrix on the device and then render that mesh, when we set the world matrix of an object that stores an actor, we do not simply set the object's matrix as the device world matrix. In fact, we use the CActor::SetWorldMatrix function, passing in the object's world matrix. This function will multiply that world marix with the root frame's relative matrix, changing the root frame of reference for the entire hierarchy. It will then need to perform a full traversal of the hierarchy to rebuild the absolute world matrices stored at each frame. Once done, each frame in the hierarchy will contain its absolute world matrix and thus any mesh attached to that frame will have the matrix it needs to set on the device prior to being rendered.

After the hierarchy matrix update to world space, the rendering step involves nothing more than traversing the hierarchy and searching for mesh containers. When a mesh container is found, the absolute matrix stored in the owner frame will be the world matrix that must be set on the device prior to rendering that mesh. As long as we call the CActor::SetWorldMatrix function and pass in the object's world matrix prior to rendering that actor, we will update the matrices of the actor that describe where the mesh components comprising the actor should be positioned in the scene (using the object's matrix as a frame of reference). If multiple objects reference the same actor, it no longer matters. As long as we update the matrices of the actor using each object's world matrix prior to rendering it.
Of course, we have to be aware of the potential overhead that comes with referencing an actor, even though this same overhead would be incurred if we loaded five unique actors. For example, if we have five CObject's that point to the same actor, then we will have to set the world matrix for the actor five times, once for each time we render the actor for a given object. This means five hierarchy traversals

will be peformed to update the matrices of the actor such that it can be rendered in five different locations. However, even if we used five unique actors, we would still need to traverse each actor's hierarchy every time its associated object world matrix was updated. Of course, this is where the subtle difference comes into play between using five separate actors and referencing the same actor five times.

In the case when five unique actors are being used, each actor would only have to have its hierarchy updated if its associated world matrix had been updated. For example, if only one of the objects had its matrix updated, the other four actors could be left alone since their matrices are currently up to date. Only the actor whose world matrix has been updated would need to have all its matrices rebuilt before being rendered. In the case of one actor being referenced by five different objects, even if none of those objects have had their world matrices changed since the last update, the matrices of the actor will always have to be rebuilt five times, once for each object that uses it. This is because we must use the actor's matrices to take a snapshot of the actor from multiple locations in the scene (once for each object). Thus we will always have to rebuild the matrices of the actor every frame for every object that references it. While this usually means many more hierarchy traversals than in the case of loading the geometry multiple times, the memory savings is significant and often the only practical solution.

> **Note:** It should be noted that a Clone function could be added to our CActor to create a new actor that is a copy. This new actor, while having its own unique hierarchy and matrices, could have mesh containers that point to the original mesh containers in the actor from which it was cloned. The result is the ability to have multiple CActor's that all share the same mesh data (model space vertices and indices) but that have their own unique hierarchies. This is like a hybrid of the non-referenced and referenced approaches. Memory would still be consumed by the multiply hierarchies maintained by each actor, and this might not always be practical, but the mesh data would be shared. With such a system, any actors that have not had their associated object's world matrix updated would not need to have their hierarchy matrices updated needlessly. We will leave the creation of such a function as an exercise for the reader. In our applications, we will be using classic referencing when more than one CObject points to a given actor. As such, there will be only one copy of an actor's hierarchy and mesh data in memory at any given time.

Instancing actors is quite simple if the actor is not animated. For example, the following code snippet shows how the objects could be rendered inside our CScene::Render function. We are assuming that managed meshes are being used to remove the setting of textures and materials from the listing and to simplify the point we are trying to make clear.

```
for ( i = 0; i < m_nObjectCount; ++i )
{
   CObject  * pObject = m_pObject[i];
   if ( !pObject ) continue;

   // Retrieve actor and mesh pointers
   CActor   * pActor = pObject->m_pActor;
   CTriMesh * pMesh  = pObject->m_pMesh;
   if ( !pMesh && !pActor ) continue;

   // Set up transforms
   if ( pMesh )
   {
      // Setup the per-mesh / object details
      m_pD3DDevice->SetTransform( D3DTS_WORLD, &m_pObject[i]->m_mtxWorld );
      m_pD3DDevice->SetFVF( pMesh->GetFVF() );
```

```
      // Draw Mesh (managed mode example)
      pMesh->Draw();

   } // End if mesh

   else

   {
      // Set world matrix and update combined frame matrices.
      pActor->SetWorldMatrix( &pObject->m_mtxWorld, true );

      // Draw Actor (Managed mode example)
      pActor->DrawActor()

   } // End if actor

} End for each object
```

As the above code shows, we loop through each object in the scene and fetch either its mesh or actor pointer. If the object contains a pointer to a mesh, then the object's world matrix is bound to the device and the mesh is rendered. If the object points to an actor, the CActor::SetWorldMatrix function is used. This function does not actually set any matrices on the device, it combines the passed world matrix with the root frame matrix, changing the frame of reference for the entire actor. The 'true' parameter that is passed instructs the function to then traverse the hierarchy and rebuild all the absolute matrices for each frame in the hierarchy. We then call CActor::DrawActor to render the managed mode actor. This function is the function that traverses the hierarchy and sets the matrices on the device prior to rendering each mesh contained there.

The above code works flawlessly whether actors or meshes are being referenced (or not). The code does not care if a CObject's associated mesh or actor is being used by more than one object because the same rendering logic works in both cases. If animation was not a factor, that is all we would have to do to provide correct instancing support for our actors. However, as we have learned in this chapter, an actor can also contain animation data and it is here that our current instancing method would break if we were to take no additional measures. In fact, the code we have used above was implemented in previous lessons so we have had support for static actor instancing for some time now. With animated actors things get a little more complicated and we will have to perform some additional logic and add two new member functions to CActor to make sure that animated actor instancing is properly done.

Who Controls the Controller?

When an actor contains animation data, we update the animations each frame by calling the actor's AdvanceTime method. This method passes the request on to the underlying animation controller which updates the relative matrices to reflect the changes caused by the advance in the timeline. As previously described, we do this inside the CScene::AnimateObjects function, and our current animation update strategy might look like the following:

```
void CScene::AnimateObjects( CTimer & Timer )
{
    ULONG i;
    static CActionHandler Handler;

    // Process each object for coll det
    for ( i = 0; i < m_nObjectCount; ++i )
    {
        CObject * pObject = m_pObject[i];
        if ( !pObject ) continue;

        // Get the actor pointer
        CActor * pActor = pObject->m_pActor;

        if ( !pActor ) continue;

        // Advance time
        pActor->AdvanceTime( Timer.GetTimeElapsed(), false, &Handler );

    } // Next Object
}
```

As you can see, the above code loops through each CObject in the scene and tests to see if that object uses an actor or a mesh. If the object uses a mesh, then there is nothing to do because a single mesh does not contain animation data. If the object uses an actor, then the actor's animation controller is advanced by calling the CActor::AdvanceTime method. If the actor has no animation data then this is a no-op and we can safely call it for all actors.

The problem happens when multiple CObject's are referencing the same actor. Since the actor houses the animation controller, if multiple objects reference the same actor, they are also referencing a shared animation controller. If we had five objects that all referenced the same actor, the above function would not advance the controller time of five actors, it would advance the time of a single actor's controller five times in a given frame update. Therefore, every object would share the same animaton data and the same position in the animation's timeline. Furthermore, that timeline would be playing back at an incorrect speed because we are advancing the timeline multiple times in a given update (once for each object referencing the actor). This will simply not do. Although we can certainly live with the fact (and will actually often desire it) that all objects that reference the actor will essentially contain the same animation data and will also have to have synchronized timelines, we certainly can not settle for those animatons playing back at faster speeds than intended. The situation obviously gets a lot worse if there were hundreds of ojects referencing that actor as its animation timeline would be updated hundreds of times in a given frame update.

We could work around such a problem by using a 'frame time' variable inside the actor so that any calls to AdvanceTime past the first that have identical frame times are ignored. That way, the actor would ignore any AdvanceTime calls except the first for a given frame update. If this technique were implemented, even if 100 objects called AdvanceTime for a single actor in a given frame update, only the first would be processed. But this is still far from ideal; the system we are going to use will provide much more flexibility. Not only will it allow each object to have independent timelines and animation speeds, it can also give each object that references a single actor its own unique animation data.

The root cause of our problem is that every object shares the same animation controller stored inside the actor they are referencing. However, if we were to change this relationship and instead give each object its own copy of the controller (cloning the original controller that was loaded with the actor data) we remove this conflict. We could update our CObject structure so that it now also maintains a pointer to an ID3DXAnimationController like so:

```
class CObject
{
public:
    //-----------------------------------------------------------------------
    // Constructors & Destructors for This Class.
    //-----------------------------------------------------------------------
    CObject( CTriMesh * pMesh  );
    CObject( CActor   * pActor );
    CObject( );
    virtual ~CObject( );

    //-----------------------------------------------------------------------
    // Public Variables for This Class
    //-----------------------------------------------------------------------
    D3DXMATRIX                  m_mtxWorld;             // Objects world matrix
    CTriMesh                   *m_pMesh;                // Mesh we are instancing
    CActor                     *m_pActor;               // Actor we are instancing
    LPD3DXANIMATIONCONTROLLER   m_pAnimController       // Instance Controller
};
```

Since each object has its own controller, it has the ability to move that timeline along at any speed and to whatever position it desires. As mentioned, we could conceivably even generate completely unique animation data for each object as long as the names of the frames comprising the actor's hierarchy are known. For this to work, before we update the animation time of each object, we would first need to attach it to the actor. We can then use the actor's animation functions to alter the timeline of the controller for that particular object. We may also want to allow the attaching of the controller to automatically synchronize the relative matrices of the hierarchy to the data contained in the controller. Simply storing the controller's pointer inside the actor will not update the hierarchy to reflect the current pose described by the timeline of that controller.

Our new version of CScene::AnimateObjects is shown below. It has an additional line of code that calls a CActor method yet to be implemented (AttachController). For now, do not worry about how the object is assigned its own animation controller; we will see this in a moment when examining the changes to the CScene IWF loading code. For now just know that if multiple CObject's reference the same animated actor, the actor will no longer contain its own animation controller -- the CObjects will have their own copy.

```
void CScene::AnimateObjects( CTimer & Timer )
{
    ULONG i;
    static CActionHandler Handler;

    // Process each object for coll det
    for ( i = 0; i < m_nObjectCount; ++i )
    {
```

```
        CObject * pObject = m_pObject[i];
        if ( !pObject ) continue;

        // Get the actor pointer
        CActor * pActor = pObject->m_pActor;
        if ( !pActor ) continue;

        if ( pObject->m_pAnimController )
            pActor->AttachController( pObject->m_pAnimController, false );

        // Advance time
        pActor->AdvanceTime( Timer.GetTimeElapsed(), false, &Handler );

    } // Next Object
}
```

As you can see, we still loop through each object searching for actors to advance their timelines. However, when we find an object that has its own animation controller we attach it to the actor. This function simply copies the passed animaton controller pointer into the actor's controller member variable (as it no longer contains its own animation controller). Once this has been done, we can then use the CActor::AdvanceTime function (and all the other CActor controller manipulation methods) to advance the timeline of the controller. Everytime we attach a new controller to the actor it overwrites the pointer of the controller that was previously stored.

The second parameter to the CActor::AttachController is a Boolean variable that dictates whether we would like the relative matrices of the actor's hierarchy to be updated to reflect the pose of the actor as defined by the current position of the controller's timeline. At this point we do not because we are simply using the actor interface to advance the timelines of each object's controller. You will see in a moment how we will call this function again in the CScene::Render function prior to rendering each CObject. That is, before we render each object in our world, if it is an actor, we will attach the object's controller to the actor, this time passing true as the Boolean parameter. This will cause the relative matrices of the actor to be synchronized to those described by the controller so that the actor is in the correct pose described by the currently attached controller. We will then set the actor's world matrix to initiate a traversal of the hierarchy and a rebuilding of the absolute matrices. These world matrices will be populated as described by the controller. We will then render the actor as we usually would. The snippet of rendering code in our CScene::Render function now looks something like this:

```
for ( i = 0; i < m_nObjectCount; ++i )
{
   CObject  * pObject = m_pObject[i];
   if ( !pObject ) continue;

   // Retrieve actor and mesh pointers
   CActor   * pActor = pObject->m_pActor;
   CTriMesh * pMesh  = pObject->m_pMesh;

   if ( !pMesh && !pActor ) continue;

   // Set up transforms
   if ( pMesh )
   {
```

```
      // Setup the per-mesh / object details
      m_pD3DDevice->SetTransform( D3DTS_WORLD, &m_pObject[i]->m_mtxWorld );
      m_pD3DDevice->SetFVF( pMesh->GetFVF() );

      // Draw Mesh (managed mode example)
      pMesh->Draw();

   } // End if mesh

   else

   {
      // Attach controller with frame synchronization
      if ( pObject->m_pAnimController )
          pActor->AttachController( pObject->m_pAnimController, true )

      // Set world matrix and update combined frame matrices.
      pActor->SetWorldMatrix( &pObject->m_mtxWorld, true );

      // Draw Actor (Managed mode example)
      pActor->DrawActor()

   } // End if actor

} End for each object
```

As you can see, the only line added is the one that attached the controller of an object to the actor prior to rendering it.

Let us now examine the two new functions we will add to CActor that will allow us to attach and detach an animation controller.

CActor::AttachController

AttachController replaces the animation controller pointer currently stored in the actor with the one that is passed in. This is our means of connecting each CObject's controller to the actor so that we can use its methods to manipulate the timeline and update the actor's matrices for the given instance.

The function takes two parameters. The first is a pointer to the new ID3DXAnimationController that will be stored in the actor. Any previous controller stored in the actor will be released. If the controller currently stored in the actor is not being referenced reference elsewhere then it will be freed from memory. Usually, the controller stored here will also have an interface reference in the CObject that is referencing the actor, so in most cases we are simply releasing the actor's claim on that interface. The second parameter is a Boolean variable that controls whether the function should take the additional step of updating the relative matrices of the hierarchy so that they are synchronized to the timeline of the new controller.

As discussed previously, this function is called twice for each CObject that references an actor. The first time it is called (inside CScene::AnimateObjects) we pass false as the second parameter because we do not want to synchronize the matrices of the actor to the controller at this point. We simply want to attach

the controller so that we can use the actor interface to advance the timeline. The second time we call this method for each CObject is when we are about to render the object. This time, we attach the controller and pass true as the Boolean parameter so that the relative matrices are synchronized to the positions described by the animation data in the controller for the current position on the timeline. We then set the world matrix of the actor, which concatenates the relative matrices in their newly animated states, to build the absolute world matrices of the actor at each frame. Finally, we render the actor.

The first section of code releases the actor's claim on any controller interface that is currently being referenced and sets the controller pointer to NULL.

```
void CActor::AttachController( LPD3DXANIMATIONCONTROLLER pController,
                               bool bSyncOutputs /* = true */ )
{
    // Release our current controller.
    if ( m_pAnimController ) m_pAnimController->Release();
    m_pAnimController = NULL;
```

The next piece of code is all in a conditional block that is only executed if the first parameter to the function is not NULL. An application could pass NULL as the first parameter instead of a valid pointer to an animation controller. The result would be the removal of the controller currently being used by the actor and the setting of this pointer to NULL.

Provided the application has passed a valid controller pointer the next code block will be executed. It stores the controller poiner in the actor member variable and increases its reference count. If the second parameter to the function was false, then our job is done. However, if true was passed, then we want the controller we have just attached to update the relative matrices of the hierarchy.

How does this happen? Well, we know that when we advance the time of the animation controller, this will automatically cause the controller to update the relative matrices (animation outputs) of the hierarchy it is animating. However, we do not want to physically advance the time of the controller. That is not a problem. All we have to do is call AdvanceTime and specify that we would like the timeline advanced by zero seconds. The remainder of the function is shown below:

```
    if ( pController )
    {
        // Store the new controller
        m_pAnimController = pController;

        // Add ref, we're storing a pointer to it
        m_pAnimController->AddRef();

        // Synchronise our frame matrices if requested
        if ( bSyncOutputs ) m_pAnimController->AdvanceTime( 0.0f, NULL );

    } // End if controller specified
}
```

By calling AdvanceTime and passing in zero seconds, we do not erroneously alter the position of the timeline (after all, we do that in CScene::AnimateObjects). However, calling this function does instruct the controller to fetch the SRT data for each matrix for the current the position on the timeline. This SRT

data is retrieved from the controller's animation data and used to rebuild the relative frame matrices. We will see in a moment when we examine the loading code that while the CObjects now own their own controllers, these controllers are all clones of the original controller that was created when the actor was first loaded from the X file. Therefore, all the controllers will have correctly had all the frames in the hierarchy that require animation registered as animation outputs.

The next function we will add to the CActor class is called DetachController and is the mirror of the current function. It just sets the controller pointer of the actor to NULL and returns the controller interface currently being used by the actor back to the application. After this function has been called, the actor's internal controller pointer will be set to NULL.

Before we discuss why the application might wish to fetch the controller currently being used by the actor and also have it removed from the actor at the same time, let us look at the function code.

CActor::DetachController

DetachController returns an interface to the controller currently being used by the actor and sets the controller pointer member variable to NULL. As such, the actor has no controller attached after this call. Here is the code:

```
LPD3DXANIMATIONCONTROLLER CActor::DetachController( )
{
    LPD3DXANIMATIONCONTROLLER pController = m_pAnimController;

    // Detach from us
    m_pAnimController = NULL;

    // Just return interface
    return pController;

}
```

The function takes no parameters and returns an ID3DXAnimationController interface pointer back to the caller. Normally, when we remove an object's claim on an interface we would call Release on that interface before setting the pointer to NULL. Notice that we do not do so in this case -- we simply set the pointer to NULL. This is because under normal circumstances, when a function returns an interface pointer, it would increase the reference count of the interface before returning that pointer. In this case, it is unnecessary. Normally we would first increase the reference count when we make the interface pointer copy that will be returned back to the application and would then call Release on that interface before setting the actor's pointer to NULL. Since these two steps cancel each other out, we will simply set the actor pointer to NULL and transfer ownership of the interface reference to the function caller. As the actor loses the reference to that interface, the caller will gain it. The calling function should call Release on this interface when it no longer wishes to use it.

In order to understand why we might need to detach a controller, we need to understand the loading process. That is what we will discuss next.

In our current applications, the only way multiple instances of an actor (or even multiple actors) can be created is if we are loading the scene file from an IWF file using CScene::LoadSceneFromIWF. This is because the alternative method of scene loading we provide (CScene::LoadSceneFromX) assumes that the entire scene is stored in a single X file and thus, only one actor will ever be created. In the case of IWF loading, the situation is different. While the IWF file may contain several internal meshes, these meshes will be loaded and stored as single mesh CObjects in the scene. We can think of these internal meshes as the brushes that you might place in GILES™ since this geometry is stored directly in the IWF file and can contain no animation or hierarchy data. The IWF function that picks these internal meshes out of the IWF file during the loading process is the CScene::ProcessMeshes function. For each mesh found in the IWF file, its data will be copied into a new CTriMesh object and stored in a new CObject. Our actor class is not used for static meshes stored in the IWF file.

However, we do use actors to load reference entities that are stored in the IWF file. A reference entity in an IWF file is an entity that contains a world matrix and a filename. This filename is the name of an X file that contains an object or object hierarchy positioned in your scene using a tool like GILES™. There are many benefits to using references in this way.

For example, imagine you have a very nice X file which contains the representation of a tree. This tree might be comprised of several meshes stored in a hierarchy inside the X file. Furthermore, this X file might also contain animation data that has been hand crafted to allow the tree to sway back and forth. If you were to import this X file into GILES™ as a regular mesh, the seperate meshes comprising the tree would all be collapsed into a single mesh and the hierarchy and animation data would be lost (as GILES™ has no native support for them). This is most likely not the outcome you want.

A better approach would be to design your animated X file in a package such as 3D Studio MAX™ or Maya™ and export the data out to an X file. You can then place multiple references to this X file in the scene using the GILES™ reference entity. For example, you might place 100 of your trees in the level. The geometry of these trees will never be stored in the IWF file. All that will be stored in the IWF file when you save the scene in GILES™ is the position and orientation of each reference (its world matrix) and the name of the X file that should be loaded by the application. This is helpful because it allows you to design your individual objects in your favorite modeling packages and use GILES™ as a simple scene placement tool. You can even create an IWF file in GILES™ which has no internal geometry whatsoever. It might just be a collection of reference entities describing where these external X file objects should be positioned in the scene.

When parsing reference entities during the loading of an IWF file our actor class will be used. The CScene::ProcessReference function is called during the loading process to extract the reference entity information. For each entity loaded we will create a new CObject. There will be a world matrix (describing its position in the scene) for that reference that we will store in the CObject's world matrix. The filename can be passed into a new CActor using CActor::LoadActorFromX as we have done in past lessons. This actor pointer will then be stored in the new CObject and added to the scene's CObject array.

None of this is new to us, but the next part is. When the LoadActorFromX method returns, the actor will have been fully populated with hierarchy data and an animation controller (if animation existed in the X file). In the past, we have simply assumed that an actor will never be referenced by more than one object

and as such, it was fine for the actor to own the animation controller. We now know however, that if more than one CObject is referencing the actor, the actor should no longer own the controller. Instead, each CObject will have its own copy of the original controller. (If an actor is only referenced by one CObject, then we should just let the actor own the controller and we can set the CObject's controller to NULL.)

Essentially, we have created two operating modes for CActor. If only one CObject references it, it will be allowed to own the controller it was originally assigned in the CActor::LoadActorFromX function. However, as soon as we discover that we are about to create an object that references an actor we have already loaded, we will detach the controller from the actor and store it in the CObject. For every CObject created that references that same actor, we will clone this controller and assign it to the CObject's controller pointer.

See this in action will make it much easier to understand, so let us now have a look at the updated code to the CScene::ProcessReference function. This is the function that is called during the loading of an IWF file to extract the information for each reference entity found in the file. This function is called from CScene::ProcessEntities since references are a type of IWF entity.

CScene::ProcessReference

This function is called by the CScene::ProcessEntities function each time a reference entity is encountered. The function is passed a ReferenceEntity structure which contains information about the reference (filename, etc.), and a reference world matrix describing where it should be positioned in the scene.

The first thing we do is test to see that the ReferenceType member of the ReferenceEntity structure is set to 1. If it is not, we return. A setting other than 1 indicates that this is an internal reference instead of an external reference. Internal references are not supported by our applications at this time.

```
bool CScene::ProcessReference( const ReferenceEntity& Reference,
                               const D3DXMATRIX & mtxWorld )
{
    HRESULT                     hRet;
    CActor                    * pReferenceActor      = NULL;
    LPD3DXANIMATIONCONTROLLER   pController          = NULL;
    LPD3DXANIMATIONCONTROLLER   pReferenceController = NULL;

    // Skip if this is anything other than an external reference.
    if (Reference.ReferenceType != 1) return true;
```

We will now extract the filename of the X file we need to load from the ReferenceName member of the input structure. As this will contain just the filename (not the complete path) we will need to append this filename to the data path string currently being used by the application. The CScene::m_strDataPath member is a string that contains the current folder where application data is stored (e.g., '\MyApp\MyData\'). This is the folder where our application expects to find textures and X file resources.

```
    // Build filename string
    TCHAR Buffer[MAX_PATH];
    _tcscpy( Buffer, m_strDataPath );
    _tcscat( Buffer, Reference.ReferenceName );
```

At this point we have the complete filename of the X file we wish to load (including path) stored in the local Buffer variable.

We now loop through every actor that is currently in the scene's CActor array and test to see if an actor already exists with the same name. If so, then it means that we have already loaded this X file for a previous actor and do not wish to load it again.

```
    // Search to see if this X file has already been loaded
    for ( ULONG i = 0; i < m_nActorCount; ++i )
    {
        if (!m_pActor[i]) continue;
        if ( _tcsicmp( Buffer, m_pActor[i]->GetActorName() ) == 0 ) break;

    } // Next Actor
```

At this point, if loop variable 'i' does not contain the same value as m_ActorCount then it means the above loop exited prematurely in response to finding an existing actor created from the same X file. When this is the case, we do not want to load the X file again; instead we will create a new CObject that references the current actor. However, there are some things we now wish to consider.

We will first need to find the CObject that currently contains a pointer to this actor and test to see if its animation controller pointer is NULL. If it is, then it means that the object is the only one that currently references the actor and at present, the actor owns its own controller. When this is the case, we will detach the controller from the actor and store it in that object instead. We will then clone this controller and store it in the object reference we are about to create. This is essentially the code that recognizes when more than one CObject is referencing an actor and removes the controller management responsibilities from the actor in favor of the object.

Next we see the code that executes this step. First we get a pointer to the actor that our new object is going to reference and then get a pointer to the pre-existing CObject that currently owns it.

```
    // If we didn't reach then end, this Actor already exists
    if ( i != m_nActorCount )
    {
        // Store reference Actor.
        pReferenceActor = m_pActor[i];

        // Find any previous object which own's this actor
        for ( i = 0; i < m_nObjectCount; ++i )
        {
            if (!m_pObject[i]) continue;
            if ( m_pObject[i]->m_pActor == pReferenceActor ) break;

        } // Next Object
```

Notice that the above code exits as soon as any CObject that currently references the actor is found. If multiple CObjects already exist at this point, and they all reference the same actor, then it does not matter which one we use. We are only going to use it to clone its controller into the new CObject reference we are about to create. If however, the object that we find has its animation controller pointer set to NULL then we know that is currently the only CObject that exists that currently references the actor. As such, the actor currently manages the controller. In this case we will detach the controller and assign it to this object. We will then clone this controller and assign the clone to the new object reference we are about to create.

The next code block is executed if an object was found in the above loop. (This should always be the case since there is currently no way that a CActor can be created that is not also assigned to a CObject.) First we get a pointer to that object and test to see if its animation controller pointer is set to NULL. If so then we know it is currently the only object that references this actor and therefore the actor currently contains the controller. As we are just about to create a new object reference to this actor we know the actor mode needs to change. Therefore, we will detach the controller from the actor and store it in the pre-existing object that we found.

```
        // Did we find an object?
        if ( i != m_nObjectCount )
        {
            CObject * pReferenceObject = m_pObject[i];

            // Is this the first reference?
            if ( !pReferenceObject->m_pAnimController )
            {
                // If this is the first time we've referenced this actor then
                // we need to detach it's controller and store in the reference
                // object
                pReferenceObject->m_pAnimController =
                                            pReferenceActor->DetachController();

            } // End if first reference
```

We have just switched the previous object from non-reference mode to reference mode by assigning it its own controller. At this point, the actor no longer owns a controller.

Our next step is to create the new object reference we actually entered this function to build. We know that the reference we are processing at this point references an actor that we already have in memory, so we just have to create a new CObject and add a pointer to the actor. We also know that this is not the only object that references the actor, so this new object will need to have its own animation controller as well.

With the previous object reference taken care of, we will prepare the data for the new object reference we are about to create. Our new object will need its own animation controller, so we will clone the animation controller that we just detached from the actor and assigned to the previous object. As the clone function requires that we pass in all the limitations of the new controller at cloning time, we will fetch these limits from the controller that we are about to clone prior to calling the clone method.

```
            ULONG nMaxOutputs, nMaxTracks, nMaxSets, nMaxEvents;
```

```
            // Retrieve all the data we need for cloning.
            pController = pReferenceObject->m_pAnimController;
            nMaxOutputs = pController->GetMaxNumAnimationOutputs();
            nMaxTracks  = pController->GetMaxNumTracks();
            nMaxSets    = pController->GetMaxNumAnimationSets();
            nMaxEvents  = pController->GetMaxNumEvents();

            // Clone the animation controller into this new reference
            pController->CloneAnimationController(    nMaxOutputs,
                                                      nMaxSets,
                                                      nMaxTracks,
                                                      nMaxEvents,
                                                      &pReferenceController );

        } // End if we found an original object reference.

    } // End if Actor already exists
```

We have now seen the code block that is executed if an actor already exists that shares the same X file as the reference entity we are currently processing. If this code has been executed, the local pReferenceController variable stores a pointer to the interface of a cloned animation controller that will be assigned to the new CObject we are about to create. The local variable pReferenceActor also points to the existing actor that we intend to assign to the new CObject.

The next section of code is executed if the X file whose filename is stored in the reference has not yet been loaded into an actor. When this is the case, we create a new actor just like we always have and use the CActor::LoadActorFromX function to load the X file into the actor. We also register the CScene attribute callback function since our application always uses actors in managed mode.

```
    else
    {
        // Allocate a new Actor for this reference
        CActor * pNewActor = new CActor;
        if (!pNewActor) return false;

        // Load in the externally referenced X File
        pNewActor->RegisterCallback( CActor::CALLBACK_ATTRIBUTEID,
                                     CollectAttributeID,
                                     this );

        hRet = pNewActor->LoadActorFromX( Buffer, D3DXMESH_MANAGED,
                                          m_pD3DDevice );
        if ( FAILED(hRet) ) { delete pNewActor; return false; }

        // Store this new Actor
        if ( AddActor( ) < 0 ) { delete pNewActor; return false; }
        m_pActor[ m_nActorCount - 1 ] = pNewActor;

        // Store as object reference Actor
        pReferenceActor = pNewActor;

    } // End if Actor doesn't exist.
```

At this point a new actor has been added to the scene's CActor array and the actor will have been fully populated with the data from the X file. If the X file contained animation data, the actor will currently store a pointer to a controller. That is where it will remain until a second CObject is created that also references it (as shown in the previous code). Finally, at the bottom of this code block we assign the local pReferenceActor pointer to point to this actor. By doing this we know that whichever of the two code blocks were executed above, the pReferenceActor variable will point to the actor that needs to be assigned to the new CObject we are about to create.

All that is left to do is allocate a new CObject structure and add it to the scene's CObject array before assigning the actor and controller pointers to that object. We also store the world matrix of the reference entity that was passed into the function.

```
    // Now build an object for this Actor (standard identity)
    CObject * pNewObject = new CObject( pReferenceActor );
    if ( !pNewObject ) return false;

    // Copy over the specified matrix and store the colldet object set index
    pNewObject->m_mtxWorld        = mtxWorld;

    // Store the reference animation controller and action status (if any)
    pNewObject->m_pAnimController = pReferenceController;

    // Store this object
    if ( AddObject() < 0 ) { delete pNewObject; return false; }
    m_pObject[ m_nObjectCount - 1 ] = pNewObject;

    // Success!!
    return true;
}
```

One important point to make about the above code is that if the second code block is executed (i.e., the actor did not exist prior to the function being called) then the pReferenceController pointer will be set to NULL and we will be assigning NULL to the object's controller pointer also. This is because, at this point only one CObject references that actor and the actor currently manages the only animation controller. This relationship will change if the function is called again later to process another reference to the same X file. In that case, the first code block is executed and the controller is removed from the actor and stored in the object that was created in the prior call. The controller is then cloned and copied into the new CObject that is created at the tail of the function.

For completeness we will also show the CScene::LoadSceneFromX function. It has been updated with an additional line that registers a callback key handler with the actor that is created.

CScene::LoadSceneFromX

Students already familiar with our application framework will know that the CScene::LoadSceneFromX method is called by CGameApp::BuildObjects when the application first starts. It is passed the filename of the X file to be loaded. It is this loading function that is used by Lab Project 10.1 to load a single X

file that contains our small space scene. We will quickly look at this function code since it demonstrates an important topic that was discussed in this workbook. It calls the actor's RegisterCallback function to register a callback key registration function with the actor. When this function is used to load a scene (instead of LoadSceneFromIWF) the scene will only contain a single actor. As only one actor exists, the actor will always own the controller and the CObject that references it will always have its controller pointer set to NULL. This loading function is much simpler since it does not have to perform the controller attach/detach process.

This function is virtually identical to the implementation we looked at in the last workbook. It creates a new CActor and uses the CActor::LoadActorFromX method to load the requested X file. It then adds this actor's pointer to the scene's CActor array. It also allocates a new CObject and attaches the actor to it before adding this new object to the scene's CObject array. Remember, our scene class deals with CObjects at the top level so that it can handle the storage of both mesh hierarchies and single mesh objects in the scene. The scene's CActor array is not rendered from directly; it is where we store pointers to all the actors so we can release them in the scene's destructor.

Finally, this function sets up a few default lights so that we can see what we are rendering. Although the entire function is shown below as a reminder, notice that adding support for animated CActors has required only one new line of code (and even this line is optional). This new code is highlighted in bold in the following listing. It shows how we register the scene's callback key callback function with the actor. The actor will add this function's pointer, along with the passed context data pointer (the *this* pointer), to the actor's CALLBACK_FUNC array. As we saw earlier, when the actor is loading the X file, it will call this callback function and allow the function to add callback keys to any of its registered animation sets. As with the registration of attribute and texture callback functions discussed in the previous lesson, the callback key callback function must be registered before the call to CActor::LoadActorFromX is made.

```
bool CScene::LoadSceneFromX( TCHAR * strFileName )
{
    HRESULT hRet;

    // Validate Parameters
    if (!strFileName) return false;

    // Retrieve the data path
    if ( m_strDataPath ) free( m_strDataPath );
    m_strDataPath = _tcsdup( strFileName );

    // Strip off the filename
    TCHAR * LastSlash = _tcsrchr( m_strDataPath, _T('\\') );
    if (!LastSlash) LastSlash = _tcsrchr( m_strDataPath, _T('/') );
    if (LastSlash) LastSlash[1] = _T('\0'); else m_strDataPath[0] = _T('\0');

    CActor * pNewActor = new CActor;
    if (!pNewActor) return false;

    // Load in the specified X file
    pNewActor->RegisterCallback(CActor::CALLBACK_ATTRIBUTEID,CollectAttributeID,this);
    pNewActor->RegisterCallback(CActor::CALLBACK_CALLBACKKEYS,CollectCallbacks,this );
    pNewActor->LoadActorFromX( strFileName, D3DXMESH_MANAGED, m_pD3DDevice );
```

```
    // Store this new actor
    if ( AddActor( ) < 0 ) { delete pNewActor; return false; }
    m_pActor[ m_nActorCount - 1 ] = pNewActor;

    // Now build an object for this mesh (standard identity)
    CObject * pNewObject = new CObject( pNewActor );
    if ( !pNewObject ) return false;

    // Store this object
    if ( AddObject() < 0 ) { delete pNewObject; return false; }
    m_pObject[ m_nObjectCount - 1 ] = pNewObject;

    // Set up an arbitrary set of directional lights
    ZeroMemory( m_pLightList, 4 * sizeof(D3DLIGHT9));
    m_pLightList[0].Type = D3DLIGHT_DIRECTIONAL;
    m_pLightList[0].Diffuse = D3DXCOLOR( 1.0f, 0.92f, 0.82f, 0.0f );
    m_pLightList[0].Specular = D3DXCOLOR( 1.0f, 0.92f, 0.82f, 0.0f );
    m_pLightList[0].Direction = D3DXVECTOR3( 0.819f, -0.573f, 0.0f );

    m_pLightList[1].Type = D3DLIGHT_DIRECTIONAL;
    m_pLightList[1].Diffuse = D3DXCOLOR( 0.4f, 0.4f, 0.4f, 0.0f );
    m_pLightList[1].Specular = D3DXCOLOR( 0.6f, 0.6f, 0.6f, 0.0f );
    m_pLightList[1].Direction = D3DXVECTOR3( -0.819f, -0.573f, -0.0f );

    m_pLightList[2].Type = D3DLIGHT_DIRECTIONAL;
    m_pLightList[2].Diffuse = D3DXCOLOR( 0.8f, 0.8f, 0.8f, 0.0f );
    m_pLightList[2].Specular = D3DXCOLOR( 0.0f, 0.0f, 0.0f, 0.0f );
    m_pLightList[2].Direction = D3DXVECTOR3( 0.0f, 0.707107f, -0.707107f );

    m_pLightList[3].Type = D3DLIGHT_DIRECTIONAL;
    m_pLightList[3].Diffuse = D3DXCOLOR( 0.6f, 0.6f, 0.6f, 0.0f );
    m_pLightList[3].Specular = D3DXCOLOR( 0.0f, 0.0f, 0.0f, 0.0f );
    m_pLightList[3].Direction = D3DXVECTOR3( 0.0f, 0.707107f, 0.707107f );

    // We're now using 4 lights
    m_nLightCount = 4;

    // Success!
    return true;
}
```

CActor - Conclusion

We have now covered all of the new code that has been added to the CActor class since Lab Project 9.1. While we have certainly added quite a large amount of code, much of it took the form of simple wrapper functions. Our actor now has built-in support for loading multiple mesh hierarchies, and is fully capable of animating of those hierarchies. Despite the myriad of code we studied here in this workbook, the API for the CActor class makes it extremely easy to use. Indeed, it can be initialized with only a few function calls by the application. This makes the CActor class an excellent tool for us as we move forward with our studies and can prove to be a powerful re-usable component in your own game projects. (And it will become even more potent when we add skinning support in the next chapter!)

Lab Project 10.2: The Animation Splitter

Our coverage of Lab Project 10.2 will be different from that of previous lab projects. We will not be covering the code in depth, but will instead discuss implementation at a high level. The reason we have decided to take this approach is that the application is essentially nothing more than a dialog box that calls the CActor functions we have already covered in this workbook. Therefore, you should have no trouble understanding the code should you decide to examine the source projects.

Design

A screenshot from the Animation Splitter is shown in Figure 10.3. The application has two main components. The first is the main render window which all of our applications have used. Just like our previous applications, this window has its contents redrawn each iteration of the game loop in the CGameApp::FrameAdvance method. Unlike our other lab projects however, there is no CScene class or CTerrain class for managing the objects in the world. This is primarily because we only load one X file at a time. The CGameApp object will load a single actor from an X file (inside CGameApp::BuildObjects) and will call CActor::DrawActor in the CGameApp::FrameAdvance method during each iteration of the main game loop. That is about the extent of the scene management that has to be done in this application.

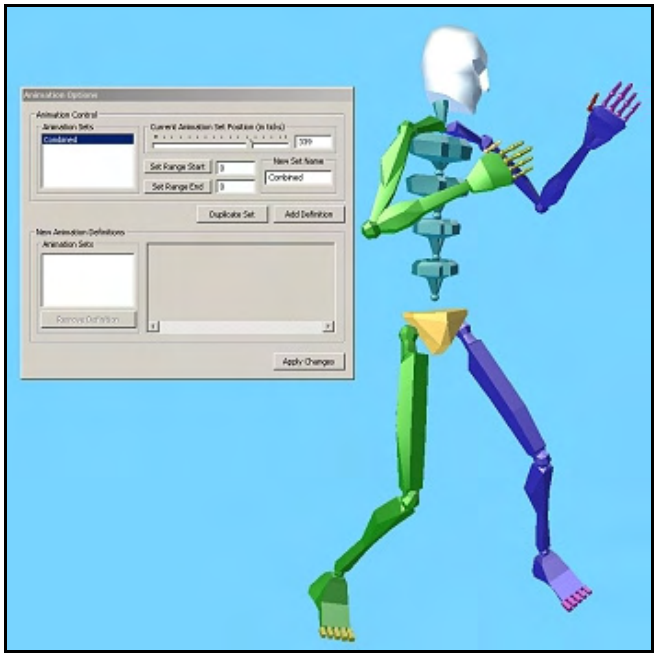

Figure 10.3: The Animation Splitter

In Figure 10.3, we see the main render window with our actor being rendered. In this example, we have loaded a file called ‘Boney.x’ which contains the skeleton of a humanoid character.

The main part of this application that is quite different from previous lab projects is the modeless dialog box that we create to provide a number of controls. We need the dialog because the purpose of this application is to provide a means for editing the animation data stored in the actor. More specifically, the purpose of this tool is to provide a means for us to take an actor's animation set and split it into multiple animation sets. Therefore, we have controls that allow us to navigate to a certain position on an animaton set's timeline and set start and end markers. We can then give this range a name and add it as a new split definition. So the controls on the dialog will not only display the contents of the animation data in the loaded X file, but they will also allow you to alter that data before re-saving the modified X file. Once we have added all the new definitions we wish to add, we can hit the Apply button. At this point, the new animation sets will be created from each split definition and the old animation sets will be released from the actor's controller. It should be obvious that this entire splitting process can be done by the application with a single function call to CActor::ApplySplitDefinitions. In order to understand how the splitter works internally, we shall first examine how it is used. Therefore, this section will also serve as a user handbook for the Animation Splitter.

Using the Animation Splitter

To demonstrate using the animation splitter, we will assume you are working with the X file 'Boney.x'. This X file contains a single animation set (called 'Combined') which contains a number of animation sequences combined into a single set. This is a typical scenario when exporting X files from applications that support only a single animation set and is the reason that this tool was created. It should be noted however, that the application works perfectly fine even if the X file already contains multiple sets. These multiple sets can also be subdivided into more sets if desired.

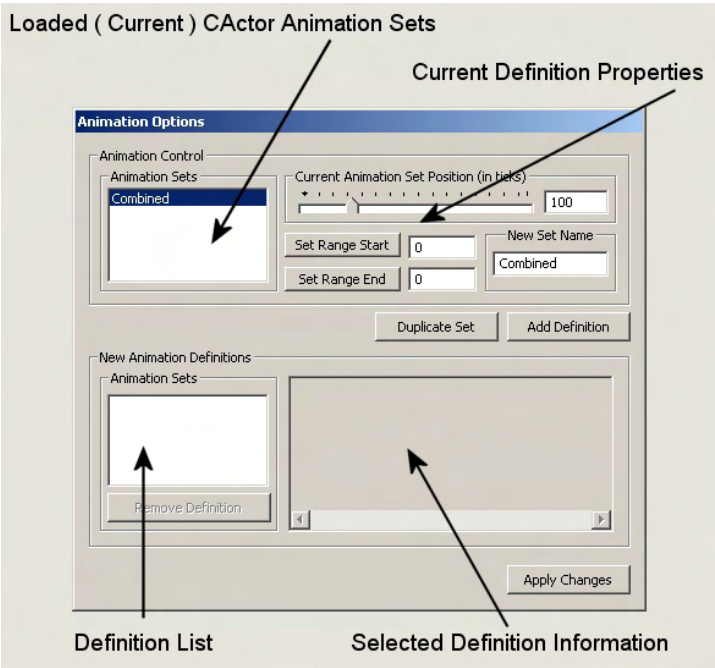

Figure 10.4: The Interface Components

In Figure 10.4 we see how the dialog controls might look after the ‘Boney.x’ file has been loaded. The uppermost list box contains animation sets that were loaded from the X file and are currently registered with the actor. As you can see, in our example the X file contained only one animation set called ‘Combined’. In Figure 10.4 we have selected this animation set, which enables the Split Definition control panel to the right of this list box (the slider, set range buttons, etc.).

Because we have selected the ‘Combined’ animation set in the list box, this tells the application that the next split definition we add will contain a subset of the animation data in this animation set. Remembering our discussion of CActor::ApplySplitDefinitions, this is the source animation set for the next split definition we are about to construct.

This application allows you to add split definitions to a list one at a time. The bottommost list box on the dialog shows the split definitions you have already added. Obviously, in Figure 10.4 this box is empty as we have not yet added any.

When a source animation set is selected from the top list box, the definition controls become active. We can move the slider to navigate to positions on the animation set’s timeline. The 3D render window will reflect the changes in the actor as we drag the slider through the actor’s timeline. This makes it easy to visually navigate to the correct position in the animation. The first thing we will want to do is set the start and end markers for this definition. In this example, we will extract an imaginary walking sequence that is positioned between ticks 100 and 200 on the timeline.

First we would move the slider to the start position and press the Set Range Start button. This will record the current position of the slider as the start marker for the definition we are currently building. We would then move the slider position again to where the walking sequence ends (200 in this example) and press the Set Range End button to record this position as the end marker. Figure 10.5 shows the dialog after we have recorded the start and end markers. Notice that the subsection of the timeline is also highlighted in blue on the slider.

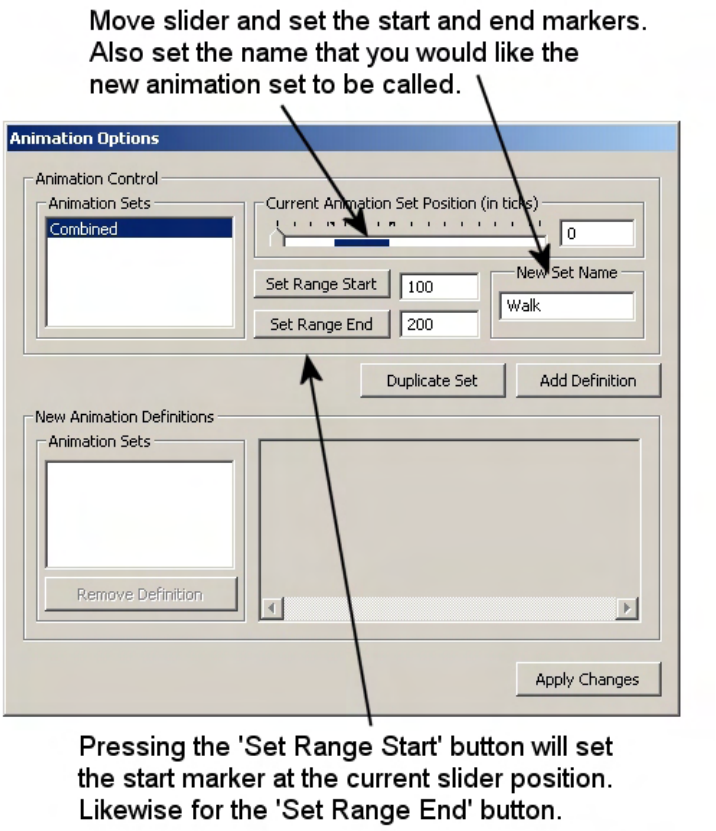

Figure 10.5: Setting up a new Split Definition

We have now marked the exact section of the original animation set that we would like to extract into a new one. That is, we are stating that we will want a new animation set to be built that will only contain the animation data that fell between 100 and 200 ticks on the timeline of the original animation set. We will also want to give this new animation set a name. As you can see in Figure 10.5, we assign it the name ‘Walk’. We just type the name into the text edit box to the right of the Set Range Start and Set Range End buttons.

At this point we have correctly set up the properties for our first split definition. We can now inform the dialog that we wish to add this split definition to a list and move on to defining another one. We add the properties to the split definitions list by pressing the Add Definition button.

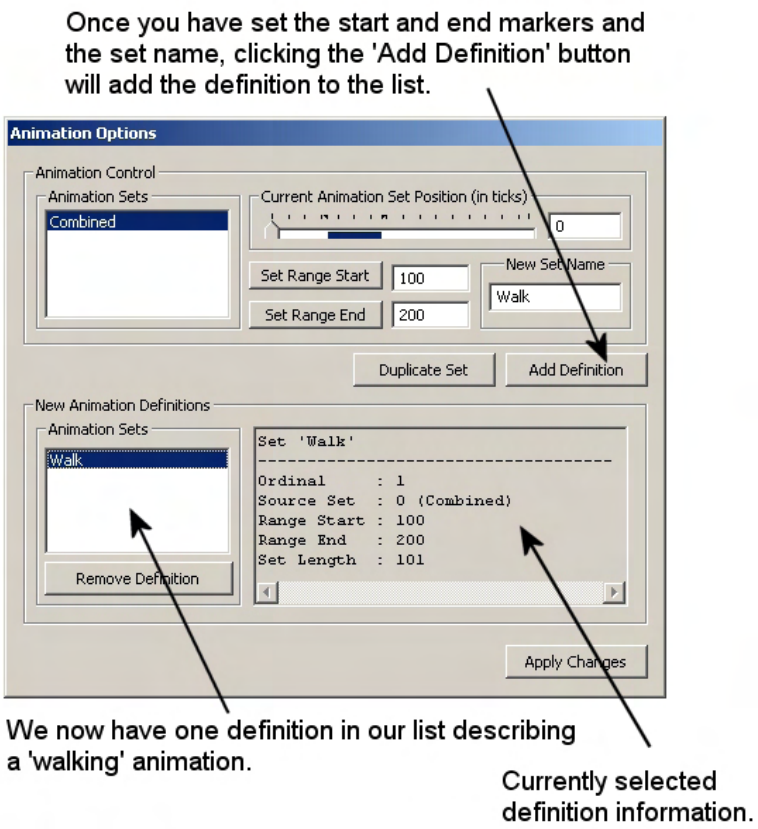

Figure 10.6: Adding the Split Definition

Once the new definition has been added you will see it appear in the bottom list box. As Figure 10.6 shows, this box contains the name of our newly added ‘Walk’ animation. What is important to realize is that at this point, no animation sets have been physically created. All we are doing is adding split definition structures to an array one at a time. This allows the original source animation sets to remain in the controller so that they can be sources for subsequent definitions we may wish to create.

At this point we have added one split definition to our list. Continuing this example we will now definine a second animation set which we will call ‘Run’. For the sake of this explanation, we will imagine that the keyframes for this sequence are also contained in the original ‘Combined’ animation set between tick positions 300 and 400.

With our new ‘Walk’ definition added to the list, we can now set the definition controls for the next definition we wish to add. In Figure 10.7 you can see that the slider has been used to set two new start and end marker positions on the animation timeline. This time, the markers bound a 100 tick range between positions 300 and 400. We then type the name (‘Run’) we would like this animation set to be called in the New Set Name edit box. We have now filled out all the information for our second split definition.

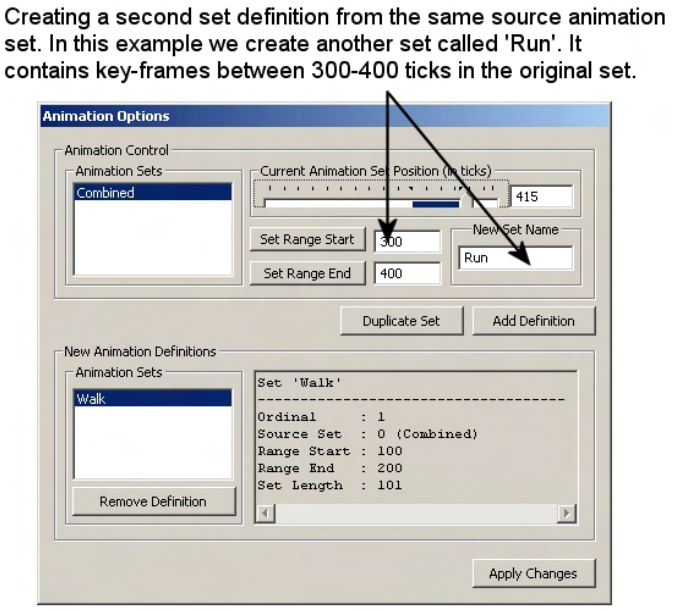

Figure 10.7: Setting up a second Split Definition

With the definition controls now containing the information for our second definition, we add it to the split definition list. We once again press the Add Definition button which creates a new split definition and adds it to the current array. If we look at the bottom list box in Figure 10.8, we can see that after this step is performed there are now two definitions in our list: ‘Walk’ and ‘Run’.

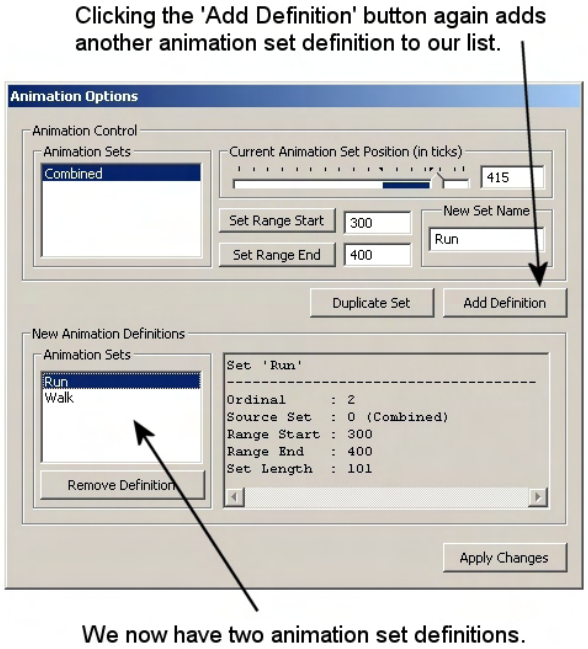

Figure 10.8: Adding the Second Definition

Assuming that we only wish to break the source animation set into two sets in this example, our work is done. It is now time to instruct the application (more specifically, the actor) to apply these split definitions.

When the Apply Changes button is pressed, the current array of split definitions stored in the dialog object is passed to the CActor::ApplySplitDefinitions method. We know that this method will create a new animation set from each definition and register them with the actor's animation controller. At this point, the original animation set(s) will cease to exist. The actor has now been modified in memory and its original animation set(s) have been replaced by the the new animation sets described by the definitions.

Finally, Figure 10.9 shows how the dialog would look after this step. At this point, the definitions list is empty since there are no longer any pending split definitions to process. Those definitions have now been turned into real animation sets and therefore, they are now listed in the top list box instead of the original source set. At this point, you could perform more subdivision steps on these new animation sets, although this is something you will probably not need to do very often.

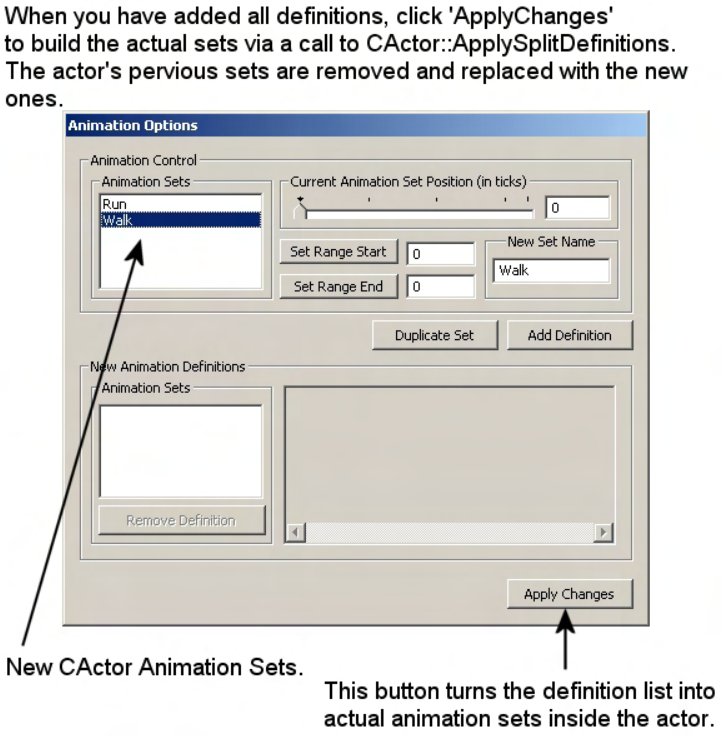

Figure 10.9: Building Animation Sets from Split Definitions

The actor's animation sets have now been changed, but no editing of the original X file has been done. Usually, when splitting animations in this way you will want to save the modified actor back out to the X file. You can do this by selecting the Save option from the file menu in the main render window.

Implementation

Most of the code to this lab project has already been covered, due to the fact that the majority of its functionaility is within CActor. We are also quite familiar with the CGameApp class, having used it in all of our lab projects from the beginning of this course series. Although we are going to make one or two changes to this class, for the most part, it is the same in this project as all the other versions that have come before it. One of the important new changes in CGameApp happens in the CGameApp::CreateDisplay method. This method has been used right from Lesson One to build our enumeration object and create the main render window of the application. Now, at the bottom of that function we also make the following call:

```
m_AnimDialog.InitDialog( m_hWnd, &m_Actor )
```

m_AnimDialog is a variable of type CAnimDialog, which is a class we will write in this lab project. This dialog class is responsible for tracking changes to controls and reflecting those changes back to the actor. The CAnimDialog::InitDialog method is the method that actually instructs the CAnimDialog object to display the modeless dialog on the screen. The dialog box layout is defined as a resource, so controls are automatically created for us when the call to the Win32 function CreateDialogBoxParam is made.

The InitDialog method accepts two parameters that our dialog class will need. The first parameter passed in by CGameApp is the handle of the main render window. Although the dialog will be modeless and not confined to being positioned within the bounds of the render window, the render window will still be its parent and the window that contains the application menu. When the parent window is destroyed, so is the child dialog.

The second paramater passed by CGameApp is the address of the actor that has been loaded. The dialog class will need access to the actor so that it can call its ApplySplitDefinitions function when the Apply button is pressed. It will also need to alter the position of the currently selected animation set in response to the user dragging the slider bar. This will ensure that when the slider bar is moved to a new position, the actor's hierarchy is updated to reflect that position change. Since the CGameApp object is consistently rendering the actor in a loop (via CGameApp::FrameAdvance), those changes made to the actor's hierarchy will be immediately reflected in the render window when the actor is redrawn in the next iteration of the render loop.

> **Note**: We are creating a modeless dialog box so that the program will not have to wait for the user to finish applying definitions before our CGameApp code can continue execution. As soon as InitDialog has created the dialog box, program flow will return back to CGameApp and the main render loop will be entered. The dialox box will remain on the screen processing input and relaying these property changes to the actor.

CAnimDialog – A Brief Overview

We will not step through the code to the CAnimDialog class line by line as we have done in other lab projects. It uses the most basic Win32 concepts (dialogs and controls) and most of the code is just concerned with setting and getting the properties of these controls and handling any messages they send and receive. Win32 controls and dialog box programming is discussed in detail in **C++ Programming for Game Developers: Module II** here at the Game Institute, so we will assume that you have either taken this course already, or that you are familiar with Win32 user interface programming techniques. We will not explain the concepts of Win32 dialog box and control programming here since it falls outside the scope of what we intend to teach in this course. If you are not comfortable with this type of Win32 programming, then we strongly recommend you take the abovementioned course before continuing (or in conjunction with) with your Graphics Programming studies.

Below, we see the CAnimDialog class declaration from CAnimDialog.h. The methods of the class are not shown here, but there are quite a few. Most of these methods are functions that react to control changes while others are called to set the default values for the controls. What we do wish to focus on here are the member variables of this class and how they are used by this object.

```
class CAnimDialog
{

 // Methods not shown here

 private:
    //-----------------------------------------------------------------------
    // Private Variables for This Class
    //-----------------------------------------------------------------------
    HWND                        m_hDialog;
    CActor                    * m_pActor;
    LPD3DXKEYFRAMEDANIMATIONSET m_pCurrentAnimSet;
    ULONG                       m_nCurrentAnimSet;
    ULONG                       m_nStartTick;
    ULONG                       m_nEndTick;

    ULONG                       m_nDefCount;
    AnimSplitDefinition         m_pDefList[MAX_DEFINITIONS];

    HFONT                       m_hFontFW;

};
```

HWND m_hDialog

When the InitDialog method instructs Windows to display the dialog, we are returned a handle to the dialog window. This handle will be needed to send and receive messages to the dialog and its controls. For example, when we wish to send a message to the dialog window (such as to enable the window on screen), we will need to send a message using the SendMessage function. This Win32 function expects the first parameter to be the handle of the window it is expected to send the message to.

CActor * m_pActor
This member is used to cache a pointer to the actor that the dialog controls will manipulate. This pointer is passed in by the CGameApp object when it issues the call to CAnimDialog::InitDialog. This provides the dialog object with a pointer to the same actor the CGameApp object is rendering. The dialog will need access to the actor on several occasions. For example, when the user alters the slider position, the dialog object will need to retrieve the new slider position and use it to set the position of the actor's currently active animation track. The dialog object will also need to communicate with the actor when the user selects a new source animation set. When a new source animation set is selected, the dialog object will retrieve the index of the animation set from the top list box and tell the actor to assign this animation set to track 0. Since we can only be editing using one source animation set at a time, the dialog can always make sure that that the currently selected animation set is bound to track 0 on the actor's mixer. That way, it can safely assume that when the slider position is changed by the user, it has to apply this position change to track 0.

LPD3DXKEYFRAMEDANIMATIONSET m_pCurrentAnimSet
This member is used to store a pointer to the interface of the currently selected source animation set. When the user selects a source animation set from the top list box, it becomes the current animation set. Changing the position slider will allow us to step through the animations in this set. Therefore, when a new set is selected, the dialog object will fetch the animation set interface from the actor and store it here. Now it can assign it to track 0 on the mixer and extract other information from it as needed to populate the controls. For example, the slider bar must represent the timeline of the animation set, so it will be necessary to extract the period of the animation set, convert it to ticks and store this range in the slider control.

ULONG m_nCurrentAnimSet
This member is used alongside the previous member. Where as the previous member stores the interface pointer of the currently selected source animation set, this member stores the index of this animation set assigned to it by the animation controller. This allows us to reference this animation set in the actor by index.

ULONG m_nStartTick
This member will be used to store the current value for the Set Range Start edit box. This is the currently set start marker position used for marking a range on the current animation set's timeline. This value will be used as the start marker when the definition is added to the list.

ULONG m_nEndTick
This member will be used to store the current value for the Set Range End edit box. This is the currently set end marker position used for marking a range on the current animation set's timeline. This value will be used as the end marker when the definition is added to the list.

ULONG m_nDefCount
This member contains the number of split definitions that have been added to the dialog's split definitions array. This will be zero when the application starts.

AnimSplitDefinition m_pDefList[MAX_DEFINITIONS]
This is an array of AnimSplitDefinition structures. Each element in this array will have been added in response to the Add Definition button being pressed on the dialog. When that happens, the split properties (end marker position, start marker position, and set name) are copied from the dialog controls into a new AnimSplitDefinition structure in this array. The definition count is then incremented.

HFONT m_hFontFW;
This is a handle to the font we use in the dialog.

While we will not look at all the helper functions for this class, we will look at a few. The first function we will look at is the dialog box procedure. This is the method that is sent the messages that are generated by the controls (sent via the operating system).

CAnimDialog::OptionsDlgProc

This function handles the basic message processing for the dialog. It is called by Windows whenever a message is generated for our dialog box. For example, if the user pressed the Apply button, a WM_COMMAND message will be sent to this function. The message will also be accompanied by the ID of the control that sent it. For example, if a WM_COMMAND message has been triggered by a control with the id IDC_APPLY, we know the user has pressed our Apply button because IDC_APPLY is the id we assigned to that button in the resource editor.

Although this function is simple (it is just a switch statement that calls processing functions) we will discuss the messages it recieves and the helper functions it calls as a result. We will not be covering those helper functions in this workbook since their code is very straightforward. You should have no problem looking through the source code since it is just basic Win32 controls programming. This function will show you how and why those helper functions get called. We will also explain here what those helper functions actually do. This will give you a better overview of the entire application without us having to examine code.

The CAnimDialog::OptionDlgProc function is called by the operating system (indirectly via a static routing function) whenever a message is generated for the dialog window or one of its controls. We can simply process the messages we want and return false for any that we do not. We return false to indicate that we did not handle the message and that Windows should still perform default processing on it. Luckily, the OS implements a lot of default behavior so that the dialog window knows when to paint itself (for example) or when it is overlapped by other windows. Therefore, we only have to intercept messages which we intend to process using our own additional logic.

When this function is called it is passed the handle of the window that generated the message, the message itself (Windows defines a large set of message codes as UINTs) and two DWORD parameters (wParam and lParam). The contents of the final two parameters will depend on the message being received, as we shall see.

The first section of the code sets up a switch statement to test the Message parameter for messages we are interested in.

```
BOOL CAnimDialog::OptionsDlgProc( HWND hWnd, UINT Message,
                                  WPARAM wParam, LPARAM lParam)
{
    ULONG  i;

    switch ( Message )
    {
    case WM_INITDIALOG:

        // Store dialog here since this is fired before the
        // CreateDialog has returned
        m_hDialog = hWnd;

        // Populate the dialog
        PopulateOptions();

        // Set focus for us.
        return TRUE;
```

The first case happens when the dialog window has received the WM_INITDIALOG message. The operating system will send this message to all dialog box windows just after the window has been created but before it has been displayed. This allows you to perform some default initialization such as filling up the list box controls with the information you want in them. As you can see, we do exactly that.

First we store the handle of the dialog window in the CAnimDialog's member variable, so this C++ object always has a handle to the GUI element to which it is attached (i.e., the dialog window itself). This is the first time we get to know about the handle of the window because the operating system has just created it for us. We store it because we will need it later when sending messages to our controls. Remember, at this point, Windows has created our dialog box and all the control windows that were specified in the resource template. However, these controls and the dialog window are not visible to the user at the moment. All controls (list boxes for example) will also be empty of content at this point.

After we have stored the window handle, we call the PopulateOptions method. This method does quite a bit of preparation. It first loops through every animation set in the actor and extracts its name and index. Each name is added to the top list box and the index of the animation set in the animation controller is assigned to the list box element as item data. When the user selects an item in this list box, we can extract the name they selected and the index of the animation set they would like to use as the new source set. This method will also initially disable the slider control because no source animation set will be selected initially. The slider is only used to scroll through the position of the currently selected source animation set and serves no purpose if a source animation set has not yet been selected.

When the PopulateOptions method returns, the top list box will be filled with all the animation set names currently managed by the actor. With the dialog controls now initialized, processing of this message is complete. We return true to let the OS know that we have handled this message and require no further default processing of this message.

In the next case, we test to see if the message passed is a WM_COMAND message. Many controls send WM_COMMAND messages. When a WM_COMMAND message has been sent to us by Windows, the

wParam parameter will contain vital information. In the low word of this variable will be stored the numerical ID assigned to the child control of the dialog (in the resource editor). This is the control that is sending the message and it usually means that the user has interacted or changed the contents of the control in some way. In the high word of wParam will be the actual event (notification message) that has occurred.

The following sections of code are all for the WM_COMMAND message case. In this first code block, we can see that if the WM_COMMAND has been received, we enter another switch statement to test which control sent the message. Since the control ID is stored in the low word of the lParam parameter, we can use the LOWORD macro to crack it out and examine it.

```
    case WM_COMMAND:

        switch ( LOWORD(wParam) )
        {
```

Now that we know we have a WM_COMMAND message, let us see what control sent it. The first test is for the control with the ID of IDC_LSTANIMSETS. This is the ID that was assigned to the top list box on the dialog box in the resource editor. It is the list box that will, at this point, contain the names of all animation sets currently registered with the animation controller. If the contents of LOWORD(wParam) matches this ID, then the user has performed some action in this list box which has triggered this message. For example, the user may have selected another animation set from the list. When this has happened, the list box control will always send a notification message to the parent window to notify it that a selection change has occurred.

Once we know it is the list box control that sent the message, we can test the high word of the wParam parameter for the notification code that was sent. The only event/notification we are interested in intercepting is the LBN_SELCHANGE list box notification message. Windows will send us this message when the user has changed the selection. In our example, it means the user has changed their choice of source animation set. You can see in the next section of code that if this is our list box that has sent the message, and if the notification it has sent is one of a selection change, we will call the CAnimDialog::CurrentSetChanged method. This method will extract the new selected animation set name and index from the list box. It will then use that set index to fetch the matching animation set interface from the actor and assign it to track 0 on the mixer. The track will be assigned an initial position of 0. This new animation set will now be the current animation set that will be manipulated by the slider control and will be the new source animation set for the split definition currently being constructed. Notice how we return true once we have processed the message so that Windows knows we have handled it.

```
        case IDC_LSTANIMSETS:
            if( LBN_SELCHANGE == HIWORD(wParam) )
             { CurrentSetChanged(); return TRUE; }
            break;
```

If the WM_COMMAND message was sent by a selection change in the bottom list box then the control sender ID will be IDC_LSTNEWANIMSETS. This is the list box which displays the currently compiled split definitions. If the user has selected one of these sets from the list, then as in the above case, a

selection change notification will be sent by that list box control. When a user selects an already added split definition from the definitions list, the details of the split definitions are displayed in the status window next to the list box. That is essentially the task of the CAnimDialog::NewSetChanged method. This helper function extracts the values from the selected definition structure and displays them in the status window.

```
        case IDC_LSTNEWANIMSETS:
            if( LBN_SELCHANGE==HIWORD(wParam) ) { NewSetChanged(); return TRUE; }
            break;
```

If the WM_COMMAND message sent was generated by the user pressing the Set Range Start or Set Range End buttons, then the IDs of the control sending the message will be IDC_BUTTON_SETSTART or IDC_BUTTON_SETEND, respectively. Once again, these are the IDs we assigned to these button controls in the resource editor. When this is the case, we call the SetRangeStart and SetRangeEnd methods. These methods simply extract the current position value from the slider control and store it in the m_nStartTick and m_nEndTick member variables depending on which of the two buttons was pressed. These values are cached in these member variables until the Add Definition button is pressed. At that time, the start and end marker values are copied into a new split definition structure in the dialog's definition array.

```
        case IDC_BUTTON_SETSTART:
            SetRangeStart();
            break;

        case IDC_BUTTON_SETEND:
            SetRangeEnd();
            break;
```

When the user has set the start and end markers for the current definition and wants to add that definition to the list, the Add Definition key is pressed. This button (whose ID is IDC_ADD_DEFINITION) sends a WM_COMMAND message. It is trapped in the next section of code and used to trigger the AddSetDefinition method. This method adds a new split definition to the end of the array. The previous cached start and end marker positions are copied into this structure and the method extracts the text the user has typed into the Set Name edit box and stores it in the split definition structure as the new animation set's name. There is also a Remove Definition button which, when pressed, triggers a call to the RemoveDefinition function. You can probably guess what this function does.

```
        case IDC_ADD_DEFINITION:
            AddSetDefinition();
            break;

        case IDC_DEL_DEFINITION:
            RemoveDefinition();
            break;
```

At some point, the user will have added all the desired split definitions to the dialog object's internal array of definition structures. At such a time, they will click the ApplyChanges button and trigger a WM_COMMAND message with the control ID of IDC_APPLY. As you can see in the following code

block, this will trigger a call to the CAnimDialog::ApplyChanges method. This method simply calls the CActor::ApplySplitDefinitions method and passes in the array of split definitions that has been compiled. When this function returns, the new animation sets will have been built and registered with the actor's animation controller and the old animation sets (the original source animation sets) will have been deleted. The following code shows the last sub-case for the WM_COMMAND message:

```
        case IDC_APPLY:
            ApplyChanges();
            break;

        } // End Control Switch
        break;
```

Not all controls send their notification messages on the back of WM_COMMAND messages. One such control is the slider control, which is not one of the original Windows controls. Instead, it belongs to a pool of controls referred to as the *common controls*. These controls were added after the core controls as a means of extending the user interface capabilities of the OS.

When a slider control is moved or changed it sends a WM_HSCROLL message (instead of a WM_COMMAND message) to the parent window. The lParam parameter will contain the *handle* of the control window that sent the message (i.e., the slider). However, what we actually want is the window ID (not its handle) just as had in the above cases, so that we can make sure that the ID of the control that sent this scroll message is indeed the ID we assigned to our animation set slider control in the resource editor.

Win32 has a function called GetDlgCtrlID which accepts a window handle and returns its control ID. In this next section of code, we are interested in scroll activity in our slider bar which has a control ID of IDC_ANIMSLIDER (assigned in the resource editor). When this is intercepted, the CAnimDialog::AnimSliderChanged method is called, which extracts the current position of the slider and uses it to update the position of track 0 on the animation controller. This is the track that the current source animation set is assigned to. This function will also force the actor to perform a hierarchy update pass so that when the CGameApp::FrameAdvance method renders the actor in the next iteration of the render loop, these changes are reflected in the output. We then return true from this function so that Windows knows we have handled this message.

```
    case WM_HSCROLL:

        switch ( GetDlgCtrlID( (HWND)lParam ) )
        {
        case IDC_ANIMSLIDER:

            AnimSliderChanged();

            // We handled it
            return TRUE;

        } // End Control Switch
        break;
```

```
    } // End Message Switch

    // Not Processed!
    return FALSE;
}
```

If the end of this function is reached, then it means that a control that we are not interested in sent the message, or a control that we are interested in sent a message of some type that we are not setup to handle. When this is the case, we return false so that Windows knows that we took no action and it can feel free to perform any default processing it may want to do. For example, we would want Windows to handle paint messages for controls when their contents need to be refreshed.

CAnimDialog::AnimSliderChanged

If we look at the source code to the CAnimDialog::AnimSliderChange function (called from the dialog procedure in response to a WM_HSCROLL message), we can see the typical interaction between the dialog box object, its controls, and how changes to those controls update the properties of the actor. This will enlighten you with respect to how the messaging system works. Remember, if your Win32 is a little rusty, controls and dialog box programming are all covered in Module II of the C++ Programming for Game Developers series here at the Game Institute.

The function first checks that a source animation set has been selected. If this is the case then the interface for that animation set will have been cached in the m_pCurrentAnimSet member variable. This interface pointer would have been extracted from the actor and stored in this member variable in response to the user selecting a new source animation set from the list (see the CAnimDialog::CurrentSetChanged method). Provided this is the case, we then need to get the window handle of the slider control using the GetDlgItem function. This function accepts, as its first parameter, the handle of the dialog box, and as the second parameter, the ID of the control we wish to get an HWND for. The ID of our slider control is IDC_ANIMSLIDER.

```
void CAnimDialog::AnimSliderChanged()
{
    HWND   hControl;
    TCHAR  Buffer[128];
    double Position, MaxSeconds;
    ULONG  TickPos = 0;

    // Break out of here if we don't have one selected atm
    if ( m_pCurrentAnimSet )
    {
        // Get the slider control hwnd
        if ( !(hControl = GetDlgItem( m_hDialog, IDC_ANIMSLIDER )) ) return;
```

If we get this far, then we have an HWND to the slider control stored in the hControl local variable. We then get the period of the currently select source animation set so we can make sure that the position they have provided is not out of the range.

```
        // Store max seconds variable
        MaxSeconds = m_pCurrentAnimSet->GetPeriod();
```

Next we need to get the position of the slider. When the animation set was first selected by the user in the CurrentSetChanged method, the period of the animation set would have been retrieved, converted to ticks, and then used to set the range of the slider control. This means that the slider control's range should be between 0 and MaxTicks at its start and end positions. We now need to extract the current position that the user has moved the slider to. We do this by sending the TBM_GETPOS message to the slider control using the Win32 SendMessage function. The function will return the current position of the slider (in ticks) so that we can set the current position of the track that the animation set is assigned to.

```
        // Retrieve the new animation set position in ticks
        TickPos = ::SendMessage( hControl, TBM_GETPOS, (WPARAM)0, (LPARAM)0 );
```

When we set the track position of the actor, we specify the new position in seconds, not ticks. So we must convert the new tick position we have just extracted from the slider control into seconds by dividing the tick position by the animation set's ticks per second ratio. We do not want the position to ever be greater than the period of the animation set; otherwise the periodic position of the animation set will loop back around to zero. Therefore, we calculate the new position as being the minimum of either the new track position extracted from the slider (in seconds) and the period (MaxSeconds) of the animation set. We never want the position to be greater than the period, so this test is done for safety. Notice we subtract epsilon from MaxSeconds to account for floating point errors and to make sure that the position is always clamped between the start and end of the animation set's period.

```
        // Convert to seconds for track (clamp - epsilon to prevent rendering loop
        //  around)
        Position = min( (double)TickPos /
                        m_pCurrentAnimSet->GetSourceTicksPerSecond(),
                        MaxSeconds - 1e-4 );
```

We now have the new position for track (always track 0 in this application) as described by the slider control. We use the CActor::SetTrackPosition method to apply this position change to the track. We then update the actor's absolute matrices by calling the AdvanceTime method. Notice how we pass 0.0 as the first parameter because we do not want to increment any track positions since we have just set the track position to the correct value. However we do pass in 'true' as the second parameter, which we know from our ealier discussion forces the actor to traverse the hierarchy and build its absolute marices for each frame. The next time the CGameApp::FrameAdvance method renders the actor, its matrices will have been updated and the new position of the actor (described by the new slider position) will be reflected in the render window.

```
        // Update track time
        m_pActor->SetTrackPosition( 0, Position );

        // Ensure all frame matrices are up to date
        m_pActor->AdvanceTime( 0.0f, true );

    } // End if animation set
```

At this point the actor has been updated, but we also have an edit box to update. Next to the slider is an edit box which displays the current position of the slider numerically for greater accuracy during the setting of the start and end marker positions. As the slider has now been updated, we should also replace the text in this edit box with the new position as well.

We do this by using the GetDlgItem method to retrieve the HWND for the edit window. The ID of this edit window is defined in the dialog template as IDC_EDIT_CURRENTPOS. Once we have the window handle, we convert the tick position that we just extracted from the slider into a string stored in a local char array (Buffer). We then change the text of the edit window to the value stored in this string using the Edit_SetText macro (defined in windowsx.h).

```
    // Get the edit control
    if ( !(hControl = GetDlgItem( m_hDialog, IDC_EDIT_CURRENTPOS )) ) return;

    // Get a string of the position in ticks
    _itot( TickPos, Buffer, 10 );

    // Set the value
    Edit_SetText( hControl, Buffer );
}
```

Note: The Edit_SetText macro is just a friendly wrapper around the SendMessage function used to send messages to all windows. All the core controls (list boxes, edit boxes, buttons, etc.) have macros defined for them just like this one in windowsx.h. They make the setting and getting of control properties easier and more user-friendly. Notice however that we do not use a macro like this when getting the position of the slider control. This is because the slider control is not one of the original core controls of the operating system and therefore has none of these macros defined for it. We have to do it the slightly more involved way for the slider (and any common control) by making the call to the SendMessage function ourselves. All the Edit_SetText macro is doing is wrapping the sending of the WM_SETTEXT message to the edit control using the SendMessage function.

CAnimDialog::CurrentSetChanged

CurrentSetChanged is called from the dialog box procedure in response to the user selecting a new item in the top list box on the dialog. This means the user has selected a new source animation set that it wishes to split.

The first thing we do is retrieve the HWND of the list box that the animation set names (and indices) are stored in. We use the GetDlgItem function again to retrieve the HWND of the list box with the control ID of IDC_LSTANIMSETS. We then use the ListBox_GetCurSel macro (see windowsx.h) to retrieve the current item that is selected in the list box as an integer index. Remember, this function was called because the user selected a new item. It is the index of this newly selected item that is returned from this function.

```
void CAnimDialog::CurrentSetChanged()
{
    HWND                          hControl = NULL;
    LPD3DXANIMATIONSET            pAnimSet = NULL;
    LPD3DXKEYFRAMEDANIMATIONSET pKeyAnimSet = NULL;
```

```
    // Get the current selection
    if ( !(hControl = GetDlgItem( m_hDialog, IDC_LSTANIMSETS )) ) return;
    ULONG nIndex = ListBox_GetCurSel( hControl );
```

We now know the index of the item in the list box that the user has just selected and we can use it to fetch the corresponding animation set from the actor and cache it in the member variables of the CAnimDialog object. First, let us release any current animation set information that may be cached from a previous selection.

```
   // Release the previously selected animation set
    if ( m_pCurrentAnimSet ) m_pCurrentAnimSet->Release();
    m_pCurrentAnimSet = NULL;
    m_nCurrentAnimSet = 0;
```

Next we test that we did get a valid selection index from the list box. If not, then it means the user has deselected an item, leaving no item selected. When this is the case, we call the CAnimDialog::EnableSetControls method, which disables all the slider and marker controls. They have no meaning if a source animation set is not selected. Also, if no animation set is selected, we make sure we also remove any previous current animation set from the first track on the mixer.

```
    // No item / error ?
    if ( nIndex == LB_ERR )
    {
        // Disable the animation set controls
        EnableSetControls( false );

        // Actor uses no set atm.
        m_pActor->SetTrackAnimationSet( 0, NULL );

    } // End if nothing selected
```

If a valid index was returned, then it is time to find out which animation set this index maps to in the actor. We can then fetch the interface of this animation set from the actor and assign it to track 0 on the mixer. Notice how each string in the list box also has assigned (as user data) the index of the animation set in the controller that the item maps to. Therefore, we use the ListBox_GetItemData to retrieve the index of the set we need to fetch from the animation controller.

```
    else
    {
        // Retrieve the item data for this
        ULONG nAnimSet = ListBox_GetItemData( hControl, nIndex );

        // We're now using this animation set
        pAnimSet = m_pActor->GetAnimationSet( nAnimSet );

        // We can only split up keyframe animation sets. Ensure this is available
        if ( FAILED(pAnimSet->QueryInterface( IID_ID3DXKeyframedAnimationSet,
                                              (LPVOID*)&pKeyAnimSet )) )
        {
            // Disable the animation set controls
            EnableSetControls( false );
```

```
            // Actor uses no set.
            m_pActor->SetTrackAnimationSet( 0, NULL );

            // We're done
            return;

        } // End if not keyframed

        // We're done with the normal animation set
        pAnimSet->Release();
```

After fetching the animation set, we make sure it is a keyframed animation set, since those are the only ones we know how to subdivide in this tool. If the selected animation set is not a keyframed set then we once again disable the marker and slider controls and clear track 0 on the animation mixer.

If we get this far, then the user has selected a valid source animation set. We set the animation set to track 0 on the mixer (ready for playback) and cache the animation set interface and its index in the member variables of the dialog object. We then enable the marker and slider controls so that the user can begin to use the slider bar and set their markers. Until an animation set is selected, these controls are ghosted and cannot be used.

```
        // We're using the keyframed animation set
        m_pActor->SetTrackAnimationSet( 0, pKeyAnimSet );

        // Store the key anim set, and don't release this one!
        m_pCurrentAnimSet = pKeyAnimSet;

        // Store the index too for later
        m_nCurrentAnimSet = nAnimSet;

        // Enable the animation set controls
        EnableSetControls( true );
```

There is one final job to do before we leave this function. When configuring the properties of a split definition, we use the slider to set two markers. We also have to assign that split definition a name using the Set Name edit box. When the user changes the source set, we will copy into this edit box the name of the source set by default. The user can change it, and will most likely want to, but if they are simply trimming an animation set, then this saves them from having to re-type the name of the new animation set when they wish to keep it the same as the original.

So before we exit this function, we fetch the name from the animation set currently selected and copy it into a temporary buffer. If the animation set has no name then we will simply fill this buffer with the string “Unnamed Animation Set”. We then get the handle of the Set Name edit control and set its text to the contents of this buffer.

```
        // Set the text for the new set name
        TCHAR   NameBuffer[512];
        LPCTSTR strName = pKeyAnimSet->GetName( );
        if ( strName == NULL || _tcslen( strName ) == 0 )
            _tcscpy( NameBuffer, _T("Unnamed Animation Set") );
```

```
        else
            _tcscpy( NameBuffer, strName );

        // Get the definition information box
        if ( !(hControl = GetDlgItem( m_hDialog, IDC_EDIT_NEWSETNAME )) ) return;
        Edit_SetText( hControl, NameBuffer );

    } // End if selected a legitimate item
}
```

CAnimDialog::AddSetDefinition

This method is called after the user has positioned the start and end markers, set the new name, and wants to add this new definition data to the list of set definitions. The first section of code just makes sure that the user does not try to add a large number of definitions. It prevents overflow of the dialog's internal array of animations which is allocated at application startup to be MAX_DEFINITIONS in size. This is set to 256 by default. This means that this tool allows you to break a single set into 256 sets. Feel free to change this value in the source code if you need more.

```
void CAnimDialog::AddSetDefinition()
{
    HWND  hControl = NULL;
    TCHAR NewName[128];
    ULONG i;

    // Validate there are enough slots left
    if ( m_nDefCount >= MAX_DEFINITIONS )
    {
        ::MessageBox( m_hDialog, _T("You have reached the maximum number of
                                    animation set definitions supported by
                                    this application."),
                                _T("Limit Reached"),
                                MB_OK | MB_ICONSTOP );
        return;

    } // End if limit reached
```

This next section of code tests that a source animation set is currently selected since each split definition must contain a source animation set. If a source animation set is not selected when the user presses the Add Definition button, then this split definition should fail to be added to the list. This should never actually happen because those controls should be disabled if no animation set is selected, but let us be cautious about this.

```
    // Validate that an animation set is available
    if ( !m_pCurrentAnimSet )
    {
        ::MessageBox( m_hDialog, _T("You must specify a source animation set to
                                    extract data from."), _T("Invalid Source"),
                                    MB_OK | MB_ICONEXCLAMATION );
        return;
    } // End if no source
```

We will also fail if the start and end markers are equal. This would essentially cause the creation of an empty animation set, which would serve no prupose.

```
    // Validate that some range of data is selected
    if ( (m_nEndTick - m_nStartTick) == 0 )
    {
        ::MessageBox( m_hDialog, _T("The data range specified is empty,
                                    you must select a portion of the animation
                                    to extract."), _T("Invalid Range"),
                                    MB_OK | MB_ICONEXCLAMATION );
        return;

    } // End if no source
```

Next we make sure that the user has supplied a name for the definition. We want to enforce this behavior so that all of our new animation sets will have unique names. This is especially important since they are displayed in the list boxes using their names. So we fetch the handle of the Set Name edit control and extract its text. If the length of the retrieved text is zero, the edit box is empty and we fail to add the definition to the list.

```
    // Get the new set name
    if ( !(hControl = GetDlgItem( m_hDialog, IDC_EDIT_NEWSETNAME )) ) return;
    Edit_GetText( hControl, NewName, 128 );

    // Empty ?
    if ( _tcslen( NewName ) == 0 )
    {
        ::MessageBox( m_hDialog, _T("All new set definitions must have a name."),
                     _T("Invalid Option"), MB_OK | MB_ICONEXCLAMATION );
        return;

    } // End if no name
```

When working with text mode X files, there are certain characters reserved by the specification for the purposes of structuring the data. These characters include semi-colons and curly braces. In certain circumstances, when we include such reserved characters in animation set names, we can actually inadvertantly corrupt the integrity of the file.

For this reason, we introduce the following loop, which forcably removes any non-alphanumeric characters from the animation set name and replaces them with an underscore. This prevents the problem from occuring.

```
    // Replace all non numeric / alpha characters with underscores
    // (the text .X file definition doesn't seem to like much else)
    for ( i = 0; i < _tcslen( NewName ); ++i )
    {
        TCHAR ch = NewName[i];
        if ( (ch < _T('A') || ch > _T('Z') ) &&
             (ch < _T('a') || ch > _T('z') ) &&
             (ch < _T('0') || ch > _T('9') ) )
        {
            // Replace
            NewName[i] = _T('_');
```

```
        } // End if invalid character
    } // Next Character
```

Now we are almost ready to add the definition information to the array. However, we must make sure that a split definition does not already exist with the same name. We enforce (for the same reasons mentioned above) the rule that all definitions must have unique names. In the next section of code, we loop through each split definition in the array and compare its name with the name of the new definition we are about to add. If the _tcscmp function returns zero, the strings are the same and we have found that a split definition already exists with the same name as the one we are about to add to the list. When this is the case, we fail to add the split definition.

```
    // Search to see if a name matching this already exists
    for ( i = 0; i < m_nDefCount; ++i )
    {
        if ( _tcsicmp( m_pDefList[i].SetName, NewName ) == 0 )
        {
            ::MessageBox( m_hDialog, _T("A new set definition with this name
                                        already exists in the list. Names must
                                        be unique."),
                                        _T("Invalid Option"),
                                        MB_OK | MB_ICONEXCLAMATION );
            return;

        } // End if matching name found

    } // Next Definition
```

If we get this far, the marker positions, the source animation set, and the name we have assigned to this new set are all valid, so we will copy the information into the array. We already have the new name stored in a local variable and the currently selected source animation set index was also cached in the member variable when the the user selected the animation set (see previous function). Also, when the user selects the Set Range Start and Set Range End buttons, the handler functions cache the current position of the slider in the m_nStartTick and m_nEndTick member variables. Therefore, the only thing left to do is add the information to the end of the definitions arrays and increase the definition count. We then call the PopulateDefinitions function to refresh the split definitions list box so that the new addition is now shown.

```
    // Populate the new definition item
    _tcscpy( m_pDefList[ m_nDefCount ].SetName, NewName );
    m_pDefList[ m_nDefCount ].SourceSet  = m_nCurrentAnimSet;
    m_pDefList[ m_nDefCount ].StartTicks = m_nStartTick;
    m_pDefList[ m_nDefCount ].EndTicks   = m_nEndTick;

    // Increment
    m_nDefCount++;

    // Repopulate Definition Items
    PopulateDefinitions();
}
```

CAnimDialog::ApplyChanges

The final method that we will examine in this lab project is the one that actually creates the new animation sets from the split definitions list. Although this might seem like it would be a large function, it actually just calls the CActor::ApplySplitDefinitions method to do all the work.

The function returns if no valid actor is available or if no definitions have yet been added by the user.

```
void CAnimDialog::ApplyChanges()
{
    // Bail if there is no actor
    if ( !m_pActor ) return;

    // Ensure there are any definitions to apply
    if ( m_nDefCount == 0 )
    {
        ::MessageBox( m_hDialog, _T("There are no definition changes to be
                                     applied."),
                                    _T("Empty Definition"),
                                    MB_OK | MB_ICONEXCLAMATION );
        return;

    } // End if no name
```

Now we know we have a valid actor and at least some definitions in our array, so we will release the currently selected animation set interface. This is because this animation set is about to be destroyed and replaced by the new ones described by the split definitions. We then call our CActor member function to create the new sets and release the old ones.

```
    // Release the currently selected animation set, it's about to be destroyed.
    if ( m_pCurrentAnimSet ) m_pCurrentAnimSet->Release();
    m_pCurrentAnimSet = NULL;
    m_nCurrentAnimSet = 0;

    // Apply the split definition
    m_pActor->ApplySplitDefinitions( m_nDefCount, m_pDefList );

    // Total re-population please
    UpdateDialog();
}
```

Finally, at the end of the function we call the CAnimDialog::UpdateDialog method to refresh all the controls with their new information. This will empty the definitions array and repopulate the top list box with the new list of source animation sets (the ones we have just created). We now have a new list of source sets and an empty array of definitions (as they have all be used and discarded). Usually, at this point you will want to save the actor back out to an X file in its new format.

Conclusion

This workbook has been one of our largest to date. In the process, we have learned alot of new material and have simultaneously turned our CActor class into a powerful tool. It now encapsulates X file loading and saving for complete multi-mesh hierarchies that include animation data. We have also exposed the powerful features of the D3DX animation controller through our CActor interface. Finally, in Lab Project 10.2 we developed a utility that better educates us about how the actor might be used in a non-game application. It is also a tool that will be extremely useful for breaking an animation set with combined sequences into multiple animations sets for the purposes of our game engine.

In the next two chapters we will extend the actor even further when we learn how to perform character skinning using both software and hardware techniques. Make sure that you are comfortable with everything we have covered thus far, as it will all be used again in the next few lessons.

Chapter Eleven

Skinned Meshes and Skeletal Animation I

Introduction

Newly emerging graphics technologies have allowed gamers to enjoy scene realism that would be unthinkable only a few years ago. With new cards now supporting some 256MB or more of on-board local video memory and features like real-time decompression of textures during rendering, we now have the ability to use greater quantities of higher resolution textures. We have also seen a dramatic increase in polygon budgets due to similar advances in vertex processing hardware. The combined effect is that the game artist experiences a larger degree of creative freedom coupled with the confidence that the game engine can handle the loads in real time. As a result, the virtual worlds we take for granted in modern computer games can often look so real as to be almost photo-realistic. But in the area of animation, and specifically with respect to game characters, until fairly recently the technology has not kept pace. Traditionally, as soon as you saw a character animating in the scene it was obvious that this was not a photo or a movie you were looking at.

In early games, comparatively low CPU speeds and the lack of dedicated 3D transformation and lighting hardware meant that per-vertex processing had to be kept to a minimum in order to maintain an acceptable frame rate. In-game characters were often constructed as segmented polygonal objects, where each limb of the character would be created as a separate mesh and attached to a frame hierarchy. The frames of the hierarchy represent the 'bones' of the character. Animations like walking or shooting could be applied to the hierarchy (as we examined in Chapter Ten), causing the meshes of the separate body parts attached to the individual frames to move. While this approach achieved its objective, it brought with it some undesirable artifacts. Because each body part was a separate mesh, when two neighboring body parts (such as an upper leg mesh and a lower leg mesh) were rotated at extreme angles with respect to each other, gaps between them became very obvious. Unless extreme care was taken on the modeling side to reduce this artifact – and it could not always be successfully done – the results were less than ideal.

As CPU speeds increased, a greater degree of per-vertex processing could be done in software and a technique called *vertex blending* emerged. Vertex blending is the process of transforming a model space vertex into world space using a weighted blending of multiple world space matrices. This is in contrast to the single world matrix concept we are familiar with. This technique allows programmers to use a single mesh for an entire character while retaining all of the benefits of a hierarchy for animation (much like the segmented character example mentioned previously). The single mesh behaves like a "skin" draped over the "bones" of the hierarchy such that when the bones (i.e. the frame hierarchy) are animated, rather than just rotating limbs constructed from separate meshes, the entire skin (i.e. mesh) is deformed -- bending and stretching to maintain the shape described by the underlying skeleton. Because the skin is a single mesh, no cracks will appear and the limbs of the character smoothly bend and stretch to provide much more realistic animation.

To make this skin/bone concept clearer, first consider a segmented object, where each mesh is assigned to a single frame in a multi-frame hierarchy. Forget about the fact that each mesh has its own vertices and forget about which meshes these vertices actually belong to. Based simply on the frame the parent mesh was originally assigned to, you can imagine that some vertices would be animated by one frame matrix, while other vertices belonging to another mesh assigned to another frame would be animated by a different frame matrix. If we were to go one step further and imagine that all of the vertices in the

hierarchy were actually a part of a single mesh and we add the ability to specify, on a *per-vertex* level, which matrix in the hierarchy should be used to transform each vertex, then we wind up with our skin concept. That is, we have a single mesh (a skin) animated by the frame hierarchy (a skeleton) such that each vertex in the mesh stores information about which matrix in the hierarchy transforms it to world space. If we were to play a walk animation on our hierarchy, then we would see that when the vertices that are assigned to the leg frames (bones) are animated, the legs of the character mesh can bend without causing cracks or visible seams.

Although assigning a single vertex in the mesh to a single frame in the hierarchy would cause the skin to deform, often this is too restrictive for producing realistic skin animation. This is where vertex blending comes in. To see where vertex blending can play a role, look at the skin around your elbow and imagine it as a mesh of vertices. If you bend your arm at the elbow, retracting the forearm up to meet your shoulder (imagine that your forearm is a bone in the hierarchy), you can clearly see that the skin at your elbow is affected by this bone movement. The skin changes to cover the new shape formed at the elbow joint. Thus we might say that the vertices of your elbow should be transformed by the forearm frame matrix in the hierarchy. That is, whenever the forearm frame is rotated, the elbow vertices that are children of that frame would be directly manipulated by that frame's matrix.

However, if you stretch out your arm in front of you and just rotate your wrist up and down, you can see that while not as severe as the previous example, the rotation of the wrist bone also has some influence on the skin near the elbow -- causing it to shift and change slightly. We could say then that the elbow vertices are directly affected by the rotation of the forearm bone and also by the rotation of the wrist bone (and theoretically other bones as well, such as the shoulder bone). Therefore, to correctly model the behavior of our skin, we would need to be able to specify not only one matrix per vertex, but in fact any number of matrices per vertex. While some vertices in the mesh may only be affected by a single bone, others may be affected by two or more different bones to varying degrees, sometimes simultaneously. Although the orientation of your wrist bone did affect the position of the skin around your elbow, it did not influence the skin position to the same degree that rotating your forearm did. Therefore, to effectively skin a mesh:

1. We need a **skeleton**. This is just a frame hierarchy where each frame is assumed to be a bone in the skeleton. Each frame matrix is referred to as a bone matrix.
2. We need a **skin**. This is just a standard mesh describing the character model in its reference (default) pose. The vertices are defined in model space just like any other standard mesh.
3. We need a **vertex/bone relationship mapping**. We want to know for each vertex, which bones (frames) in the skeleton (hierarchy) directly affect it. The bone(s) will ultimately be used to calculate the world space position of the vertex. As described, a single vertex may be directly connected to several bones, such that movement of any of those bones will influence its final world space position to some degree.
4. We need **weights** for each vertex describing how influential a particular bone will be in calculating its final world space position. If a vertex is influenced by N bones, then it should also contain N floating point weight values between 0.0 and 1.0. These describe the influence of that bone on the vertex as a percentage. For example, if a vertex stores a floating point weight value of 0.25 for matrix N, it means that the transformation described by bone N (the frame matrix) should be scaled to 25% of its strength and then applied to the vertex. So if a vertex is influenced by N matrices, then it should store N weights. The sum of the N weight values should add up to exactly 1.0.

So now we need the ability to assign individual vertices, rather than entire meshes, to frames in our hierarchy. We also need the ability to perform vertex blending. Item four in the previous list is where vertex blending comes in. We know that the first thing the DirectX transformation pipeline will typically do is transform vertices into world space using the currently set world matrix (a single matrix). Things are a little different now however because, for any skin vertex currently being transformed, a vertex might need to be transformed into world space using contributions from a number of bone matrices. This is how vertex blending works. If we were going to implement vertex blending ourselves (not using APIs like DirectX or OpenGL), then our code would have to include a vertex blending function. That function would be called for each model space source vertex and generate a world space destination vertex that had been transformed using the contributions of several matrices. Vertex blending is actually a remarkably easy thing to do as we will briefly describe below.

> **Note**: The DirectX pipeline will perform vertex blending on our behalf, but an understanding of the blending process is essential to understanding skinning. This next section is intended to show you how vertex blending works and what is going on behind the scenes.

Imagine that we wish to perform vertex blending with three matrices for a given model space vertex. In this example we can think of the model space vertex as being a vertex in the mesh which is assigned to three bones in the skeleton. Remember that bones are ultimately just frame matrices and the skeleton is just a frame hierarchy.

First we take the model space vertex and, in three separate passes, transform it by each world space bone matrix to create three temporary vertices:

ModelVertex = Model Space vertex we wish to transform into world space

M1 = 1st World Space matrix to use in blending
M2 = 2nd World Space matrix to use in blending
M3 = 3rd World Space matrix to use in blending

```
TempVertex1  = ModelVertex * M1;
TempVertex2  = ModelVertex * M2;
TempVertex3  = ModelVertex * M3;
```

At this point we are midway through the process. When performing vertex blending, each vertex also stores some number of weights (sometimes referred to as *beta weights* or *skin weights*) with values between 0.0 and 1.0. These weights describe how influential a specific matrix will be when determining the final position of the world space vertex. For example, if a vertex is to be blended into world space using three matrices as above, the vertex would contain three weights describing how strongly the transformation in each matrix will contribute to the final vertex position. If we were to sum these weights, they should add up to 1.0. If the vertex used in the above example had weight values of 0.25, 0.5, and 0.25, then we know that the matrix M1 would contribute 25%, matrix M2 would contribute 50%, and matrix M3 would contribute 25% to the final vertex. Therefore, after we have generated the temporary vertex for each matrix, we can scale each temporary vertex position by the corresponding weights. The second part of our vertex blending procedure would do just that:

TempVertex1 = TempVertex1 * ModelVertex.Weight1; //*(Weight1 = 0.25)*
TempVertex2 = TempVertex2 * ModelVertex.Weight2; //*(Weight2 = 0.5)*
TempVertex3 = TempVertex3 * ModelVertex.Weight3; //*(Weight3 = 0.25)*

Now that we have scaled each temporarily transformed vertex position by the corresponding weight, we sum the results to create the final blended world space vertex position.

Blended Result = TempVertex1 + TempVertex2 + TempVertex2;

That is all there is to vertex blending. Note that although it is not *required* that the weights add up to 1.0, there may be strange and unpredictable results when they do not. We generally want our fractional transformations to add up to one complete transformation.

The following code gives us a bit more insight into the vertex blending process. It takes a model space vertex, an array of matrices, and an array of vertex weights (one for each matrix in the array) and returns a final blended world space vertex.

```
D3DXVECTOR3 TransformBlended (D3DXVECTOR3 *pModelVertex ,
                              D3DXMATRIX *pBlendMatrices ,
                              float * pWeights , float NumOfMatrices )
{
      D3DXVECTOR3 TmpVertex;
      D3DXVECTOR3 FinalVertex ( 0.0f , 0.0f , 0.0f );

      for ( int i = 0 ; i < NumOfMatrices; i++ )
      {
            TmpVertex = ( *pModelVertex * pBlendMatrices[I] ) * pWeights[I];
            FinalVertex += TmpVertex;
      }

      return FinalVertex;
}
```

Vertex blending is the key process behind character skinning and skeletal animation. With vertex blending, we can state that some vertices in the mesh are connected to more than one bone in the hierarchy, like our elbow vertices as discussed previously. In such a case the vertices in this area might be attached to both the upper arm bone and the lower arm bone. Since each bone is just a frame in the hierarchy, we can transform the vertices in this region of the mesh into world space simply by performing a blend (as shown above) using the matrices for both the forearm bone and the upper arm bone. When either or both of these bones are animated, the vertices of the skin move and change shape to accommodate the new bone positions, much like our skin does in real life. Because all of the vertices in the skin are a single mesh, we do not suffer the crack problems between the joints of the character's limbs. We will see later that it is the job of the 3D artist to construct the bone hierarchy and assign vertices in the mesh to these different bones. The artist will also be able to alter the weights of each vertex to tweak the model and get the weights of all influential matrices for a given vertex just right.

From the programming perspective, one of our first jobs will be to load the skeleton. Fortunately, we already know how to do this because a skeleton is just a D3DXFRAME hierarchy loaded automatically

by the D3DXLoadMeshHierarchyFromX function. Each frame in the hierarchy will be a bone and its frame matrix is called a *bone matrix*.

> **NOTE:** While we are now referring to the frame hierarchy as a *skeleton* and the frames as the *bones* of this skeleton, nothing has actually changed with respect to chapters 9 and 10. This is just a naming convention we are using because it is more appropriate under these circumstances.

Most gamers were quite impressed the first time they saw the skeletally animated skinned mesh characters in the original Half-Life™. Their smoothly deforming skins set a precedent that could not be ignored. Pretty soon, almost all new games were implementing character skinning and skeletal animation as the technique of choice, and the characters in computer games have become a lot more believable as a result. Keep in mind that skinning techniques are not reserved exclusively for character animation only. One of the lab projects in this chapter will use skinning and skeletal animation to create some very nice trees for our landscape scenes. Such a system works quite nicely for this purpose and you will soon be able to play wind animations that cause swaying branches and rustling leaves.

While increased CPU speeds meant that vertex blending could be performed in real time, things are even better today since vertex blending can now be performed by the GPU. This is true for most T&L graphics cards released since the days of the first geForce™ cards. The DirectX 9.0 API exposes these features to our application so that we can perform hardware accelerated vertex blending on the skin and bones system that we implement.

There are a number of additional advantages to using a skin and bones system beyond the removal of cracks and seams discussed earlier. First, the artist has to do very little repetitive mesh building. The artist only has to create a single mesh in its ‘reference pose’ and then use the modeling package of his/her choice to fit a skeletal bone structure neatly inside the mesh. After assigning which vertices will be influenced by which bones and specifying the appropriate weights, the main work is done. From that point forward it is a matter of applying any animation desired to the skeleton to see the results.

Another great thing is that many of the more popular commercial modeling packages export the skin and bones data into X file format. The mesh is stored as a regular mesh and the skeleton is just stored as a vanilla frame hierarchy (like the ones we looked at in previous lessons). Later in the chapter we will examine all of the X file data in detail.

From our perspective as programmers, we benefit from the fact that animating the bones of a character is no different from animating a normal frame hierarchy. Thus our last chapter will serve us well as we work through our lab projects. We will still use the animation controller to choose the animation we wish to play and call AdvanceTime to update the frame matrices in the hierarchy. Once the matrices have been updated, we traverse the hierarchy and build the absolute world matrices for each frame (bone). Then all that is left to do is set the matrices and render our mesh.

Transforming and rendering the mesh is where things will change a fair bit. We must now be able to set multiple world matrices on the device so that the transformation pipeline can calculate the world space position of each vertex using all of the world space bone matrices to which it is connected. We will also see how the vertex structure of the mesh has to change so that it can store a number of weights (one for each bone matrix that affects it). Once the device has this information however, we can call DrawPrimitive as usual and let the pipeline render each subset. The device will use the multiple matrices

we have set from our bone hierarchy to perform the vertex blending. This is certainly going to be exciting material for sure, but we do have a fair bit to learn about before we can perform this process properly.

We have now had a rapid tour of what skinning and skeletal animation is and why it is the technique of choice for most game programmers. Very little code is needed to implement it, and it takes up very little memory compared to other techniques (such as tweening, as we will see next). It also gives us control over every aspect of the character's body. You can instruct the artist to create bones that can be moved to cause wrinkles in the skin, twitch the character's nose, or cause the characters hair to blow in the wind. These are all very cool animation effects that we are seeing in today's computer games and now we are going to learn the foundations for how to do achieve this. But first, we will take a very brief diversion…

11.1 Vertex Tweening

There are alternatives to skinning that can produce very good results. One popular choice is called **tweening** (or **morphing**). id Software® used this technique in the Quake II™ engine to produce smooth character animations without cracks or other visual artifacts.

Tweening is similar to the keyframe animation approach we discussed in our last lesson. In the case of Quake II™ for example, the file (.md2 file in this instance) stores a number of keyframes, but these keyframes do not store a timestamp and transform (SRT) data. Instead they store a timestamp and an entire mesh in a given pose. Each mesh represents exactly what the vertex data of the mesh should look like at the specified time stamp. The file will therefore contain a large list of pre-posed meshes.

Let us imagine an .md2 file containing a 'walk' animation cycle. The file will store a number of meshes, where each mesh can be thought of as a snapshot of the character at a certain time throughout the life of the walk animation.

To render the mesh for a given time (say T = N + 0.5 -- where N is an arbitrary time through the duration of the animation) the first thing we would do is find the two keyframes in the mesh list that bound this time. In this example it would be keyframe N and keyframe N+1. Our two keyframes would now be two separate meshes of the character in different poses as shown in Fig 11.1.

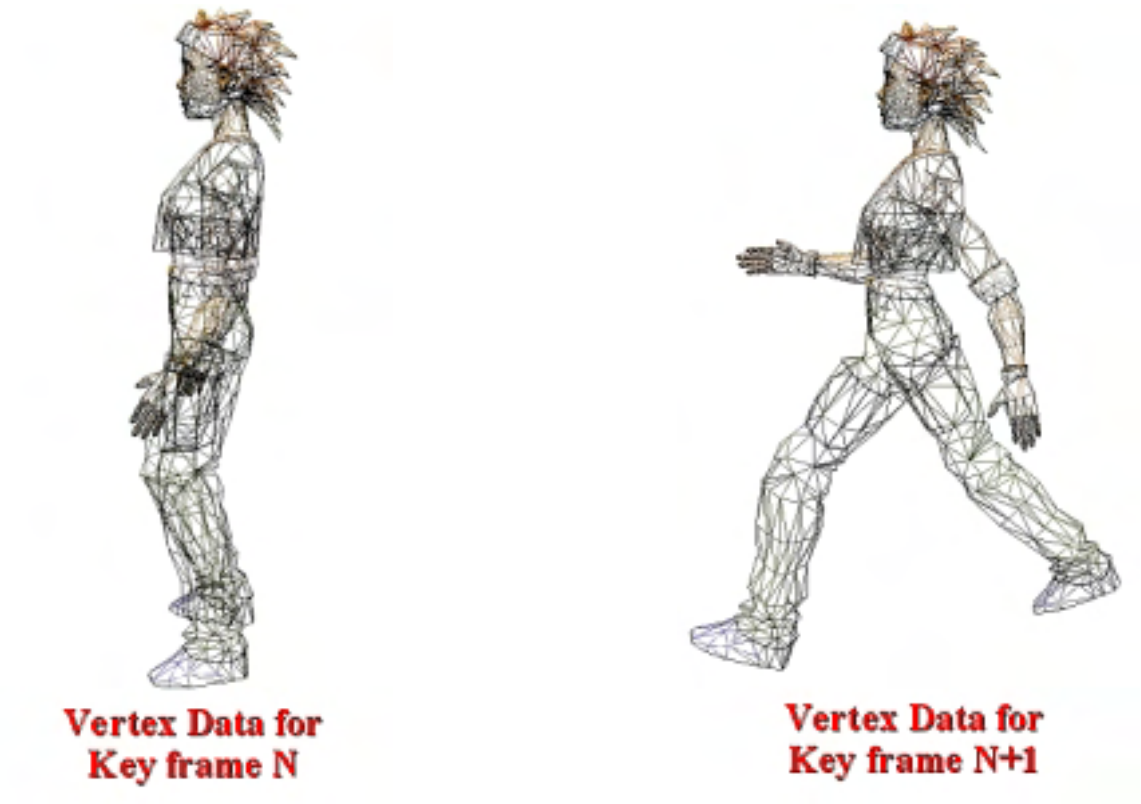

Figure 11.1

To calculate the final position of each vertex in the mesh we will interpolate between matched vertices in both sets. We will use the amount that the requested time is offset between the time stamps of both keyframes as the interpolation weight factor. So we are actually building a new mesh on the fly by interpolating between the vertex sets of two input meshes. The interpolation would look something like the following pseudo code:

```
t = AnimTime – KeyFrame[N].Time;

for( I = 0 to NumVertices )
{
     Vertex V1 = KeyFrame[N].Vertex[I];
     Vertex V2 = KeyFrame[N+1].Vertex[I];

     FinalMesh.Vertex[I] = V1 * (1.0 – t)  +  V2 * t
}
```

In the current example, AnimTime is the time we request to render the mesh and N and N+1 are assumed to be the indices of keyframes that bound the requested AnimTime. Since each mesh is simply the same object in different poses, we know that there will be the same number of vertices in both of the source meshes. We also know that there will be exactly this many vertices in the dynamically generated output mesh.

If we imagine that we would like the mesh generated for an animation time of N+0.5 (midway between the two keyframe poses above) we would have a temporary vertex buffer containing the interpolated vertex data. The mesh would look like the results in Fig 112.

Figure 11.2

We could now transform and render this mesh just as we would any other standard mesh.

So as you can see, during each frame we generate a new model space mesh by interpolating between keyframe meshes. Once we have the vertices for both of the source meshes, we interpolate between them to generate the in-be***tween*** pose, which is where the term ***tween***ing originates.

While this is a simple technique to implement in software and it does allow us to use single skin meshes, it does have its drawbacks. The main problem is that it can consume a good deal of memory because we have to store multiple copies of the mesh vertex buffer (one for each key pose).

DirectX 9 exposes hardware support for tweening and many graphics cards support the acceleration of tweening on the GPU. However, we will not cover tweening in this chapter for a number of important reasons. First, we cannot implement tweening without using declarator-style vertex formats (non-FVF) and these will not be discussed until Module III in this series . Second, many programmers have now abandoned tweening/morphing as a means of generically animating characters in their games in favor of skin and bone systems (mostly due to the memory costs). However, that is not to say that vertex tweening is without value -- far from it. Tweening is still a very popular technique in the area of facial animation. With the release of Half-Life 2™, facial animation is certainly something that is on the minds of game developers everywhere. An artist can build multiple facial expressions that can be easily morphed from one to the other to add lots of additional personality to a game character. However, it is worth noting that skin/bones can also be used for this purpose and is rapidly gaining popularity. Tweening will be covered in a little later in this course series, so do not worry too much about it for now.

11.2 Segmented Character Model Animation

For completeness, before we work our way up to skinned meshes and skeletal animation we will first look at how we might perform character animation the old fashioned way -- by using what we learned in the previous chapter on hierarchical animation. This is the way characters used to be implemented in the games of a few years ago. This was because per-vertex processes (such as vertex blending) were too expensive to be performed in real-time due to the low CPU speeds and the lack of 3D hardware acceleration in most end user systems. Taking a look at this older approach however should help us understand the origins of skinning as well as why skeletal animation and skinning are such useful techniques to have in our tool chest.

Armed with only the animation knowledge from the previous chapter and instructed to create an animated character that can play a number of animations (such as walk, run, and jump for example), we might imagine that we could use the exact same system from Lab Project 10.1. We would perhaps instruct our game artist to build a character object using multiple mesh body parts and arrange them in a hierarchy inside the modeling program. This is no different from how we constructed the space scene in the previous lesson. We had multiple meshes (the space ship, the bay doors, and the radar dishes) each attached to frames in a hierarchy and it all worked nicely. The fact that we are now using the hierarchy to represent meshes of human body parts should theoretically work just as well.

For the sake of simplicity, let us work only with the bottom half of a character. This lower body might consist of five separate meshes: a pelvis, a left upper leg mesh, a left lower leg mesh, a right upper leg mesh and a right lower leg mesh. The five separate meshes might be arranged in the hierarchy as shown in Figure 11.3.

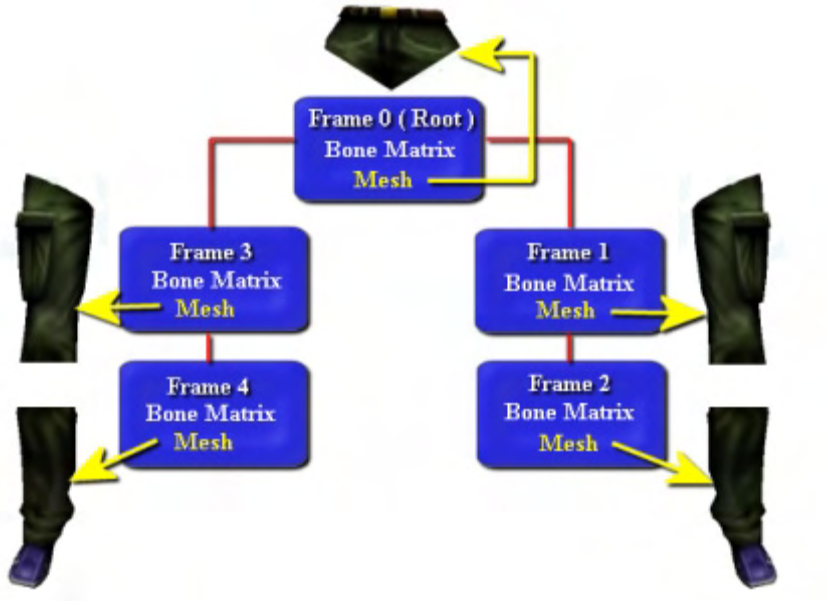

Figure 11.3

You should already have a good idea about how this frame hierarchy would be exported and stored in an X file. Certainly there would be little trouble loading it in using D3DXLoadMeshHierarchyFromX as we learned in previous lessons. Because we are now using the frame hierarchy to represent a character instead of a generic scene, we will refer to each frame in the hierarchy to which a body part is attached as a 'bone'. This works well because they will behave very much like a set of human bones. That is, when we rotate one of our bones in real life, our skin and clothes around that bone move also. Likewise, when we rotate a frame in our hierarchy, a single body part attached to that frame will move (along with any child frames and their respective meshes). So we will think of each frame as an individual bone and the frame hierarchy as a skeleton. In Fig 11.3, we can see that the pelvis is the root bone and that it has a pelvis mesh child. It also has two child bones which are the upper parts of each leg (along with their meshes). Each upper leg bone also has a lower leg child bone (each of which has a lower leg mesh).

After the artist has constructed the hierarchy of meshes in Fig 11.3 he could create a series of appropriate animation keyframes for walking, running, crouching, etc. and export everything to an X file. From our perspective, nothing has changed. We can still use D3DXLoadMeshHierarchyFromX to load this character model hierarchy using exactly the same code we used in the last chapter to load our scene (a scene of body parts now). We will get back a fully loaded hierarchy along with an ID3DXAnimationController so that we can start assigning the different animation sets (walk, run, etc.) to tracks on our animation mixer. To play a given animation requires only a call to ID3DXAnimationController::AdvanceTime, just as we saw in our last two lab projects.

So it seems as if we have achieved character animation free of charge simply by re-using the code we already have. However, as discussed in the introduction, this approach is not without its problems. The obvious problem with representing characters using the segmented character model is that in real life our various limbs are not separate detached entities. While it is true that our bones most definitely are individual segments of our skeleton and that they can move independently, our skeleton is covered with muscle and a continuous layer of skin which behaves very differently. Because this is not the case with our segmented character representation, certain artifacts which do not arise in real life become unavoidable.

Fig 11.4 shows one of the legs in our segmented character. We know already that the leg consists of two bones and two meshes -- the upper leg mesh is attached to the Frame 1 bone and the lower leg mesh is attached to the Frame 2 bone. These are the frame matrices in their default pose (commonly referred to as the *reference pose*) where the character meshes have been carefully arranged so that no cracks or spaces can be seen between the two separate leg meshes. The red dashed line in Fig 11.4 shows the boundary where the two leg meshes meet.

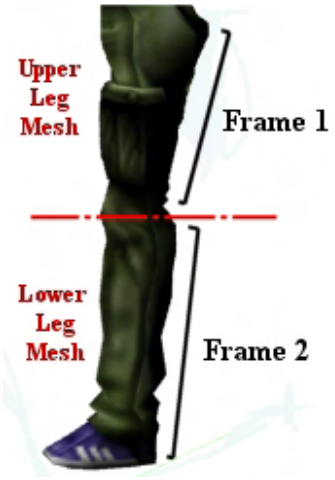

Figure 11.4

If we were to rotate Frame 1 (which we can think of as the joint at the top of the upper leg mesh where it meets the pelvis) relative to its pelvis parent, the leg would rotate without any artifacts. The lower leg is a child of the upper leg, so it too would be rotated. The entire leg would rotate much like the hand of a clock. However, if we were to rotate just the Frame 2 bone, (located in the knee area at the center of the leg) we would want the leg to bend in the middle (required if we want to play a realistic walking or running animation). But Fig 11.5 shows us what happens to the segmented character model system if the Frame 2 bone is rotated (thereby rotating its attached mesh).

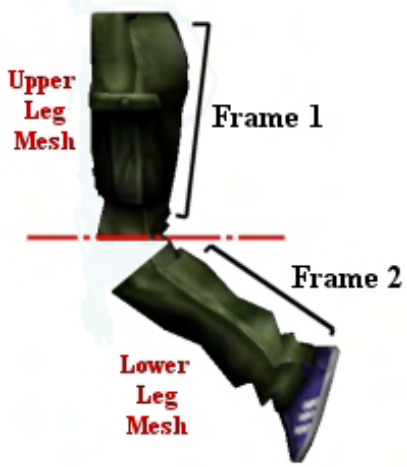

Figure 11.5

Fig 11.5 makes it instantly clear that the leg mesh is not one smoothly skinned entity, but is in fact two meshes. While this artifact can be minimized to some degree by careful modeling of the separate body part meshes (ex. tapering and overlapping them where they meet so that the crack is not so obvious) this is not something we can entirely avoid using the segmented character model. The problem is that each mesh is also being treated exactly like its associated bone. If we were to remove the skin from our own bodies, we would see that our skeletons would suffer the same artifacts (where each bone would be connected by a ball joint for example but would appear quite distinct).

So what are we to do to remedy this problem? Tweening would be one possible solution, but we have already discussed why it might not be the best choice for us. Beyond the memory concerns, consider as well that we spent a good deal of time learning how to animate hierarchies and use the D3DX animation system. We have already experienced the power and flexibility of the animation controller and it would be a shame to have it stripped away from us. Ideally we want a system where we can still store and play our animations using the same techniques we are already comfortable with but that addresses the concerns discussed thus far. This means that we want to represent our characters using a bone hierarchy (just like the previous example) but we do not want to use a segmented geometry model.

> **Note:** One final point in favor of using a hierarchical bone structure over a tweening system that is worth thinking about is that tweening is quite restrictive. Essentially we are locked into having to interpolate frames provided by the artist. With a skeletal structure, while we will most often be playing back animation created by the artist in a modeling package, we still have the freedom to programmatically apply transformations to any bones in the hierarchy we see fit (even at run time). In that sense, there are an infinite number of ways that we can animate a skeletal structure.

11.3 Skinning

Mesh skinning, used in conjunction with a skeletal structure, provides the solution to the problems previously discussed (although it is not without its own issues). The skeleton remains the same – it is a frame hierarchy and we can generate and play back SRT keyframe animations exactly as we did before. But instead of assigning separate meshes to individual frames, we are now going to use a single mesh, referred to as a *skin*. That is, rather than assign different meshes to different bones we will instead assign different *vertices* within a single mesh to different bones.

In the simplest case, each vertex in the skin is assigned to only one bone. We could theoretically imagine the skin as being constructed from separate sub-meshes, where each sub-mesh is a group of vertices attached to the same bone. The difference is that all sub-meshes share a single vertex buffer because they are all part of the same mesh object. In the more complex (and probable) case however, the logical division of the mesh into imaginary subsets is not so clear because we can assign a single vertex to more than one bone in the hierarchy. When a vertex is to be transformed, several bone matrices are used (to varying degrees) to determine the final world space position of that vertex. When a bone is rotated, any vertices that are assigned to that bone will be rotated also. The degree to which they will rotate will depend on the weights specified for that bone on each vertex. For the moment, do not worry about how the mesh is stored in the hierarchy or how the vertices are attached to frames, we will get to that a little later in the chapter.

While the artist is responsible for generating this mesh and constructing the bone hierarchy such that it correctly describes the mesh in its reference pose, the artist will also be responsible for determining which bones in the skeleton will influence each vertex, and by how much (using the weight value). This is not as hard as it might seem and we will discuss creation of skin and bone data from the artist's perspective in just a moment.

Fig 11.6 depicts the leg section of our single skin as it might look in our skinning application. The bones still exist in the same places since the skeleton is unchanged from our previous segmented example (Fig

11.6). The leg mesh depicted here however is now part of a single unified skin. In this example we are focusing on the knee joint (the Frame 2 bone). Most of the vertices in the lower leg section of the skin might be assigned to just the lower leg bone (Frame 2) and most of the vertices in the upper section of the leg might be mapped to just the upper leg bone (Frame 1). However, the vertices about the knee joint (within some limited radius) are probably going to need to be influenced by both bones.

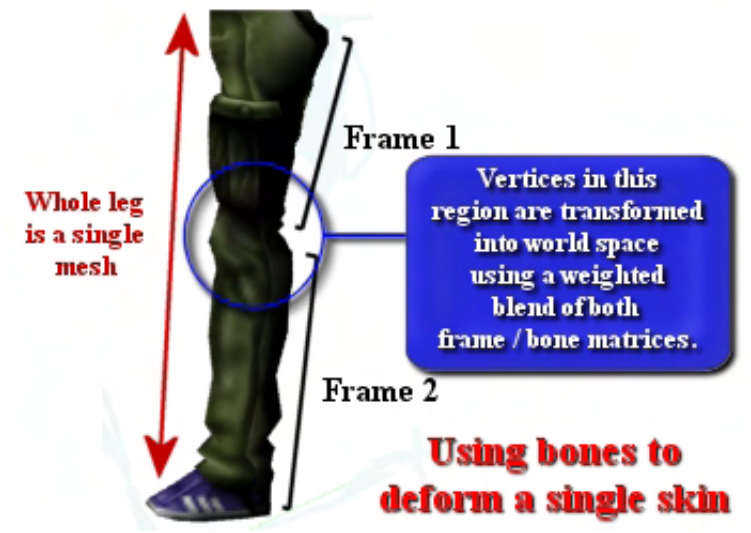

Figure 11.6

Because this is a single mesh, when the knee bone is rotated (Frame 2) all of the vertices attached to that bone will also move by some amount determined by the weight stored in the vertex for that bone. The vertices outside the blue circle in the lower part of the leg will be 100% influenced by this bone because they are attached to only the Frame 2 bone. However, the vertices in and around the knee joint are also influenced to some degree by both bones, so their positions will change also but not quite to the same extent. As the vertices in this area move, they stretch the skin polygons of which they are a part so that they occupy the space that would have caused a gap in the segmented character model. We see in Fig 11.7 that this rotation causes no cracks to appear -- the section of the skin around the knee joint smoothly deforms to give the impression of a single skin covering our skeleton.

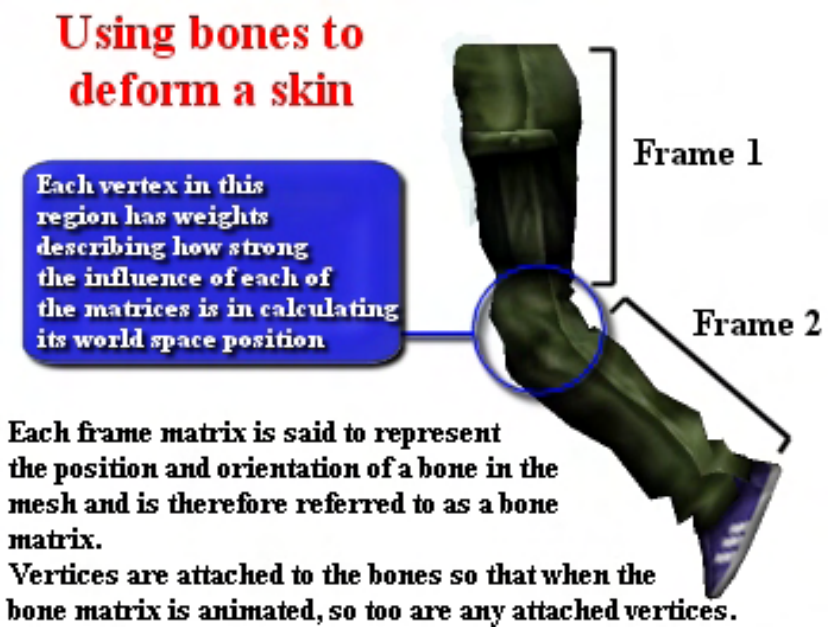

Figure 11.7

The result in Fig 11.7 is much more realistic than our earlier segmented character results.

As mentioned earlier, DirectX 9.0 supports hardware acceleration of the vertex blending process used to transform each vertex from model space into world space. There is support for using up to four different bone matrix influences per vertex, which is generally more than enough. Since many of the more recent graphics cards provide acceleration of vertex blending in hardware, skinning becomes an exciting prospect. Further, even if hardware support for skinning is not available on the user's machine, we can instruct DirectX to use software vertex processing to transform our skins. In this case the vertex blending will be carried out in the software module of the pipeline. Unlike some of the software processing alternatives supported by the DirectX pipeline, the software vertex blending module is very efficient and can be considered extremely useful even in a commercial project. You may even find that on some systems (depending on the video cards and CPU speeds) there is very little performance difference between hardware accelerated blending and software vertex blending performed by the Direct X transformation pipeline (although to be clear, this is not typically the case). The bottom line is that with or without hardware acceleration, we can still perform real-time skinning.

11.3.1 Generating Skinned Mesh Data

We already know how to animate a skeletal hierarchy but we still have no idea how the skin will be represented in memory. Nor do we know how to let the transformation pipeline know which vertices in the skin should be influenced by which matrices in the hierarchy and what weight values should be used. Rather than dive straight into API specific function calls, let us start with an analysis of the data first. It will be helpful to start at the beginning of the process and briefly discuss the steps the artist must take to assemble the skin and skeleton. It will also be helpful to know how that data will be exported into X file format. This means we can examine how we load the bone hierarchy and the accompanying skin from

the X file so that we are familiar with all of the data structures and where they come from. This knowledge will make it very easy to understand how to work with skinned meshes in the DirectX pipeline. So let us start our discussions at the art pipeline stage.

While we cannot possibly hope to cover the implementation details of generating skinned meshes in the modeling application (there are entire books devoted to the subject) we will take a look at the basic steps an artist must take in order to create the skinned mesh data for the programmer. This provides extra insight into how the data is generated and stored and thus will aid us in understanding the key concepts of character skinning in our game engine. This section will be kept deliberately brief and generic as the exact process for creating a skinned character and a skeletal hierarchy will vary between modeling applications.

1. Creating the Skin

The first thing the artist will usually do when generating the data for a skinned character system is to build the skin. The skin is just a mesh of the character in its default pose. There is no hard and fast rule about what the default pose should be, but modelers will usually prefer to start off with a pose that allows the skeletal structure to be more easily placed inside the character mesh. As it pertains to building the skin vertex data, this is all the artist typically has to do. Unlike a tweening system where the artist would have to create several copies of the same character mesh in many different poses, in the character skinning system, the artist just has to make this one mesh in its reference pose. Fig 11.8 is an example of a character skin mesh. As you can see, it is just a normal geometric character model and there is nothing special or unique about it. This mesh can be created in whatever modeling application is preferred so long as it can be imported into the application that will be used for building and applying the skeletal structure.

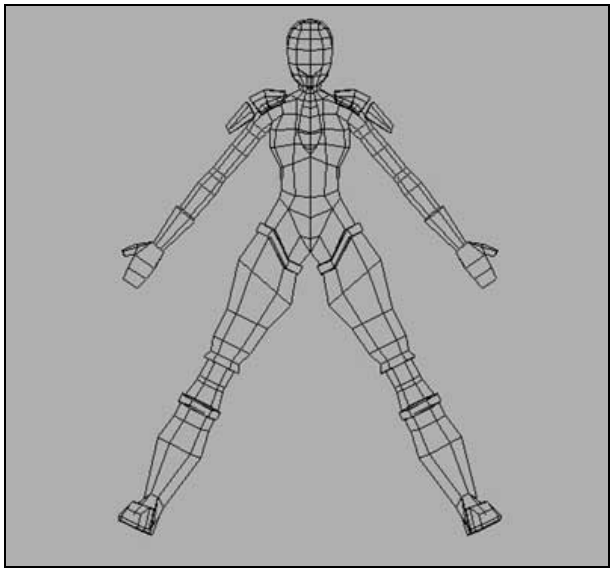

Figure 11.8

Note: The process of creating a set of individual meshes for use in a tweening system can actually be aided by the skeletal animation system most 3D modeling programs provide. For example, an artist can create a skeletal character and animate it within the package, but rather than export the skin and skeleton (which we would do for use in a skinned mesh system), he/she could just save out the transformed meshes at individual keyframes throughout the animation cycle. This essentially means saving the mesh data only and discarding the skeleton data as it will no longer be needed. Whether or not you wish to do this when the skeleton is available depends on the needs of your project, but it is important not to assume that each individual keyframe pose used in tweening must be a unique mesh constructed by hand every time.

2. Applying a skeleton to the skin

Once the mesh is imported into the application that we are going to use to apply the skeletal structure, the next step is for the artist to map this skin to a hierarchy of bones. The process of building and applying a skeleton will vary between 3D modeling packages, but the basic concepts are generally the same. In this discussion we will look at some screenshots of various processes and describe those processes with relation to Character Studio™. Character Studio™ started its life as a powerful animation plug-in tool for 3D Studio MAX™, but in the latest versions of 3D Studio MAX™ has now been fully integrated as part of the MAX package. If you have an earlier version of 3D Studio MAX™ (pre version 5.0) then you will need to purchase the Character Studio™ plug-in separately.

Character Studio™ allows you to visually insert skeletal structures inside of your skin mesh. Although you can build your own skeletal structures (linking one bone at a time together into a hierarchy), Character Studio™ ships with several pre-packaged skeletal structures which you can use directly. The package also ships with numerous test-bed animation scripts (more can be downloaded, purchased or created) that can be assigned directly to the skeletal structure. The test animations run the gamut from smooth motion captured walking scripts to slipping on a banana peel. Many of them are actually quite fun to watch, even using just the default skeleton.

The skeletal structure is referred to as a **Biped** (for obvious reasons) and the animation files are generally stored with a .bip extension. Below you can see the Biped rendered as a simple skeleton in Character Studio™.

While it is not much to look at (perhaps a bit like the Battle Droids from Star Wars™) it is in fact the graphical representation of what will eventually become our bone (frame) hierarchy.

The pre-packaged (or downloadable) test animation scripts are specifically designed to animate this skeletal structure. Therefore, all we have to do is fit this skeletal structure inside our mesh, attach it, and our mesh will benefit from those same animations.

To fit the Biped to the mesh, the artist will scale and orient its limbs to match the reference pose of the skin (this is why it is helpful to keep the arms and legs splayed out away from the torso as shown in Figure 11.8).

Fig 11.9 shows what the current biped might look like after being fitted to the skin shown in Fig 11.8. Notice how the joints of the biped have been rotated and scaled so that they accurately represent what the skeleton of our mesh would look like in its reference pose. The rotation and position of each bone joint will be recorded and will be described by a bone matrix in our hierarchy when the skeletal structure is exported to X file format. We will learn more about that a little later in the lesson.

The mesh with the Biped inside

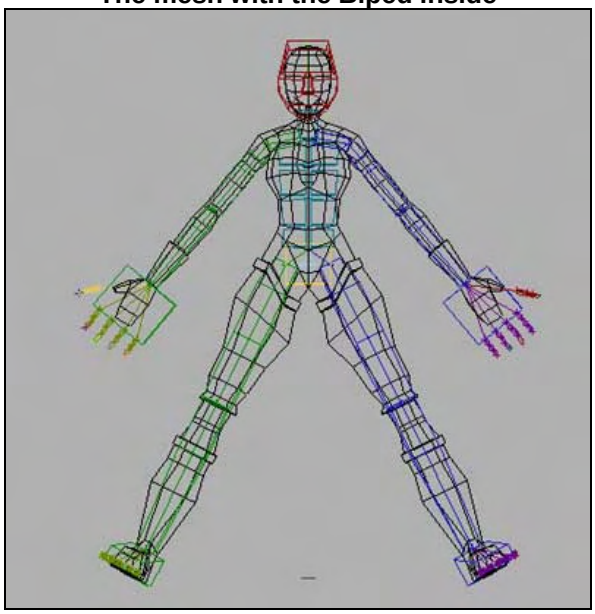

Figure 11.9

Once the skeletal structure has been properly aligned with the skin, the artist will use the 3D Studio MAX™ Physique Modifier to auto-calculate which vertices in the skin are influenced by which bones in the skeleton. It is probable that some (or even many) vertices in the skin will be influenced and thus attached to more than one bone in the skeleton. We saw this earlier with our knee joint.

Furthermore, the weight of each matrix's contribution to each vertex is also calculated for all influential bones for a given vertex. The default calculation that 3D Studio will do for us will involve testing each bone matrix for each vertex to see if that vertex is in a region of influence (also referred to as an *envelope*) for a given matrix. If so, then that vertex will be attached to that bone and the weight of the matrix for that vertex will be calculated as a product of the distance from the vertex to the bone. To calculate the region of influence for a bone, an ellipsoidal bounding volume is used around each bone. Any vertices that fall within this ellipsoidal region will be attached to the bone and influenced by the bone to some degree.

3. Tweaking the bone influences and skin weights

Although the Physique modifier is a completely automated process, after it has been applied, it is not uncommon to find that the mapping of the skin to the skeleton requires some manual tweaking. For example, the default envelope size used to calculate a region of influence for each bone may well

include vertices that we would not like to be influenced by the movement of that bone. Alternatively, we might want the vertex influenced by a bone, but perhaps not to such a large degree. In some cases, we may even find vertices that were not attached to the skeleton at all. By playing the test-bed animation scripts we can easily identify problem areas and correct them. We simply look for places where the skin is not animating in as natural way as we would like given the default matrix contributions and skin weights automatically calculated for us. We will often find that by adjusting the region of influence for a given bone we can address these inaccuracies. The process involves a good deal of trial and error, with us running the animation scripts again and again between tweaks to verify the adjustments just made. Again, this is all in the domain of the project artist, but is helpful to understand how it works (especially if you intend to do your own art and animation).

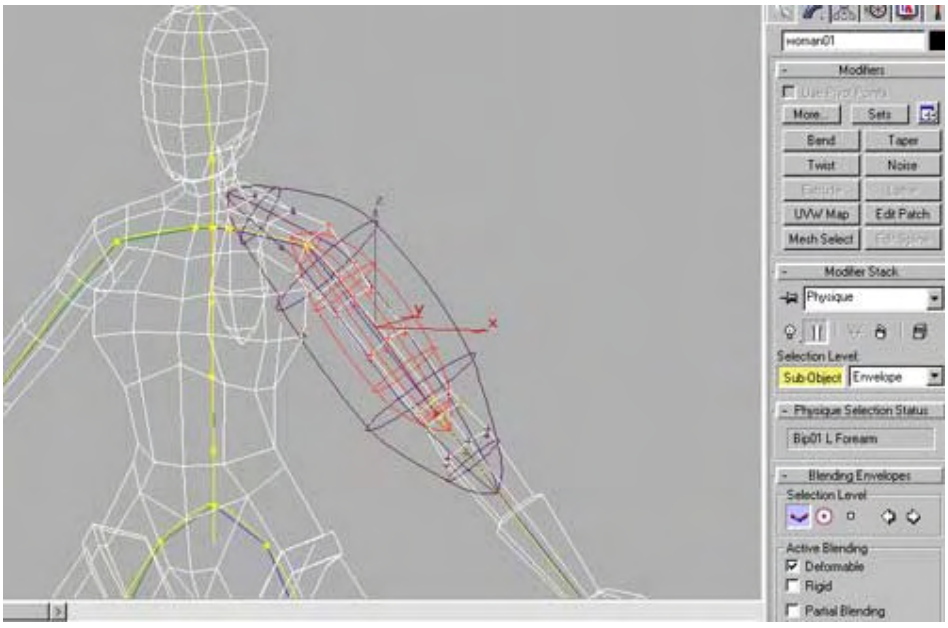

Figure 11.10

Figure 11.10 is a screenshot of an interface for adjusting the envelope (region of influence) for the upper arm bone using the Physique modifier. The size of the ellipsoidal region of influence for that bone can be adjusted to consume more or less of the surrounding vertices of the skin.

4. Applying Animations

Once the skeleton and skin system has been tuned, any number of pre-canned animations can be selected to animate the skeletal structure. This automatically animates the attached skin. There are many animation scripts available for Character Studio™ (usually .bip or .mot files) that can be purchased or downloaded, but most game projects generally entail the artist coming up with original data. Whether this is done by hand in the animation program or by spending time in a motion capture studio, most games involve their own proprietary animation sequences. Ultimately we need keyframes for the animations timeline one way or the other.

5. Exporting the character skin and skeletal structure

Once the artist has the skin and bone system animating correctly, the next step is to get that data into a format that our application can easily load and process. While the DirectX SDK ships with X file exporters for both Maya™ and 3D Studio Max™, there are third party exporters available as well. One of the better free X file exporters available for 3D Studio MAX™ is the Panda™ DX Exporter plug-in. This is a great exporter that converts all the data we need into X file format, including not only the skin and bone data, but the animation data as well. The skeletal structure will be exported as a vanilla X file frame hierarchy and the animation data will be exported as standard keyframe animation data. The only thing we will need to come to grips with is the extra data stored in the X file containing the mapping information which describes which bones in the hierarchy influence which vertices in the mesh. We will discuss this in a moment.

> **Note:** In many file exporters that work with 3D Studio MAX™, you have to be very careful not to mix MAX bones with Character Studio bones (they are different). Keep this in mind when you are designing your skeletons.

If you have 3D Studio MAX™ and wish to use the Panda™ DX Exporter you can visit their website and download it for free at http://www.pandasoft.demon.co.uk/directxmax4.htm.

There are other plug-in exporters available for 3D Studio MAX™ which do not export the data in X file format, but rather in some other easy to read format. The excellent Flexporter™ plug-in, designed by our colleague and friend Pierre Terdiman, exports to a proprietary file format called .ZCB. While .ZCB files are easily read, the real power of Flexporter™ comes from the fact that it is actually a plug-in SDK that lets you define your own file formats and write your own plug-ins. Flexporter™ will simply provide your plug-in with the data it reads from MAX and you can store it however you see fit. This saves you the trouble of having to learn the entire MAX Plug-In SDK. You can download the Flexporter™ plug-in SDK at http://www.codercorner.com/Flexporter.htm.

Finally, we would be remiss if we did not mention some of the non-free export tools available to you as well. One of the most popular workhorse applications available for dealing with export of scene data and animation is Okino Software's PolyTrans™. It is a very powerful tool that supports data import and export from almost all of the popular 3D modeling programs (MAX, Maya, Lightwave, etc.) and it has an X file exporter built in. This means that you can support art and animation from just about every modeling tool on the market and get it all into X format with a few clicks of a button. A similar tool that has most of the same bells and whistles as PolyTrans™ is DeepExploration™. Neither of these tools are free (unlike the other exporters just mentioned), although they are both reasonably priced given their power and flexibility. If you have the budget, either one is a worthwhile investment for any professional project.

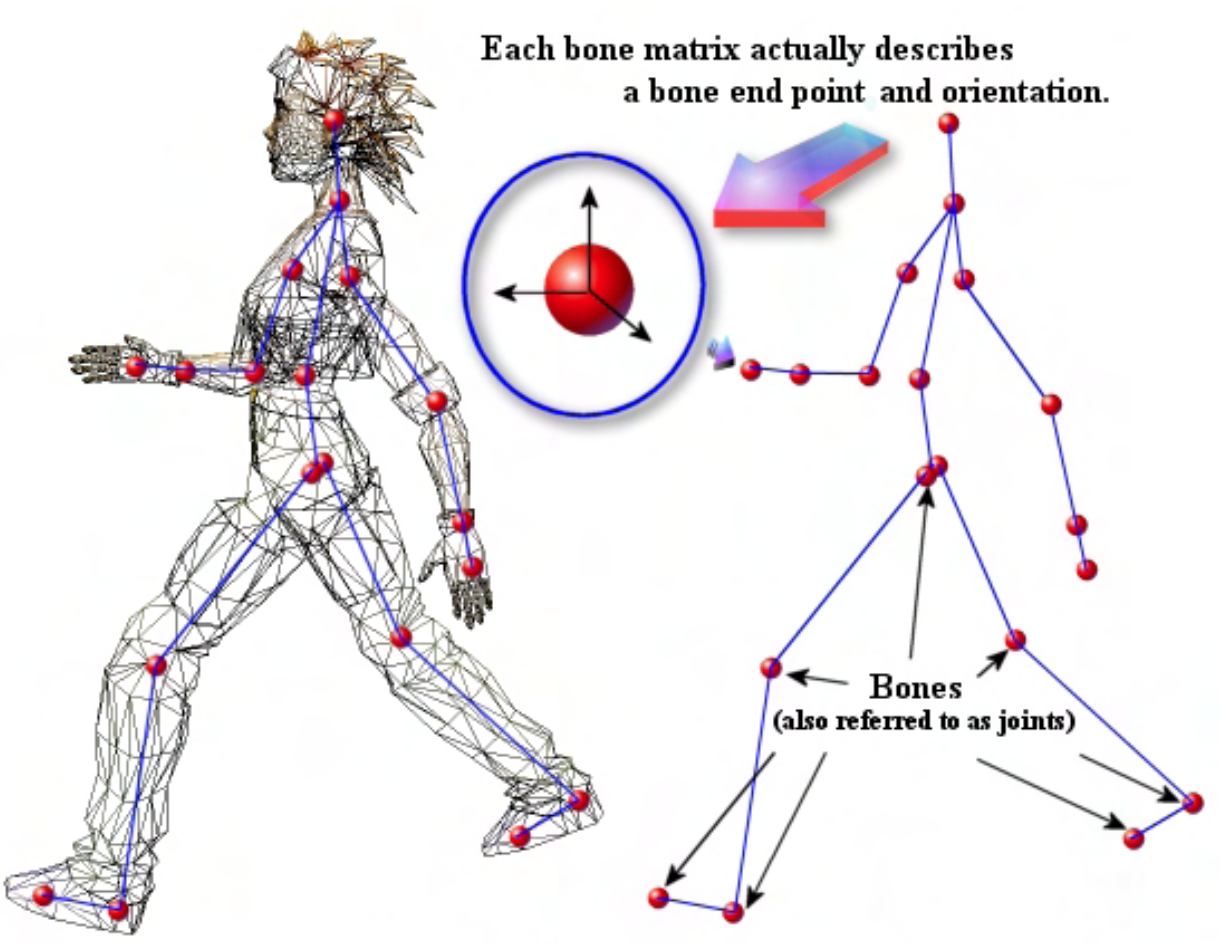
So even if none of the X file exporters fit your needs, you could always use a system like Flexporter™ and write some code to build your own plug-in file format. If you intend to use the D3DX animation system then you will need to write the code that also uses this data to populate the animation controller, its animation sets, and its underlying keyframe interpolators. Fortunately, we learned how to do this in the last chapter, so you have some knowledge of how to approach such a system.

We now understand skin mesh creation at a high level. Although there will be differences between various modeling applications, the underlying system we are creating still consists of two separate entities: the skin and a skeletal structure. When saved out to an X file, the skeleton is saved as a frame hierarchy that D3DXLoadMeshHierarchyFromX will load automatically. Each frame in the X file will be a bone in the skeleton and the matrices stored in each frame will contain the parent-relative transformation of that bone. Each bone in the hierarchy will have also been assigned a name so that the animation controller can manipulate the bone matrix. This also allows us to identify the matrices which affect each vertex. This will all be dealt with at load time and, as we will see later, is something that we will need to know in order to make sure that the Direct3D device has the correct bone matrices available when rendering specific subsets of the mesh.

For the remainder of this chapter we will be assuming that you have exported your skinned character and skeletal animation structure into X file format. You should have a single X file which contains at least one skin, one skeletal hierarchy, and a collection of animation data. You do not have to export keyframe animation data with the skinned character since you may choose to apply the animations to the bone matrices programmatically instead. However, by storing the various animations in separate animations sets inside the X file, you have the benefit of using D3DXLoadMeshHierarchyFromX to load the various animation sets and register them with the animation controller. This way you can just select the pre-canned animation you wish to play, assign it to a track on the animation mixer, and start animating your character immediately. If you do not have a character X file handy to practice with, you can use the samples accompanying this course, or those (like tiny.x) that ship with the SDK.

11.3.2 Bones and Joints

In Fig 11.11 we can see that the animation data manipulates the bones in the skeleton and that because the skin vertices are attached to those bones, the entire mesh is animated as a result. Although in 3D Studio MAX™ (and in Fig 11.11) we have rendered the skeleton as a physical entity existing inside the skin, it will not exist in our applications as a visual object. The bones of the skeleton are ultimately just matrices describing a position and orientation relative to a parent bone in the hierarchy. We render them just to get a feel for what is happening behind the scenes.



It is common to represent the hierarchy in diagrams by connecting up the bone matrix positions with lines to form a skeleton. Whilst this is useful for visualizing the underlying skeleton that the mesh is using, we must remember that in such diagrams the lines themselves are not what our bone matrices represent, each bone matrix actually represents a bone end point.

Figure 11.11

As Fig 11.11 mentions, it is very common for people to think of the bones themselves as being the links between joints. While of course this is technically true in real life, it is important to bear in mind that a bone in our hierarchy behaves much more like a joint. That is, In the context of a skeletal structure in computer graphics, it is perhaps more intuitive to think of a bone in the hierarchy as being just the bone end-point (or a ***joint***).

Recall that the 'bone' is a frame of reference in our system. Therefore, in the diagram we can see that the bones in our hierarchy will actually be the red spheres shown in the skeleton and technically not the blue lines connecting them. It can be a bit confusing that the word 'bone' is the more common way to refer to these frames instead of the (perhaps more applicable) term 'joint' which better describes what is being animated. Technically, it is really both (the joint plus the bone that emerges from it – much like the Z axis emerging from a coordinate system origin) but the actions that we apply to a given bone really take place at the joint itself (i.e. the system origin).

> **Note:** Many modeling applications and texts on the subject of 3D skeletal animation still refer to bones as 'joints'. We will use the 'bone' terminology in this course in keeping with the DirectX naming convention for such entities but just try to keep this concept in the back of your mind.

To really understand the bone/joint equivalence concept, take another look at Fig 11.3. Because we are describing Frame 1 in this example as being the 'upper right leg bone', we might envisage this bone as being a long white thing that spans the length of the upper leg mesh. While this is understandable, and not entirely false, just keep in mind that a bone is described by a matrix that contains a position and an orientation. The important point to note is that the position in that frame matrix describes the *end-point* of the bone that starts at the top of the leg. Keep in mind that like any line, the term 'end-point' can apply to both the terminal point (the 'end') of the bone as well as its origin (the 'beginning'), but that we are referring to the origin. The bone extends down through the length of the thigh to the kneecap (the next bone in the hierarchy), but rotations are governed by what takes place at the origin (the hip).

In this discussion we have changed nothing from the previous chapter; we have simply started referring to things using different names. Because the frame hierarchy is being used to represent a character, we are referring to it as a skeleton, with each frame as a bone and each frame matrix as a bone matrix. The bone matrix still describes the position and orientation of the body part mesh that is attached to that bone relative to the parent bone.

In the next section we will examine how the skinned mesh(es) will be stored in an X file. This will prove to be a very short discussion since most of the standard templates we have already covered in the previous chapter will be used again. While it is not strictly necessary for you to understand how the skinned mesh and skeletal structures are stored in an X file in order to be able to load and render them, examining how the data is stored (especially the way that the vertices are mapped to bones in the hierarchy along with weights) will help greatly in understanding how to store and render that data once it is loaded.

11.4 X File Skins and Skeletons

When a skinned mesh and a skeletal structure are exported to an X file, the skeletal structure is exported as a generic frame hierarchy, where each frame is a bone. The name of the frame will be the name that the artist assigned to the bone in the modeling package. This frame hierarchy is represented using the standard Frame template that we looked at earlier in the course. If we use our example of a pair of legs constructed from a skeletal structure consisting of five bones (a pelvis, two upper leg bones and two lower leg bones) we can see that the skeleton is represented in the X file as shown in the file snippet that follows.

Recall that each frame contains a transformation matrix (which we will now refer to as the parent-relative bone matrix) and any number of child frames. As we can see in this example, the pelvis frame is the root frame, which contains two immediate child frames -- the left upper leg bone and the right upper leg bone. Each one of these two child bones themselves have a child bone -- the left upper leg bone has the left lower leg bone as a child and the right upper leg bone has the right lower leg bone as a child. Notice that each bone in the skeletal structure that will be animated and have vertices assigned to it is given a name. In this example we have just set the matrix data of each bone to identity, but in a real world situation this would contain the position and rotation information of the bone.

```
Frame Pelvis   // Root Frame
{
      FrameTransformMatrix  // Pelvis Bone Matrix
      {
       1.000000,0.000000,0.000000,0.000000,
       0.000000,1.000000,0.000000,0.000000,
       0.000000,0.000000,1.000000,0.000000,
       0.000000,0.000000,0.000000,1.000000;;
      }

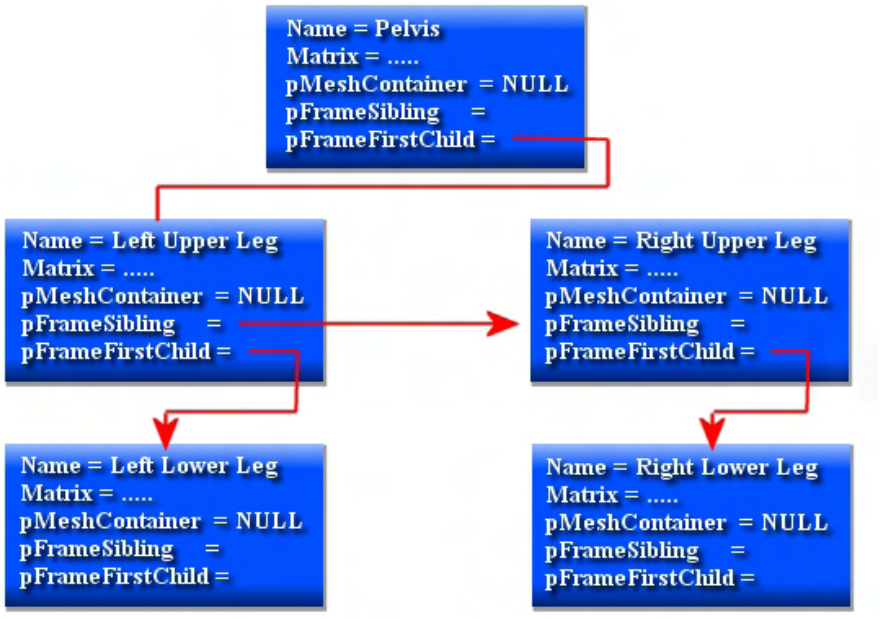
      Frame LeftUpperLeg            // Child Bone of Pelvis
      {
         FrameTransformMatrix       // LeftUpperLeg Bone Matrix
         {
           1.000000,0.000000,0.000000,0.000000,
           0.000000,1.000000,0.000000,0.000000,
           0.000000,0.000000,1.000000,0.000000,
           0.000000,0.000000,0.000000,1.000000;;
         }

      Frame LeftLowerLeg      // Child of LeftUpperLeg Bone
      {
        FrameTransformMatrix // LeftLowerLeg Bone Matrix
        {
          1.000000,0.000000,0.000000,0.000000,
          0.000000,1.000000,0.000000,0.000000,
          0.000000,0.000000,1.000000,0.000000,
          0.000000,0.000000,0.000000,1.000000;;
        }
      }
   }
```

```
  Frame RightUpperLeg         // Child Bone of Pelvis
  {
      FrameTransformMatrix          // RightUpperLeg Bone Matrix
      {
       1.000000,0.000000,0.000000,0.000000,
       0.000000,1.000000,0.000000,0.000000,
       0.000000,0.000000,1.000000,0.000000,
       0.000000,0.000000,0.000000,1.000000;;
      }

      Frame RightLowerLeg           // Child Bone of RightUpperLeg
      {
         FrameTransformMatrix       // RightLowerLeg Bone Matrix
         {
          1.000000,0.000000,0.000000,0.000000,
          0.000000,1.000000,0.000000,0.000000,
          0.000000,0.000000,1.000000,0.000000,
          0.000000,0.000000,0.000000,1.000000;;
         }
      }
   }
}
```

Forgetting about how the character skin is stored for now, we know that if we were to use the D3DXLoadMeshHierarchyFromX function to load this hierarchy it would create a D3DXFrame hierarchy for our skeleton as shown in Fig 11.12.



The D3DXFrame Hierarchy that would be created by the D3DXLoadMeshHierarchyFromX Function

Figure 11.12

Our application would be returned a pointer to the root frame (the pelvis bone). The pelvis bone would have its child pointer pointing at the LeftUpperLeg bone, which would be connected to the RightUpperLeg bone via its sibling pointer. So, both of these frames are considered to be child bones of the pelvis bone. The LeftUpperLeft bone would have its child pointer pointing at the LeftLowerLeg bone and the RightUpperLeg bone would have its child pointer pointing at the RightLowerLeg bone.

However, while the frame hierarchy representation in the X file is unchanged when representing bones, the big change in a skin and bones representation is that there is no longer a mesh attached to the various frames in the hierarchy. So, where exactly is this single skin (mesh) data stored?

As it turns out, there is no hard and fast rule about where the skin needs to be stored. What we do know is that it will no longer be assigned to a single frame in the hierarchy and that it will have the appropriate information contained inside the Mesh data object describing which vertices map to which bones. Therefore, the mesh might be embedded as a child mesh of the root frame or even some arbitrary child frame. Because the position of the mesh in the hierarchy no longer directly dictates which frames animate it (this will be described by a bone table inside the mesh object) or the order in which rendering takes place, the skin can pretty much be defined anywhere in the hierarchy (although it is generally defined in the root frame). When D3DXLoadMeshHierarchyFromX detects that the Mesh data object has 'skinning information' inside its data block, it knows to treat this mesh differently and supply our application with bone-to-vertex mapping information. Note that we no longer need to render the mesh hierarchically because it is a single mesh (although we still need to update the hierarchy matrices recursively). So if the Mesh data object is defined inside the root frame, then the root frame's pMeshContainer will point to the mesh container that stores the skin. This is the pointer we will use to access and render the subsets of the mesh.

You will be pleased to know that the definition of a skin mesh is no different from the regular Mesh X file definition. All of the same standard templates are used to define the Mesh data object itself as well as the child data objects such as the material list, the texture coordinates, and vertex normals. The only difference with a mesh that will be used for skinning is that it will contain additional child data objects. So we might imagine an arrangement as shown in the next example, where the Mesh object is defined as a child of the root frame. In this example we have not shown ***all*** of the mesh data and child objects, but you will get the general idea.

```
Frame Pelvis   // Root Frame
{
      FrameTransformMatrix  // Pelvis Bone Matrix
      {
        1.000000,0.000000,0.000000,0.000000,
        0.000000,1.000000,0.000000,0.000000,
        0.000000,0.000000,1.000000,0.000000,
        0.000000,0.000000,0.000000,1.000000;;
      }

      Mesh LegsSkin
      {
            4432;                         // Number Of Vertices
            -34.720058;-12.484819;48.088928;,   // Vertex List
            -25.565304;-9.924385;26.239328;,
            -34.612186;-1.674418;34.789925;,
```

```
             0.141491;7.622670;25.743210;,
            -34.612175;17.843525;39.827816;,
            -9.608727;27.597115;38.148296;,
            …  Remaining Vertex Data Goes Here….

            6841;              // Number of Faces
            3;28,62,1;, // Face List

             }
      }
}
```

Fig 11.13 shows how the loaded hierarchy and mesh container would be arranged in memory after the D3DXLoadMeshHierarchyFromX function has finished executing. There is a single mesh attached to the root frame although, as mentioned, the mesh could have been attached to another frame in the hierarchy. Your application will probably want to store this mesh pointer in some other more easily accessible application variable. Fetching from the root frame structure every time is also fine.

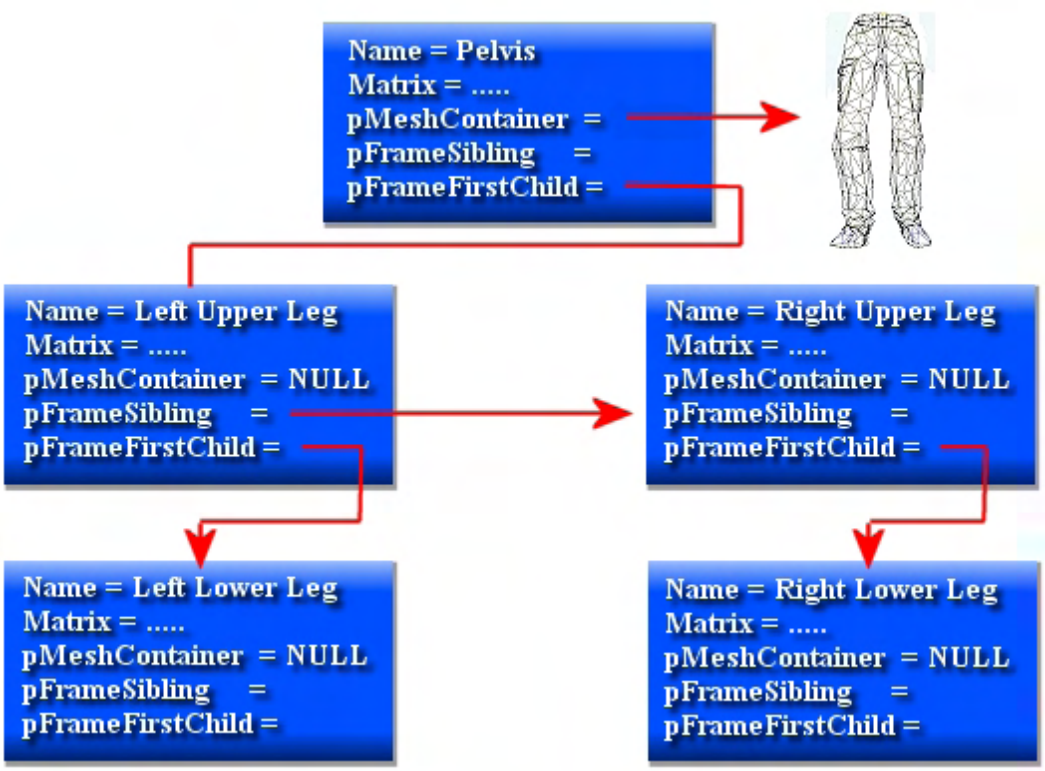

Figure 11.13

While things have not changed much from our previous chapters, we still need to address the bone/vertex relationship. As it happens, a skin mesh data object will be like a normal mesh data object with the exception that it will now have two additional types of child data objects embedded within its definition (not shown in Fig 11.13). These new object types are both standard X file templates. Together they will contain the information that describes which vertices a bone affects and by how much. The existence of these standard templates in the file is how D3DXLoadMeshHierarchyFromX identifies the mesh as a skin and thus takes additional action to load the bone-to-vertex mapping table. We will examine these templates in the next two sections.

11.4.1 The XSkinMeshHeader Template

The first standard template we will discuss is the XSkinMeshHeader template. There will be exactly one of these data objects defined as a child of the mesh data object. This template stores information about the maximum number of bone matrices that affect a single vertex in the mesh and the maximum number of bone matrices that are needed to render a given face. A 'face' is a triangle consisting of three vertices, so if (for example) each of a triangle's vertices were influenced by four unique bone matrices, then we know that in order to transform and render this triangle we would need to have access to the (3 * 4) 12 matrices that influence this single face.

It may not yet be obvious why we would need to know how many matrices collectively affect a face. After all, we are just transforming each vertex into world space, one at a time, using the matrices that affect that vertex. It would seem that all we would need to know is how many matrices affect the specific vertex being transformed. As it turns out, this is true when we perform software skinning (discussed later), where we basically just perform vertex blending one vertex at a time. However, if the hardware supports vertex blending, then things will change a bit. We learned early in this course series that when calling the DrawPrimitive family of functions, the pipeline transforms our vertices in triangle order (i.e. we pass in lists of triangles to be rendered and they are processed one at a time). Thus, in order for the pipeline to transform a triangle's vertices using vertex blending, the device must have access to all of the matrices that influence all of the triangle vertices before we issue the DrawPrimitive call. All of this will make a lot more sense later on in this chapter when we start looking at API specific skinning.

Let us first have a look at the XSkinMeshHeader type. It is a very simple template with just three members. Again, there will be exactly one of these child data objects inside each skinned mesh data object.

```
template XSkinMeshHeader
{
     <3cf169ce-ff7c-44ab-93c0-f78f62d172e2>
     WORD nMaxSkinWeightsPerVertex;
     WORD nMaxSkinWeightsPerFace;
     WORD nBones;
}
```

WORD nMaxSkinWeightsPerVertex
This will describe the maximum number of bones (matrices) that influence a vertex in the mesh. For example, some vertices might only be influenced by a single bone, others by two. Perhaps there are also a few vertices that are affected by three bone matrices. In this example, this value would be set to 3 to let DirectX know that at most, a vertex in this mesh will only be influenced by three matrices. This is actually very useful information. We will see later that when we create a skinned mesh for hardware skinning, the vertex format used will also contain a number of floating point weight values per vertex. These weights describe the influence for each bone that affects it. Since all of the vertices in a mesh's vertex buffer will need to be the same format, we need to make sure we specify the correct FVF flags when creating the mesh. We want to ensure that enough storage space is allocated per-vertex for the maximum number of weights needed by any given vertex in the mesh.

WORD nMaxSkinWeights
This value will describe the maximum number of bones that influence a single triangle in the mesh. If a triangle in the mesh used four unique bones for ***each of its vertices*** but other triangles in the mesh used fewer, this value would still be set to 4*3 = 12. This will tell our application how many matrices we must make available (at most) to the device in order for a given triangle to be transformed by the pipeline using vertex blending. Not all triangles will need access to this many matrices to be transformed and rendered, but the system must be setup such that we can cope with those that do.

WORD nBones
This value describes how many bones (frames) in the hierarchy influence this skinned mesh. At first you might assume that all bones must affect the mesh, but that would not be correct. This is because the X file might contain multiple skeletal structures all linked in one big hierarchy and it might also contain multiple skins for those skeletons. In that case we could say that the hierarchy contains multiple skinned meshes where each mesh is mapped only to the bones for its own skeleton in the hierarchy. The X file might also contain an entire scene hierarchy of which a skinned mesh's bone hierarchy is just a subset. Suffice to say, all of the frames defined in the X file might not belong to a single skeletal structure or might not belong to the skeletal structure attached to a given skin. Quite often however, a skinned mesh and its skeletal structure will be stored in its own separate X file.

11.4.2 The SkinWeights Template

The SkinWeights template stores information about which vertices in the parent mesh data object are affected by a single bone in the hierarchy. It also stores the weights by which those vertices are influenced by the bone. Therefore, the nBones member of the XSkinMeshHeader data object describes how many SkinWeights child data objects will follow it in the mesh definition. If a skin's skeleton consists of five bones, there will be one XSkinMeshHeader child data object followed by five SkinWeights data objects (one SkinWeights child data object defined for each bone in the skeleton for this mesh).

```
template SkinWeights
{
      <6f0d123b-bad2-4167-a0d0-80224f25fabb>
      STRING transformNodeName;
      DWORD nWeights;
      array DWORD vertexIndices[nWeights];
      array FLOAT weights[nWeights];
      Matrix4x4 matrixOffset;
}
```

STRING transformNodeName

This member is a string that will store the name of the bone for which this information will apply. For example, if this string contained the name RightUpperLeg, then the data that follows (the vertices attached to this bone and their weights) will describe the vertices attached to the RightUpperLeg bone in the skeletal hierarchy.

DWORD nWeights

This value describes how many vertices in the skin will be influenced by this bone. As a result, it will tell us the size of the two arrays that follow this member which contain vertex indices and vertex weights for this bone.

array DWORD vertexIndices [nWeights]

Following the nWeights member is an array of vertex indices. The number of vertices in this array is given by the nWeights member. For example, if nWeights = 5 and the vertexIndices array held the five values {4, 7, 20, 45, 100} then it means that the fourth, seventh, twentieth, forty-fifth and one hundredth vertex defined in the parent mesh's vertex list are mapped to this bone. Therefore, when these vertices are being transformed into world space, this bone's matrix should be used to some extent. We deduce then that if a vertex is influenced by *n* bones, then its index will be included in the vertexIndices array of *n* SkinWeights data objects.

array DWORD weights[nWeights]

We looked at some pseudo-code earlier in the chapter that performed vertex blending using multiple matrices. Recall that we multiplied the model space vertex with each bone matrix (one at a time) to create *n* temporary vertex positions (where *n* was the number of matrices being used in the blend). Each temporary vertex position was then scaled by the weight assigned to the matrix that transformed it, which scaled the contribution of the matrix. Recall as well that the combined weights are equal to 1.0 and that the sum of these scaled temporary vectors was the final vertex position in world space. So we know that it is not enough to define for each bone the vertices that are influenced by it; we must also define weights describing the strength of the bone's influence on each of those vertices. Therefore, following the vertexIndices array is another array of equal size defining the weight of this bone on the corresponding vertex in the vertexIndices array. Each of these weights will usually be a value between 0.0 and 1.0.

Matrix4x4 matrixOffset

The final member of the SkinWeights data object is the bone offset matrix. The bone offset matrix is often a cause for much confusion for students who are new to skeletal animation. We will examine the bone offset matrix in detail very shortly.

Before we finish our X file discussion, let us look at an example of how the skin/bone data is stored in the file. To save space, we will not show our leg hierarchy again, we will just concentrate on the mesh data object (which we already know will exist as a child of one of the frame data objects). We will also pare down the amount of mesh data and standard child objects shown so that we can concentrate on the skin information. We really just want to focus on how the XSkinHeader data object and the multiple SkinWeights data objects will be embedded as child data objects of the mesh. We will not include the SkinWeights data object for each bone (to save space) and instead will simply show two of them along with their vertex mappings. Since our skeleton actually consists of five bones, we know that in reality there would be five SkinWeights data objects defined for this mesh.

           -8.131670,   62.204407,   -2.611076,  1.000000;;
      }

… Remaining SkinWeights objects defined here. There should be 5 in total, one for each bone…
}  // End mesh definition
```

So we can see that the data is stored in the X file in a simple fashion. There will be a hierarchy of bones and a single mesh. That mesh will contain SkinWeights data objects (one for each bone) describing which vertices in the mesh are attached to each bone in the hierarchy, along with the weight describing the influence of that bone matrix on its attached vertices. Furthermore, each SkinWeights data object also contains a bone offset matrix for the bone being described. Before we talk about loading the hierarchy and configuring the API for skinned mesh rendering, let us first examine the bone offset matrix.

11.5 The Bone Offset Matrix

The bone offset matrix stores the inverse transformation of the bone's absolute (not relative) position and orientation in the hierarchy with the skeleton in its reference pose. Although bone offset matrices are provided for each bone in the X file, you could create you own bone offset matrix for each frame by traversing the hierarchy (arranged in its reference pose) starting at the root, and for each frame calculate the absolute matrix for that frame (remember that they are stored as relative matrices in the hierarchy initially). Once you have the absolute matrix for a given frame, just invert it and you will have the bone offset matrix for that bone. The following snippet of code should make this clear.

Note: The code sample that follows is for illustration only. This information is already contained in the X file and loaded automatically by the D3DXLoadMeshHiearchyFromX function.

In the next code example, we have derived our own structure from D3DXFrame just as we did in the last chapter. Recall that we added an additional member called the combined matrix (i.e. the world space matrix of the frame). We will do the same thing again this time, but also add a new member to store the bone offset matrix that we will generate.

Just as a reminder, the standard D3DXFRAME structure is defined as:

```
typedef struct _D3DXFRAME
{
      LPTSTR Name;
      D3DXMATRIX TransformationMatrix;
      LPD3DXMESHCONTAINER pMeshContainer;
      struct _D3DXFRAME *pFrameSibling;
      struct _D3DXFRAME *pFrameFirstChild;
} D3DXFRAME, *LPD3DXFRAME;
```

We will derive our own structure from it with one matrix to contain the absolute transform for each frame when we update the hierarchy and another to contain the bone offset matrix for the given bone.

```
struct D3DXFRAME_DERIVED : public D3DXFRAME
{
      D3DXMATRIX mtxCombined;
      D3DXMATRIX mtxBoneOffset;
}
```

The following function would then be called when the bone hierarchy is first constructed and is still in its reference pose (i.e. before any animations have been applied). ***pRoot*** is assumed to be the root bone returned to the application by D3DXLoadMeshHierarchyFromX. Thus it would be called as:

```
CalculateBoneOffsetMatrices( pRoot, NULL );
```

The function implementation is almost identical to the UpdateFrameHierarchy function we wrote in the previous chapters. It steps through the bone hierarchy using recursion, combining relative matrices along the way to calculate the absolute matrix for each frame. We can think of the combined matrix as being the absolute bone matrix. It describes the actual position of that bone in the representation. Once we have the bone matrix, we invert it to get the bone offset matrix. This offset matrix describes an inverse transformation that provides access to the local space of the bone (as it was defined in its reference pose). You should refer back to our discussion in Chapter Four about the relationship between local space and inverse transformations if this does not sound familiar to you.

```
void CalculateBoneOffsetMatrices (D3DXFrame *pFrame , D3DXMATRIX *pParentMatrix)
{
    D3DXFRAME_BONE * pMtxFrame = (D3DXFRAME_BONE*) pFrame;

    if( pParentMatrix != NULL)
        D3DXMatrixMultiply( &pMtxFrame->mtxCombined,
                            &pMtxFrame->TransformationMatrix, pParentMatrix);
```

```
    else
        pMtxFrame->mtxCombined = pMtxFrame->TransformationMatrix;

    // Calculate the bone offset matrix for this frame
    D3DXMatrixInverse (pMtxBoneOffset, NULL, pMtxCombined);

    if(pMtxFrame->pFrameSibling)
      UpdateFrameMatrices( pMtxFrame->pFrameSibling, pParentMatrix );
    if(pMtxFrame->pFrameFirstChild)
      UpdateFrameMatrices(pMtxFrame->pFrameFirstChild,
                          &pMtxFrame->mtxCombined );
}
```

It is very important to note that while the bone matrices in the hierarchy change when animations are applied to them, this is not true of the bone offset matrices. They will not change throughout the life of the character (otherwise there would be little point storing the information in the X file). Using code similar to the above example, they would be calculated once when the mesh is first loaded and stored away for later use. Remember, we never need to calculate them as shown above; this code was provided as a means of describing how the bone matrices stored in the X file were initially calculated by the modeling application that created it.

11.5.1 The Necessity of the Bone Offset Matrix

Early on in this chapter we looked at some vertex blending code that showed a vertex in the skin being transformed from model space to world space using a blend of multiple world matrices. If we were to use this function to transform the vertices of our skin, the matrices we would use to transform a given vertex would be the absolute bone matrices calculated when we updated the frame hierarchy. We would certainly not apply the relative transformations because we wish to render the vertex and thus require that it exist in world space. So before we transform the skin vertices from model space to world space, we would first need to apply any relevant animations to the frame hierarchy (using the ID3DXAnimationController::AdvanceTime) method. These animations result in a new set of parent-relative frame matrices being stored (as described in the previous chapter). Then we would traverse the hierarchy and concatenate all of the appropriate matrices together (as we did in the previous chapter also) to update the absolute matrices stored in each frame. These combined matrices in each bone store the world space transform for the bone and thus should be used to transform any attached vertices during vertex blending.

Without the bone offset matrix, this final transformation presents a problem. Imagine for the sake of simplicity that we are transforming a single vertex in the skin from model space to world space. Also imagine that the vertex is only attached to one bone (e.g., RightUpperLeg) and that the vertex has a weight of 1.0 stored for that bone. We might assume that we could transform the vertex into world space by doing the following (given that mtxCombined has just been updated to contain the correct position and orientation of the bone in world space):

World Space Vertex = Model Space Vertex * RightUpperLeg->mtxCombined.

This looks like it should work, until we remember that the vertex is defined in model space. That is, the vertex is defined relative to the origin of the model space coordinate system instead of being defined relative to the bone via which it is being transformed. Why is this necessary? Well let us think for a moment about what we would like to have happen. If an animation is applied to a bone, we want that motion to propagate out to all of the skin vertices that are attached to that bone so that they move along with it. Where have we seen this sort of behavior before? In Chapter Ten, of course. When we animated a given frame in our hierarchy, that animation was propagated down to all of its children and they experienced the same animation themselves. This is exactly what we want to have happen in our bone/vertex case. But recall that our frame hierarchy is set up in a relative fashion. That is, each frame is defined in the local space of its parent. Unfortunately this is not the case for our vertices. We know that the vertices of our skin are defined relative to the origin of the model (their 'parent', if you will). They exist in model space. So if we want them to move along with the bone, they will need to be defined relative to the bone (i.e. exist in bone local space). Or more to the point, we want to attach our vertices to the hierarchy such that they behave as children of the bone.

So then why not just store the vertex as a position relative to the bone instead of the model space origin? That is not possible either because the vertex may need to be transformed by multiple bones, and in each case the vertex would need to be defined relative to that bone. That is clearly not going to work unless we wish to store multiple copies of our vertices (which is problematic and obviously not very appealing).

Just for clarity, let us see what happens anyway if we simply transform the vertex by the bone matrix. To simplify this example we will forget about orientation for now and just concentrate on the position of a bone in its reference pose.

Let us imagine that we have a bone that has a combined matrix such that, in its reference pose it is at position **b(50,50,50)** . Let us also assume that we have a vertex that will be influenced by this bone and it is positioned at position **v(60,60,60)** with respect to the model space origin (in its reference pose). We can see right away that the vertex is offset (10,10,10) from the bone when both the bone hierarchy and the skin are in the reference pose. So what we are going to do next is simply assume that the skeleton is still in its reference pose and transform our vertex by our bone matrix.

We know for starters that the vertex should be at position (60,60,60) in its default pose. So if we used the above transformation approach, this is where the vertex should be after being multiplied by the bone matrix (since the bone has also not moved from the default pose). You might see already that this is clearly not going to work. If we think about the case of simply transforming and rendering the mesh in its reference pose, the vertex is already in the correct position (with respect to the bone) even before we transform it using the bone matrix. If we were to transform vertex **v** by bone **b**, we know that with the bone at (50,50,50) the vertex should be at (60,60,60). But look at what happens next:

$$\begin{aligned} \textit{World Space Vertex} &= v * b \\ &= (60, 60, 60) + (50, 50, 50) \\ &= (110, 110, 110) \end{aligned}$$

Note: We are dealing with only the translation portion of the bone matrix to make the example easier. We are assuming that the bone is not rotated in its default pose. Therefore **v** * **b** = **v** + **b**.

Of course, if the vertex was originally defined in bone space instead of model space then the position of the vertex would have been stored as v(10,10,10). This vertex position which is defined relative to the position of its influential bone would indeed create a transformed vertex position of (60,60,60) as expected.

So given that our vertices are not defined in bone space, but in model space, what we need to do before we transform any vertex by a given bone matrix is first transform the vertex into that bone's local space. This way, the vertex is defined in bone space *prior to* being transformed by the bone matrix. Using our simple example again, this would mean performing an inverse translation of the bone's position for the vertex to convert it from a model space vertex position to a bone space vertex position.

First we transform model space vertex **v** into the space of bone **b** by subtracting the bone's offset (i.e. position) from the model space vertex.

Bone Space Vertex = v * -b = (60 , 60 , 60) + (-50 , -50 , -50)
= (10 , 10 , 10)

We now have the vertex in bone space, so we can just apply the combined bone matrix to transform the bone space vertex into world space:

World Space Vertex = Bone Space Vertex * b = (10 ,10 , 10) + (50 , 50 , 50)
= (60 , 60 , 60)

Now we can see that the vertex has been transformed correctly by the matrix into world space. This was made possible by first transforming (in this case translating) the vertex into bone space and then transforming it into world space. We can think of the transformation into bone space as attaching the vertex to the bone as a child. The vertex becomes defined as bone-relative, just as the frames in a hierarchy are defined relative to their own parents. Thus if the parent moves or rotates, so do the children. This is exactly the behavior we want from our vertex-bone relationship. Remember that in our X file, the skin mesh was not actually defined as a child in the local space of any frame (which was why it would have been fine to store it in any frame node – it was just for storage purposes). But in our last chapter of course, our non-skin scene mesh vertices were defined relative to the frames that they were in. So what we are doing with this transformation of the vertex to bone local space is an extra step to get us back to where we were in our last demo – where mesh vertices lived in frame local space.

Again, as we discussed in Chapter Four, to get object A into the local space of object B, assuming both objects currently exist in the same space (i.e. same frame of reference) we need to transform A by the inverse matrix of B. Note that in the case of our reference pose mesh, both the bone frame (once it has been concatenated) and the vertex are both defined in model space. Remember that the reference pose mesh has not been moved out into the world. That is, the root node frame matrix is identity.

If this all makes perfect sense to you, then feel free to skip the next section. However, if you still need a bit more insight into how this all works, please read on. We will go through this process a bit at a time and use some diagrams to try to make everything as clear as possible.

11.5.2 The Bone Offset Matrix: A Closer Examination

The mathematics of 3D transformations and all of the different 'spaces' can sometimes get a little confusing for new students. After all, just look at our last example of the vertex/bone transformation from the previous section:

Bone Space Vertex = v * -b = (60 , 60 , 60) + (-50 , -50 , -50)
= (10 , 10 , 10)

World Space Vertex = Bone Space Vertex * b = (10 , 10 , 10) + (50 , 50 , 50)
= (60 , 60 , 60)

It looks like all we have done is subtracted the bone's position from the vertex and then added it right back on again! But when you really think about it, it starts to make some sense. Since we were transforming the vertex using the skeleton in its reference pose, we expect that the resulting vertex we get back from the transformation is the vertex position we already have stored. After all, nothing has actually moved, so the relationships should be the same as they were before the transformation.

So let us go one step further. This time let us assume that our animation controller has assigned some transformation to bone **b** translating it from position (50,50,50) to (100,100,100) when all is said and done. We certainly want the vertex to correctly move when the bone that influences it moves. The system above does exactly that because we first subtract the bone's reference position from the model space vertex to transform the vertex into a bone local space position (i.e. the vertex is defined relative to the bone origin). We then use the newly modified combined bone matrix to transform the vertex into world space, thus maintaining the relationship between the vertex and the bone.

In the following formula, **b** is the bone's reference position (how it is stored in the X file's bone offset matrix) which never changes, **v** is the model space vertex, which also never changes and **c** is the current world transform (the combined matrix) of the bone that changes when animations are applied or when the character is moved about the world.

First we transform the vertex into bone space by subtracting the inverse ***reference*** position of the bone from the model space vertex.

Bone Space Vertex = v * -b (60 , 60 , 60) + (-50 , -50 , -50) = (10, 10, 10)

Now we transform the bone space vertex using the ***current*** world transform of the bone so that the vertex is correctly positioned in the world. In this example we are assuming the current world space position of the bone is (100,100,100) after animation and hierarchy matrix concatenation has occurred.

World Space Vertex = Bone Space Vertex * c = (10, 10 ,10) + (100, 100, 100)
World Space Vertex = (110 , 110 , 110)

As we can clearly see, the vertex has moved along with the bone. Although the bone has moved to position (100,100,100) the vertex has still maintained its relationship of a (10,10,10) offset from the bone, which placed it at world space position (110, 110, 110).

Now in these simple examples, we are assuming that the vertex is influenced by only one matrix. If the vertex is influenced by multiple matrices then the above steps would need to be performed for each matrix. The resulting temporary world space vertex positions would each be scaled by their respective weights before being added together to create the final world space vertex position, just as we saw earlier in our vertex blending code. It is also worthy of note that in the above example we are only showing the translation component of the process; the bone can also be rotated. So the fact that we have access to the bone offset matrix means that we always have the ability to transform the vertex back into bone space for a given bone and then apply the current world matrix of the bone. If the bone has been rotated, then the vertex will also be rotated about the bone space origin as expected rather than the model space origin.

So now we know that the X file will contain a bone offset matrix for every bone. We also know that when this matrix is applied to a model space vertex, it will transform the vertex from model space to bone space. This process essentially attaches the vertex to our bone as a child, just as we saw with our meshes in the last two chapters, which solves all of our problems. Remember that the bone offset matrices never change, while the world space bone positions do (when animated). With this in mind, we will rewrite our vertex blending function discussed earlier to first transform the vertex into each bone's space before applying the world transform for that bone.

> **Note:** You will not have to write your own vertex blending function when you are using the DirectX pipeline. You will just need to make sure that it has access to both the world matrix and the bone offset matrix for each bone for the proper vertex transformations.

Our function parameter list has now been modified from our earlier example to include a pointer to an array of bone offset matrices. We pass in each world space (combined) bone matrix in the pBoneMatrices array and we will also pass in each bone's corresponding bone offset matrix (loaded from the X file) in the pOffsetMatrices array. Notice that in this function, rather than applying the inverse transform matrix to the vertex and then applying the world bone matrix to the bone space vertex in two separate steps, we can combine the bone's world matrix with its offset matrix first to get a resulting matrix that will perform both steps with a single vertex/matrix multiply. So we will transform the vertex from model space straight into world space with this one combined matrix.

```
D3DXVECTOR3 TransformBlended ( D3DXVECTOR3* pModelVertex ,
                               D3DXMATRIX * pBoneMatrices ,
                               D3DXMATRIX *pOffsetMatrices ,
                               float *pWeights ,  float NumOfMatrices  )
{
      D3DXVECTOR3 TmpVertex;
      D3DXVECTOR3 FinalVertex ( 0.0f , 0.0f , 0.0f );
      D3DXMATRIX  mtxTempMatrix;

      for ( int I = 0 ; I < NumOfMatrices; I++ )
      {
            D3DXMatrixMultiply ( &mtxTempMatrix , pOffsetMatrices[I],
                                 pBoneMatrices[I]);
```

```
            TmpVertex = ( *pModelVertex * mtxTempMatrix ) * pWeights[I];
            FinalVertex += TmpVertex;
      }

      return FinalVertex;
}
```

Remember that the bone offset matrices never need to be recalculated. They are loaded (or created) during initialization and are re-used during each iteration of the game loop. When combined with the bone's world transform, we get a matrix that can correctly be used in blending operations to transform any vertices that are influenced by that bone.

As promised, before moving off the topic of the bone offset matrix, we will look at some additional examples with the aid of some diagrams to make sure that you fully understand the concept of the bone offset matrix.

In the following example we will see why the bone offset matrix is needed to transform a vertex that is influenced by two different bones in the hierarchy.

In Fig 11.14 we see two bones that influence a single vertex. For simplicity, we are working with 2D vectors. The absolute position of bone 1 in the skeleton reference pose is (5, 5) and the absolute position of bone 2 in the reference pose is (3, 8). The model space vertex in the reference pose is positioned at (5, 8). Although the bone matrices are initially stored as relative matrices in the X file, we are assuming in this example that the hierarchy has already been traversed and that the absolute position of each bone in the reference pose has been determined. We could say at this point that both of the bones and the vertex are now defined in the model space of the skin (assuming we have not moved the skeleton by updating the position of the root bone).

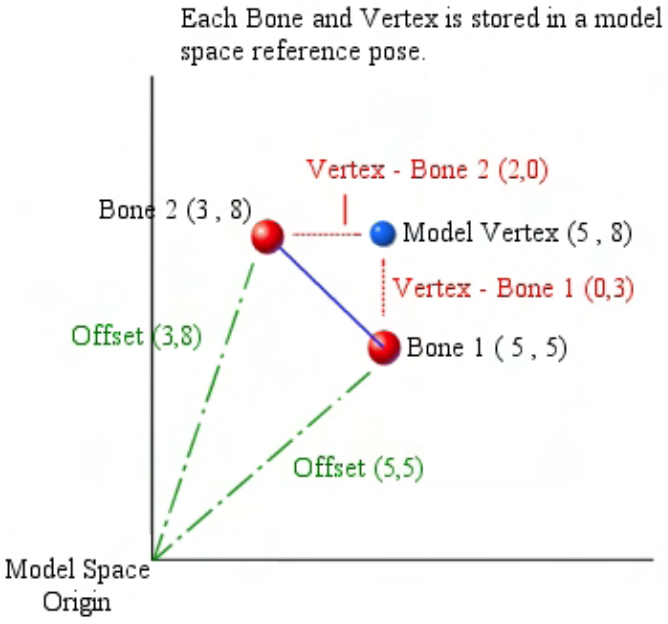

Figure 11.14

We note that the vertex is offset (0, 3) from bone 1 and (2, 0) from bone 2. We will assume that the weight of influence of each (bone) matrix on this vertex will be 0.5. That is, they will both be used in equal measure to transform the vertex into world space.

The two green lines in the diagram (labeled 'Offset') tell us how far from the model space origin each bone is offset. We can think of the bone offset matrix as being the reverse of these two lines. In other words, for bone 1, the offset matrix would have a translation vector of (-5, -5) and for bone 2 the bone offset matrix would have a translation vector of (-3, -8).

We know that in order to transform this model space vertex into world space we must transform it by each bone matrix, scale the resulting vectors by the respective weights, and then sum the results. If you recall our vertex blending function, you will remember that this is done one transformation at a time. We would first need to transform the vertex by bone 1 and then scale the result by bone 1's weight to create a temporary world space vertex for that matrix. We would then do the same for bone 2 and combine the results. So let us start our example with how the vertex would be transformed by bone 1.

For this example, we will discuss how to transform the vertex into world space *after* the two bones to which the vertex is attached are moved into a new world space positions.

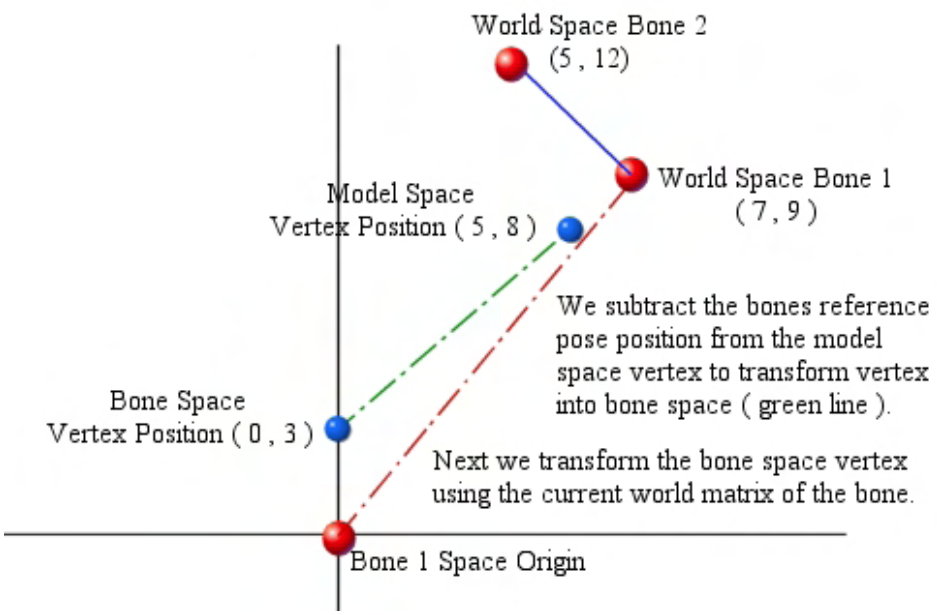

Figure 11.15

In Fig 10.15, both bone 1 and bone 2 are moved into world space positions (7, 9) and (5, 12) respectively. Beginning with bone 1 we apply the bone offset matrix to the model space vertex. This slides the blue vertex in the diagram from its model space position of (5, 8) into a bone 1 space position of (0, 3). As you can see, we have slid the vertex back along bone 1's offset vector. In bone 1 space we can imagine that bone 1 is now at the origin of the coordinate system and that the vertex is offset (0, 3) from the bone, as was the case in the reference pose.

Since the world transform for bone 1 is now (7, 9), we apply this transformation to the bone space vertex (0, 3) as shown in Fig 11.16.

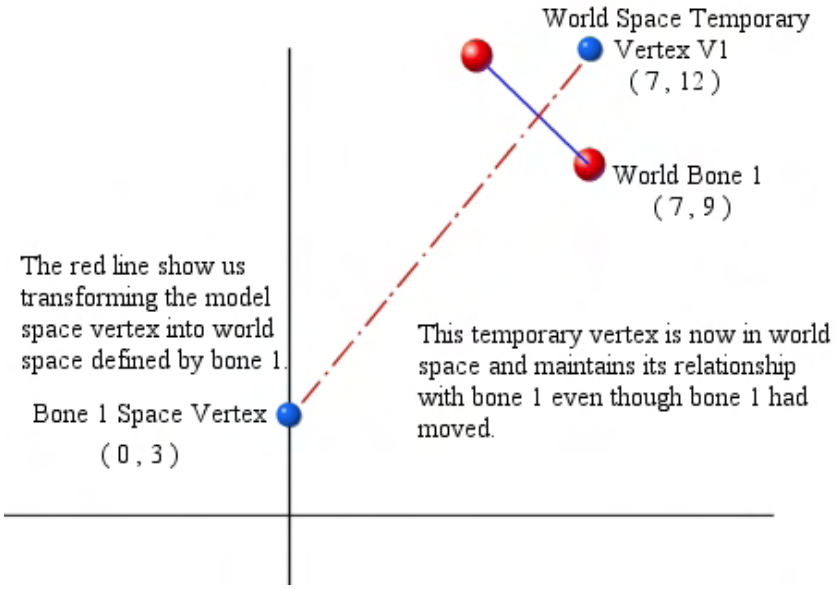

Figure 11.16

We can see in Fig 11.16 that we have now slid the vertex into position (7, 12) and it remains correctly offset (0, 3) from bone 1. So the relationship between the bone and the vertex in the reference pose has been correctly maintained even with the bone in its new world space position.

The next step is to scale the temporary world space vertex by the weight of bone 1 (0.5) for that vertex. This will effectively halve the length of the vector. In Fig 11.17 we can see that the final position of the temporary vertex, when multiplied by the weight of 0.5 (3.5, 6) is halfway along the red dashed diagonal line.

We now repeat the process all over again for bone 2. First we subtract the offset of bone 2 from the model space vector to get the vertex into bone space. We then multiply this vertex by the world matrix of bone 2 to create another temporary vertex of (7, 12) which is scaled by the weight of bone 2 (also 0.5) and we wind up with a temporary vertex position of (3.5, 6). Because both matrices influence the vertex equally, this means that we end up with two temporary vertex positions of (3.5, 6). When these two temporary vectors are added together we have the final world space position of the vertex (7, 12). Obviously, if the weights of the matrices for this vertex were altered so that one bone influenced the vertex more than the other and/or if the vertex was not positioned equidistant from each bone, the final world position of the vertex would be different.

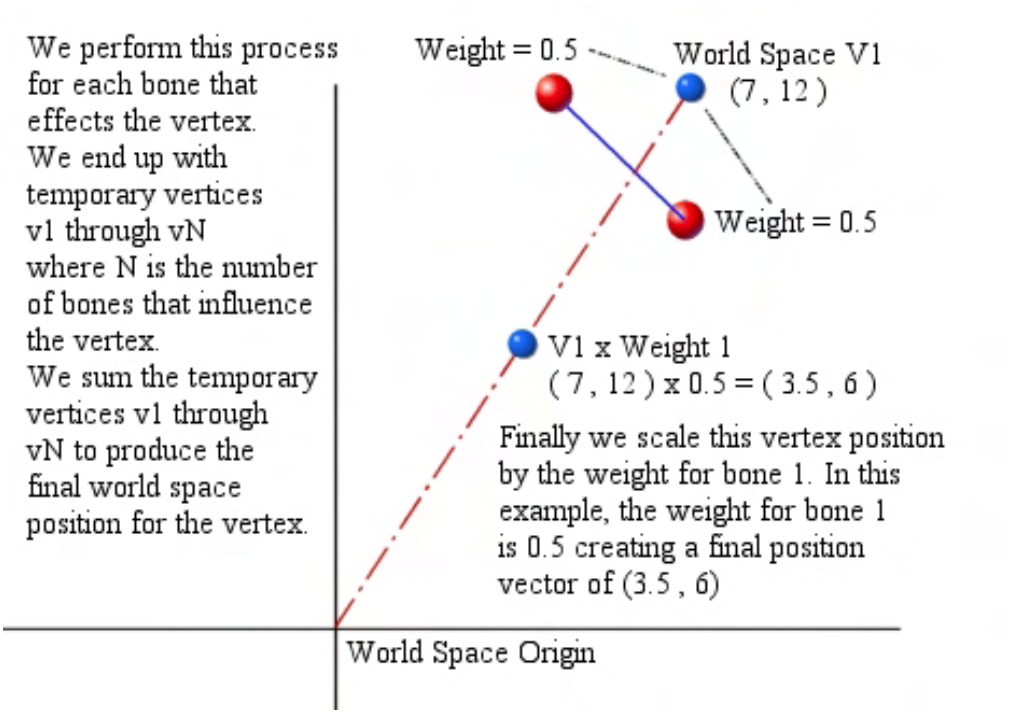

Figure 11.17

Bear in mind that we are showing a simple example here based on only translations. If any of the bones world matrices contained rotations, then the vertex would be rotated about the bone space origin before being translated into position.

Let us now tackle a slightly more complex example. In Fig 11.18 we see a model space vertex that has a position of (30, 20, 0) and is influenced by three bones. The diagram shows the position of each of the three bones in the reference pose and also shows the influence of each bone on the vertex. As you can see, the weights for this vertex are 0.25, 0.5, and 0.25 for bones 1 through 3, respectively. Therefore, we could say that bone 1 and bone 3 contribute 25% of the vertex world space position each, while bone 2 will contribute half with its influence at 50%. Once again, we are looking at the absolute bone positions for the reference pose calculated by traversing the hierarchy and combining the relative matrices stored therein.

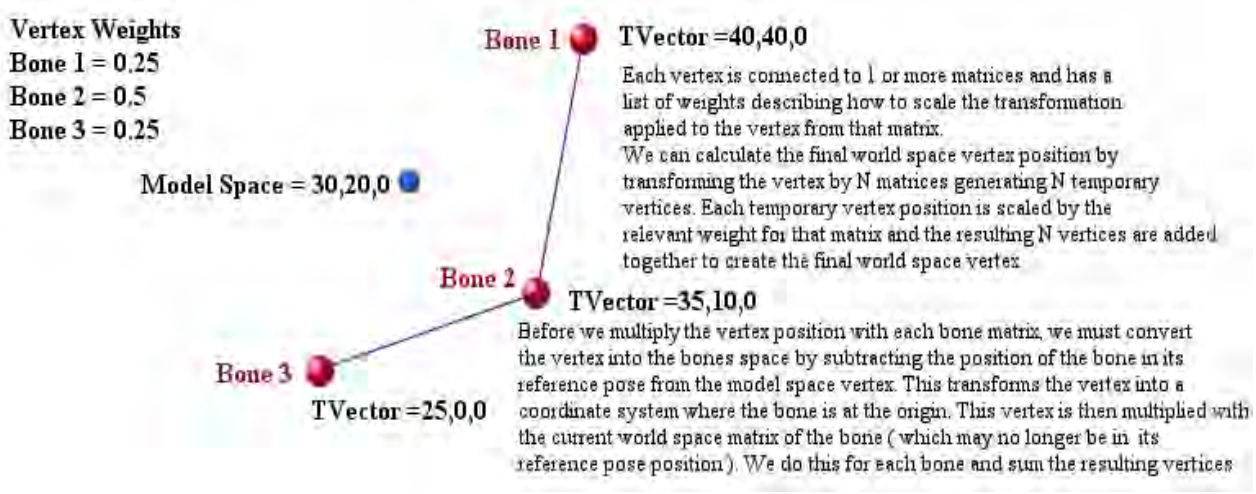

Fig 11.18

If we imagine that these three bones define the arm of a skeleton which is bent in its default pose, let us see what happens to the model space vertex when we move bone 3 to straighten the arm (Fig 11.19).

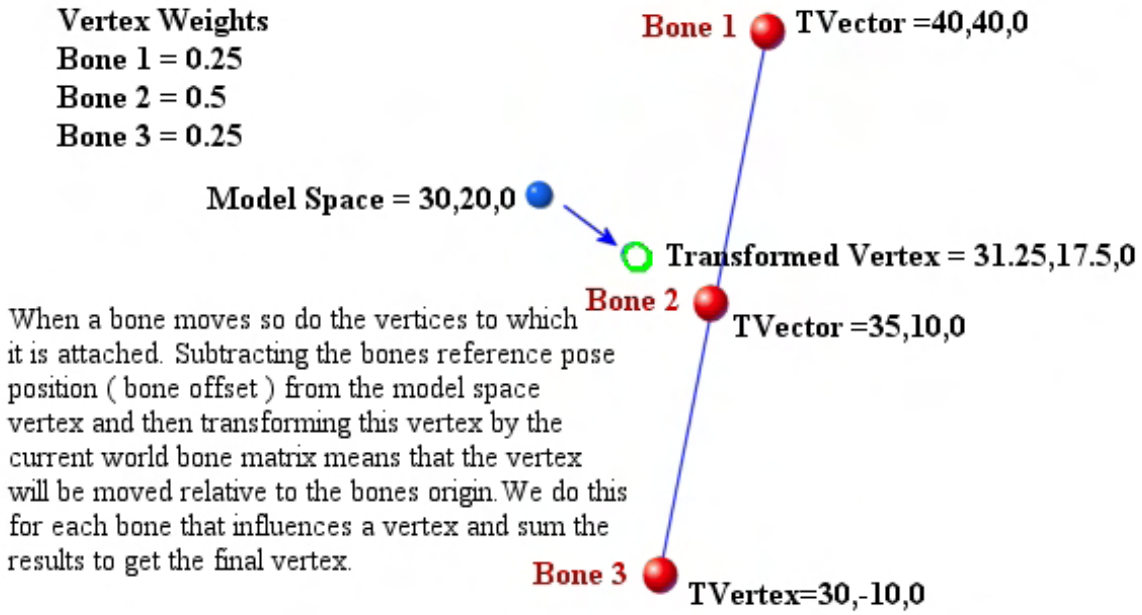

Fig 11.19

We already know that in order to calculate the final position of the vertex we must calculate (for each bone) a temporary vertex position by subtracting the bone's offset in the reference pose from the model space vertex. (Do not forget that technically this step is a bone offset matrix multiplication that accounts for rotation as well. We are focusing on translation only because the math is easier to grasp.) Then we have to transform the bone space vertex using the bone's combined world matrix and scale the result using the weight value. This will be done in three separate steps (once for each bone matrix) before summing the three temporary vertex positions to create the final world space vertex position.

The following calculations walk through the process. They demonstrate exactly what our vertex blending function would do if given the model space vertex, the three bone matrices, and their respective bone offset matrices from Figure 11.19.

Notice that for each of the three bones we transform the model space vertex into bone space using the current bone's inverse transformation (the bone offset matrix). We then transform the bone space vertex position with the current bone transformation and scale the resulting vector by the weight for that bone. Notice that in Fig 11.19, only bone 3 has been moved. Therefore, we expect that the transforms for bones 1 and 2 should just output the same model space vertex because the relationship between the vertex and those bones are the same as they were in the reference pose. However, when transforming the vertex by bone 3 (which has moved), the bone position is no longer equal to the reverse of the transformation described by the bone's offset matrix. Therefore, the vertex position in step three will not be the same model space vertex, and thus the sum of these vertices produces a different world space vertex position as well. The new world space vertex position is shown in Fig 11.19 as a green circle.

Transform Vertex V with Bone 1

Bone Space V ***= (30 , 20 , 0) + (- 40 , -40 , 0) = (-10 , -20 , 0)***
Un-Scaled World V1 ***= (-10 , -20 , 0) + (40 , 40 , 0) = (30 , 20 , 0)***
Scaled World V1 ***= (30 , 20 , 0) * 0.25 = (7.5 , 5 , 0)***

Transform Vertex V with Bone 2

Bone Space V ***= (30 , 20 , 0) + (-35 , -10 , 0) = (-5, 10, , 0)***
Un-Scaled World V2 ***= (-5 , 10 , 0) + (35 , 10 , 0) = (30, 20 , 0)***
Scaled World V2 ***= (30 , 20 , 0) * 0.5 = (15 , 10 , 0)***

Transform Vertex V with Bone 3

Bone Space V ***= (30 , 20 , 0) + (-25 , 0 , 0) = (5, 20, , 0)***
Un-Scaled World V3 ***= (5 , 20 , 0) + (30 , -10 , 0) = (35, 10 , 0)***
Scaled World V3 ***= (35 , 10 , 0) * 0.25 = (8.75 , 2.5 , 0)***

Sum the 3 temporary vectors to create the final vertex position

Final World Space Vertex = Scaled V1 + Scaled V2 + Scaled V3
= (7.5 , 5 , 0)
+ (15 , 10 , 0)
+ (8.75 , 2.5 , 0)

= (31.25 , 17.5 , 0)

Hopefully you now understand the purpose of the bone offset matrix. At its most basic level, it is used to temporarily attach the model space vertex to the bone hierarchy such that the vertex exists in bone local space before it is transformed into world space. This allows animation of the hierarchy to filter down to the level of each individual vertex in the skin because the vertex becomes a temporary child of the bone. Thus any movement of the bone will move the vertex, just as we saw in our last chapter when we noted that the transformation of a parent node affected the children of that node.

11.6 D3DXLoadMeshHierarchyFromX Revisited

We now know how all of the data for our skin and bone entities are stored in the X file. The next logical step then is to take a look at how we can load all of this information into our application. In this chapter we will use D3DXLoadMeshHierarchyFromX, but if for some reason you do not want to use this function, you should be in good position, given the information covered in this chapter and the last, to write code that parses the X file manually.

Because a skinned mesh is really just a mesh that has its vertices attached to various frames/bones in the hierarchy, we are not limited to storing only a single skinned mesh or skeleton per X file. It is entirely possible that the X file might contain a vast number of frames representing an entire scene, and embedded in that hierarchy might be several branches of the frame hierarchy that represent skeletal structures for several skinned meshes contained within that scene. After all, as far as the frame hierarchy and the animation controller are concerned, bones are just frames. The fact that a mesh may be contained within the file that uses some section of the frame hierarchy as a skeleton is insignificant in the grand scheme of things as far as the loading function is concerned. Of course, it is not insignificant to us since we would like to be able to separate the components in such a file according to the logical design requirements of our game engine. So when we load the various skinned meshes from the file, we will need to be able to identify the frames in the hierarchy that are being used as the mesh skeletons and make sure that we set everything up so that the appropriate meshes are associated with their skeletons and that their vertices are properly deformed during the frame animation step.

The D3DXLoadMeshHierarchyFromX function was covered in detail in the last chapter, but here is its definition again for convenience:

```
HRESULT D3DXLoadMeshHierarchyFromX
(
    LPCTSTR Filename,
    DWORD MeshOptions,
    LPDIRECT3DDEVICE9 pDevice,
    LPD3DXALLOCATEHIERARCHY pAlloc,
    LPD3DXLOADUSERDATA pUserDataLoader,
    LPD3DXFRAME* ppFrameHeirarchy,
    LPD3DXANIMATIONCONTROLLER* ppAnimController
);
```

We know already how this function works; it returns the root frame in the hierarchy, which may be the root bone of a single skinned mesh skeleton or, if the file contains multiple skinned meshes or an entire scene, might just be the root frame of the scene itself and not mapped to any mesh vertices contained within. Either way, this is our handle to the entire scene and our means to traverse the frames/bones being used.

It is quite common (although not required) for each skinned mesh to be stored in a separate X file so that each call to D3DXLoadMeshHierarchyFromX creates a new hierarchy for each skinned mesh, with its associated animation data and its own animation controller. When this is the case, each frame hierarchy will contain the skeletal structure for a single mesh and its accompanying animation data. This is

generally the cleanest way to deal with skinned mesh characters and will be the method we prefer in this course.

Recall that if any animation data is stored in the X file, then an interface to a D3DXAnimationController object will also be returned. This will allow us to play back those animations to update the bones of our skeleton (and consequently, the skin). As discussed, the pAlloc parameter is only used when parsing custom data objects in the X file. Since we will not be requiring custom data in this chapter, we can assume that this value will be set to NULL.

So one of our first questions needs to be, how do we know when the loading function detects a skinned mesh in the file? A follow up question is, once identified, how do we setup and store that data for later use? The answers, as you may have already guessed, are to be found in the implementation of our ID3DXAllocateHierarchy derived class, and in particular our implementation of its CreateMeshContainer function. You should recall from the previous chapter that this function is called by the loading function whenever a mesh is encountered in the file. The mesh data is passed to this function allowing us to store it in the mesh container in the hierarchy as well as make any optimizations to the mesh data before we do so. It is in this function that we are informed that the mesh data we are being passed is intended to be used as a skin. We will be passed additional information about the mapping between the vertices of the mesh and the bones in the hierarchy in the form of an interface to an ID3DXSkinInfo object.

The ID3DXAllocateHierarchy::CreateMeshContainer definition is shown next for our convenience. It should already be quite familiar to you since we covered this function in detail in the previous chapter.

```
HRESULT CreateMeshContainer
(
    LPCSTR Name,
    LPD3DXMESHDATA pMeshData,
    LPD3DXMATERIAL pMaterials,
    LPD3DXEFFECTINSTANCE pEffectInstances,
    DWORD NumMaterials,
    DWORD *pAdjacency,
    LPD3DXSKININFO pSkinInfo,
    LPD3DXMESHCONTAINER *ppNewMeshContainer
);
```

This function is called for each mesh found in the X file. Our derived implementation is responsible for allocating a new D3DXMESHCONTAINER structure, taking the data passed into the function and storing it in this new mesh container, and then returning the newly populated mesh container back to the loading function. From there it will be attached to the relevant frame in the hierarchy. In Chapter Ten we saw that this was a relatively trivial task, but it was important because it allowed our application to own the memory for the meshes in the hierarchy. However, you might also remember that we ignored the LPD3DXSKININFO parameter – this will no longer be the case.

The pSkinInfo parameter is set to NULL when we are passed a normal (non-skin) mesh. For normal meshes, we simply store them in the mesh container and return as we did previously. If however, the pSkinInfo parameter is not NULL, then it means that the mesh we have been passed is to be used as a skin and it should have its vertices mapped to different bones in the hierarchy. When this is the case, we

have a fair bit of work to do. We have to make sure that we setup our mesh container so that we know which matrices have to be used to render a given subset in the mesh.

As it turns out, setting up a skinned mesh differs quite significantly depending on the type of skinning we are performing and whether or not hardware support is available. Since the different techniques can sometimes confuse matters when discussed collectively, what we will do in this chapter is talk about each skinning technique in isolation. On a case by case basis we will examine the skinned mesh creation process, the data structures needed to store it, and how to animate and render the skinned mesh.

In our lab project code we will implement all of the skinning techniques using a single class, but for now, we will consider each one separately for a more constructive analysis. This will make implementing any of the (three) methods we will study quick and easy. We will begin with the most basic skinning method -- software skinning. Essentially, this is a technique where the vertex blending stage is done in software (on the CPU) and not by the DirectX transformation pipeline on the GPU.

While examining each skinning technique we will look at how the CreateMeshContainer method should be written to correctly generate the skinned mesh for use with that technique.

11.7 DirectX Skinning I: Software Skinning

Software skinning is the first skinning technique that we will study in this chapter. As the name implies, it is not dependant on hardware support for vertex blending. As a result, it is not bound by the same limitations as hardware skinning, although it is generally not as fast. For example, when we use a hardware skinning technique, we are often limited to only a few bones being allowed to influence a single vertex. In the software case however we are not limited at all -- we can calculate our world space vertex positions using as many bone matrices as we desire. Therefore, while hardware skinning is preferable in most situations given the performance advantage, if you ever need to perform very complex skinning which requires large numbers of influential bones per vertex (more than would be supported by the DirectX transformation pipeline in hardware), software skinning would be your solution.

> **Note:** Even though software skinning is not as fast as hardware skinning, it still performs very respectably.

When we use software skinning, the skin vertex data will be stored in a standard ID3DXMesh. There is nothing special or unique about this mesh -- it will be passed to our CreateMeshContainer function and stored in our mesh container just as we saw in the previous chapter. During iteration of our game loop, the frame hierarchy is animated and we traverse it to build our absolute bone matrices. Our next task is to take the model space mesh vertex data we have stored in our mesh container and transform it into world space. We certainly do not want to overwrite the skinned mesh vertex data because this is the model space reference pose of the skin that we will need to transform against each time. Thus, an additional mesh will be needed to store the transformed results. We call this the *destination mesh*.

To render the skinned mesh, we will take the vertices in the original (*source*) mesh and transform them into world space (using multi-matrix blending) and store the resulting world space vertices in the vertex

buffer of the destination mesh. It is this destination mesh that we will render each frame. It is worth noting that because this destination mesh has its vertices already stored in world space, we should set the world matrix of the device to an identity matrix before we render the destination mesh.

So how do we transform the mesh from model space to world space when performing software skinning? Well, when a skinned mesh is found in the X file, our CreateMeshContainer function will be passed an ID3DXSkinInfo interface as well as the mesh for the skin. ID3DXSkinInfo contains lots of information, such as the bone offset matrix for each bone in the hierarchy and the mapping table which describes which vertices in the skin are mapped to which bones in the hierarchy and with what weight. We will store this ID3DXSkinInfo interface in our mesh container, so that we can access it in our game loop when we need to transform and render the mesh.

It just so happens that when performing software skinning, things could not be easier for us as programmers. Indeed, the ID3DXSkinInfo interface contains a helper function called UpdateSkinnedMesh which performs the entire transformation process for us. We will take a detailed look at this interface in a moment along with the many helper functions it provides, but first let us examine this vitally important method that is used to perform software skinning.

```
HRESULT UpdateSkinnedMesh
(
    CONST D3DXMATRIX *pBoneTransforms,
    CONST D3DXMATRIX *pBoneInvTransposeTransforms,
    PVOID pVerticesSrc,
    PVOID pVerticesDst
);
```

We pass this function the source mesh vertex buffer, our array of absolute bone matrices, and our array of bone offset matrices for each bone that influences the mesh. We also pass in the vertex buffer of a destination mesh where the transformed vertices will be stored. Because the ID3DXSkinInfo object contains all of the bone-to-vertex mapping information and the bone weight values, this function can quickly step through each vertex in the source mesh vertex buffer and use vertex blending (similar to the vertex blending code we introduced earlier) to transform each vertex using the relevant bones in the passed matrix arrays.

The resulting vertices will be copied to the destination vertex buffer (in a separate destination mesh that we will store in the mesh container structure). On function return, the destination mesh can then be used for drawing. Note that the source vertex buffer is read-only and is never modified by this function. We always maintain the original model space mesh. Every time the hierarchy is updated or animated, we must perform this step to calculate new values for the destination mesh. Again, because the destination vertex buffer that we render from always contains the mesh vertices in world space, we need to set the device world matrix to an identity matrix before rendering.

The way this function is designed does cause a small, but easily solved, problem for us. We need to pass in an array of absolute bone matrices as the first parameter, but our absolute bone matrices are not stored in array format – they are stored throughout the hierarchy in their respective frames. Therefore, in the CreateMeshContainer function, we will need to do two things. First, we will need to extract all of the bone offset matrices from the ID3DXSkinInfo and store them in an array inside the mesh container.

Second, we will need to fetch the corresponding absolute bone matrices in the hierarchy and store pointers in the mesh container as well. This means that our mesh container will store an array of pointers to absolute bones matrices and a corresponding array of bone offset matrices. Finding out which bone offset matrix belongs with which frame matrix in the hierarchy is the only tricky part, and we will examine how that is done momentarily, when we look at some code for an example CreateMeshContainer function.

> **Note:** While we could write our own vertex blending code, it is generally a better idea to use the ID3DXSkinInfo::UpdateSkinnedMesh function. On the whole, it performs vertex blending at a very respectable speed.

The basic steps for software skinning are shown next along with a detailed account of how we can implement this process.

1. Load and store the mesh as a standard mesh in the mesh container and store the passed ID3DXSkinInfo interface in the mesh container as well. This is all done inside the ID3DXAllocateHierarchy derived object's CreateMeshContainer method. We will also fetch the name of each bone stored in the ID3DXSkinInfo object and store pointers to those bones' absolute matrices in the mesh container. This gives us easy access to that information when transforming the mesh without having to traverse the hierarchy. We also retrieve the bone offset matrix for each bone from the ID3DXSkinInfo object and store them in the mesh container as well. In the end, we will have an array of bone matrix pointers and an array of their corresponding bone offset matrices ready to be sent to the UpdateSkinnedMesh method.

2. In our game loop, we animate the skeleton as usual using the animation controller (i.e. activate an animation set and call the AdvanceTime method). This will apply animation changes to the parent-relative matrices stored in each bone.

3. After calling AdvanceTime, we build the absolute (world) bone matrix for each frame by concatenating matrices as we step through the hierarchy. At the end of this stage, each bone in the hierarchy will contain an absolute world space matrix for that bone. It is these matrices that have pointers stored in the mesh container.

4. Now we call the ID3DXSkinInfo::UpdateSkinnedMesh function to transform our source mesh vertex data into a destination vertex buffer in a destination mesh. The destination vertex buffer will contain the updated world space positions of the skin's vertices. We pass this function the array of absolute bone matrices we have just updated and an array containing each bone's corresponding bone offset matrix. This function will combine each bone matrix with its corresponding bone offset matrix and use the resulting matrix to transform each vertex that is attached to that bone. The ID3DXSkinInfo object already stores the weight values, so it will manage the vertex blending calculations with little trouble.

5. We now have a destination mesh with the skin's world space vertices stored in its vertex buffer. We set the device world matrix to identity and then draw the mesh as usual -- loop through each subset, set the required textures and materials, and call DrawSubset. Remember that the destination mesh is just a regular ID3DXMesh.

Now that we know the basic steps involved in software skinning, let us look at some implementation details.

11.7.1 Storing the Skinned Mesh

Before we can render a skinned mesh we must be able to load it, and before we can do that we will need to setup some data structures to store the required information. This is what we will discuss in this section.

First, we will use the same D3DXFRAME derived structure that we used in the previous chapter. You will recall that we derived a structure from D3DXFRAME that contained an additional 4x4 matrix that to store the absolute world transform of each frame when we do our hierarchy update. We will now think of each frame as being a bone, and the frame hierarchy as the skeleton of our skinned mesh, but the core ideas remain the same.

```
struct D3DXFRAME_MATRIX: public D3DXFRAME
{
    D3DXMATRIX   mtxCombined;
};
```

The next structure that we will need to add new members to is the D3DXMESHCONTAINER. Let us first remind ourselves what the standard version of this structure looks like:

```
typedef struct _D3DXMESHCONTAINER
{
    LPTSTR              Name;
    D3DXMESHDATA        MeshData;
    LPD3DXMATERIAL      pMaterials;
    LPD3DXEFFECTINSTANCE pEffects;
    DWORD               NumMaterials;
    DWORD               *pAdjacency;
    LPD3DXSKININFO      pSkinInfo;
    struct _D3DXMESHCONTAINER *pNextMeshContainer;
} D3DXMESHCONTAINER, *LPD3DXMESHCONTAINER;
```

We will use this structure to store all of the necessary data for our skin. Unlike the previous chapter, we will now be using the pSkinInfo member to store the ID3DXSkinInfo interface that is passed to the CreateMeshContainer callback during the loading of the hierarchy. The ID3DXSkinInfo object will contain the names of all the bones used by this skin, the bone offset matrix for each of these bones, and the indices and weights describing which bones influence which vertices and to what extent. We do not have to manually create the ID3DXSkinInfo object -- it will be automatically created and populated by D3DXLoadMeshHierarchyFromX and passed to the CreateMeshContainer callback. All we have to do is store it and eventually use it to transform the mesh in our render loop. The rest of the members of this structure are used to store the ID3DXMesh (inside the MeshData member) and additional information such as materials and textures that are used by its various subsets.

Now we need to derive from this structure and add a few members of our own. For starters, we know that when we transform the model space source mesh into world space using ID3DXSkinInfo::UpdateSkinnedMesh, we will need a place to store the resulting vertices. Since we wish to maintain the original mesh data, we will add an ID3DXMesh to the mesh container called OriginalMesh. It will always store the mesh that was originally loaded and passed to the CreateMeshContainer function. Thus, we will use the mesh that is stored in the MeshData member of the mesh container as our destination mesh. MeshData will always contain the current world space transformation of the vertices and will be the mesh that we render each frame. Therefore, every time we call ID3DXSkinInfo::UpdateSkinnedMesh, the vertices from OriginalMesh will be transformed and stored in MeshData. This first new data member that we will add to our derived mesh container is shown below.

ID3DXMesh *pOriginalMesh

The next thing we have to consider is ease of access to the world matrices for each frame in the hierarchy. Recall that we need to pass this into UpdateSkinnedMesh as its first parameter. Theoretically, we could just copy the absolute bone matrices each time the hierarchy is traversed and updated, but that is cumbersome and time consuming. Instead, when we first create the mesh we will traverse the hierarchy and find all the bones used by the skin and store pointers to each of their absolute bone matrices in a bone matrix array. This array will be stored inside the mesh container so that when animation has been applied and the matrix for each bone has been updated, the mesh will have an array of pointers to these matrices. With these pointers on hand, we can build an array of bone matrices quickly that can be passed into the UpdateSkinnedMesh method. So the next new mesh container member is an array of matrix pointers:

D3DXMATRIX **pBoneMatrixPtrs

Note that this new member is an array of matrix pointers and not an array of matrices. This is very important, since we want each element in the array to point to the world matrix of each bone in the hierarchy used by this mesh. When the matrices are updated, these pointers will still point to them, so we will always have direct and efficient access to the absolute bone matrices used by this skin. They will not be invalidated when the bone matrices are recalculated.

We also know that before we use each absolute bone matrix to transform a vertex, it must be combined with the bone offset matrix first, so that transformations are performed in bone space. So in addition to our bone matrices, we must pass an array of corresponding bone offset matrices to the UpdateSkinnedMesh function. The function will automatically combine the matrices in these two arrays and use the resulting matrices to transform our skin vertices. Therefore, we will need to add another matrix array to our mesh container for the corresponding bone offset matrices. We will populate this array inside the CreateMeshContainer function (a one time process) with the bone offset matrices that we extract from the ID3DXSkinInfo object we are passed.

D3DXMATRIX *pBoneOffsetMatrices

Both the ppBoneMatrixPtrs array and the pBoneOffsetMatrices array should each have N elements, where N is the number of bones in the hierarchy used by the skin. We will see in a moment how the matrices will be stored such that pBoneOffsetMatrix[N] is the bone offset matrix for the bone stored in *pBoneMatrixPtrs[N]. This gives us a nice one-to-one mapping when it comes time to pass this data to the UpdateSkinnedMesh function.

We mentioned that the first parameter to UpdateSkinnedMesh should be an array of absolute matrices for each bone. The second parameter of course is an array of corresponding bone offset matrices. Perhaps you have already noticed the problem? Passing in the bone offset matrices is not a problem because we will already have these stored in the mesh container as an array (just as the function expects). But we do seem to have a problem with the absolute bone matrices. Right now, all we have is an array of matrix pointers, but the function expects an array of matrices.

So we will have to loop through all of the bones in the mesh container's bone matrix pointer array and copy the actual matrix data into a temporary array so that it can be passed to UpdateSkinnedMesh. Once we call UpdateSkinnedMesh, the original mesh will be transformed into the destination mesh and this combined matrix array will not be needed again until the next time we need to transform the mesh. Therefore, we will make this a global array that can be used as a temporary storage area for any skinned mesh that we are about to transform and render. Remember, these next two variables will not be part of the mesh container; they will be global variables. It is this temporary matrix array that we will pass to the UpdateSkinnedMesh function:

D3DXMATRIX *pgbl_CombinedBoneMatrices
DWORD gblMaxNumBones

Now this is where we will change the rules a bit. Since we have to loop through each element in our bone matrix pointer array and copy it into this temporary array before sending it into the UpdateSkinnedMesh function, we might as well combine each bone matrix with its corresponding bone offset matrix as we do so. Otherwise, UpdateSkinnedMesh will end up having to loop through each matrix array we pass and combine them anyway. So before calling UpdateSkinnedMesh, we will loop through each bone in our bone pointer array and combine each one with its corresponding bone offset array, storing the resulting matrices in this temporary array. As the matrices in this array are already combined, we can pass this array as the first parameter to UpdateSkinnedMesh and set the second parameter (the bone offset array parameter) to NULL. Thus, the matrix copy that we have to do is essentially free.

Our approach will be to allocate one global array that has enough elements to store the maximum number of bones used by any skinned mesh in our scene. When we are loading our skinned meshes from their X files, we will use a global variable called glbMaxNumBones to record the highest bone count so far so that we can make sure this global temporary array is large enough to accommodate any of our skinned meshes. Although this might sound complicated, it really is not -- this matrix array is just like a scratch pad where we combine each mesh's bone matrix with its corresponding bone offset matrix prior to passing it into the UpdateSkinnedMesh function. We will see it in use when we look at the code momentarily.

But first, let us have a look at our new derived mesh container:

```
struct D3DXMESHCONTAINER_DERIVED : public D3DXMESHCONTAINER
{
   ID3DXMESH   * OriginalMesh;
   D3DXMATRIX ** pBoneMatrixPtrs;
   D3DXMATRIX  * pBoneOffsetMatrices;
}
```

We now have proprietary data structures with everything we will need to store for software skinning. Populating these structures is done inside the CreateMeshContainer method of our ID3DXAllocateHierarchy derived object, called by D3DXLoadMeshHierarchyFromX for every mesh encountered in the X file. Let us next have a look at what this interface looks like, the information contained within the underlying object, and how we can use its member functions to access this information and store it in our mesh container structure. After that, we will take a look at one possible implementation of a CreateMeshContainer function to see how the mesh data is loaded and stored for software skinning.

11.7.2 The ID3DXSkinInfo Interface

For every mesh found in the X file that contains bone information, D3DXLoadMeshHierarchyFromX will create a new ID3DXSkinInfo object and pass its interface to our CreateMeshContainer callback. We will usually store this interface in the mesh container, especially in the case of software skinning where we will wish to use some of its member functions (such as UpdateSkinnedMesh). Besides having useful helper functions, it also contains vital information that we will need to retrieve. For starters, it will contain an array of all of the names of the bones in our skeleton to which vertices in the mesh are assigned. It also contains an array of bone offset matrices for each of those bone matrices. This is very important because the bone matrices themselves are stored in the hierarchy with their respective names, so this is our only means of identifying which bone offset matrix in the D3DXSkinInfo object belongs with (and should therefore be combined with) each bone matrix in the hierarchy. Therefore, one of the first things we will do with this interfaces is pair the bone offset matrices with their corresponding bones in the hierarchy. We will do this using the new matrix arrays that we added to our derived mesh container structure.

To accomplish this, we will first call the ID3DXSkinInfo::GetNumBones method to find out how many bones in the hierarchy are mapped to this mesh. Then we will implement a loop that iterates over this bone count and call ID3DXSkinInfo::GetBoneName to retrieve the name for each bone index. Once we have the name of the current bone, we will traverse our hierarchy and search for the frame with the same name. Once located, we will store a pointer to this frame's absolute matrix in our mesh container at ppBoneMatrixPtr[N] (N is the current loop counter). We will follow this with a call to the ID3DXSkinInfo::GetBoneOffsetMatrix function to return the bone offset matrix for bone N also. This matrix will be stored in pBoneOffsetMatrix[N] in our mesh container. At the end of the loop we will have a bone matrix pointer array and a bone offset matrix array in our mesh container that has a one-to-one mapping.

Before we transform the mesh we must loop through each bone in the mesh container's bone pointer array, and for the current iteration (N) we multiply *ppBoneMatrixPtr[N] by pBoneOffsetMatrix[N] to create a combined bone matrix that we store in our global array pCombinedBoneMatrix[N]. Once we have done this for each matrix, we can pass the pCombinedBoneMatrix array to ID3DXSkinInfo::UpdateSkinnedMesh function to transform our skin mesh into world space so that it is ready to be rendered.

This might sound complicated, but it can actually be done using only a few lines of code. This will be clear enough in a moment when we look at a simple example of a CreateMeshContainer implementation. But before we do that, let us first look at the member functions of the ID3DXSkinInfo interface that are applicable to software skinning. There are a few functions in this interface that are applicable only to hardware skinning, so we will postpone their coverage until later in the chapter. Since the D3DXSkinInfo object is really just an object that encapsulates all of the SkinWeights data objects found in the X file for a given mesh, most of the functions are used to simply retrieve or modify this vertex/weight/bone data.

ID3DXSkinInfo Member Functions

`HRESULT Clone( LPD3DXSKININFO *ppSkinInfo );`

Given a pre-populated ID3DXSkinInfo interface, we can use this function to clone the object. We pass in the address of an ID3DXSkinInfo interface pointer and on function return it will point to the newly created object. All of the bone name, bone offset matrix, and vertex weight data contained in the original skin info object will be copied into the clone.

`DWORD GetNumBones(VOID);`

This function returns the number of bones in the hierarchy referenced by this skin. The bone matrices themselves are not stored in this object (they are stored in the frame hierarchy) but this object does contain a list of bone names and their respective bone offset matrices. We can use the bone names to pair the bone offset matrices with their matching bone matrices in the hierarchy. In our lab projects, the value returned by this function will be used to allocate the matrix arrays we have added to our D3DXMeshContainer structure.

`LPCSTR GetBoneName( DWORD Bone );`

This function returns the name of the bone stored at the index specified by the input parameter. We will use this function when setting up our mesh container inside the CreateMeshContainer function to get the name of each bone and match it to a bone in the hierarchy. We can then store this bone matrix and its accompanying bone offset matrix in the mesh container.

`LPD3DXMATRIX GetBoneOffsetMatrix( DWORD Bone );`

This is the function we will use to retrieve the bone offset matrix for each bone in the hierarchy. Our code will first use the GetNumBones member function to find out how many bones influence this skin. This count value also defines the number of bone offset matrices (and bone names) stored in the skin info object's internal arrays. We can loop through each of these bone indices and call GetBoneName to fetch the current bone name and GetBoneOffsetMatrix to fetch the 4x4 bone offset matrix that belongs with that bone name. Once we have the bone name and bone offset matrix, we can traverse the hierarchy

to find the matching frame in the hierarchy to access its bone matrix. After we have both a pointer to the bone matrix in the hierarchy and the bone offset matrix, we can then store them in the mesh container in their corresponding data arrays (ppBoneMatrixPtrs and pBoneOffsetMatrices).

> **Note:** Writing code to find a bone in the hierarchy would be simple enough to do. But it is even easier if we use the D3DXFrameFind function. We will see this in a moment.

```
HRESULT GetBoneInfluence(DWORD Bone, DWORD *vertices, FLOAT *weights);
```

This function allows us to retrieve the indices of the vertices in the mesh that are attached to the bone specified in the first parameter, along with the weights for each of those vertices. When using software skinning, we will not have to worry about the weight data for each vertex/bone combination because this information is stored inside the ID3DXSkinInfo object. The ID3DXSkinInfo::UpdateSkinnedMesh function will automatically use the stored vertex weights to perform the vertex blending. This function would be useful if you are performing hardware vertex blending and you need to extract the weight information for each vertex and store it in the vertex structure (but there is even a helper function that does that for us as we will see later in the chapter). This function might also be useful diagnostically if you need to output or log this information.

The first parameter is the index of the bone that we would like the vertex/weight data returned for. The second and third parameters are pointers to pre-allocated arrays that should be large enough to hold the vertex index and vertex weight data. Each element in the DWORD array describes the index of a vertex in the skin that this bone is attached to. There is a corresponding weight defined in the float array describing how much that vertex is influenced by the bone matrix. The amount of memory that we must allocate for these arrays can be determined by calling the next function we will examine (GetNumBoneInfluences).

```
DWORD GetNumBoneInfluences( DWORD bone );
```

This function is used to find out how many vertices are attached to a bone. We pass in the index of the bone that we would like to enquire about and we are returned the attached vertex count. So if the bone in question influenced four vertices, the return value would be 4. We can use this value to allocate the vertex index and weight arrays passed in as the second and third parameters to GetBoneInfluence. We will not need to use this function during software skinning but it might be useful for diagnostic purposes.

```
HRESULT GetMaxVertexInfluences( DWORD *maxVertexInfluences );
```

This function can be used if you wish to enquire about the maximum number of vertices attached to a given bone in the hierarchy. We pass in the address of a DWORD which, on function return, will be filled with this value. For example, if this value was 3 on function return, then it means that at least one of our bones (but perhaps many) has three vertices attached to it and that there are no other bones that have more than this number of vertices attached to them.

```
FLOAT GetMinBoneInfluence(VOID);
HRESULT SetMinBoneInfluence( FLOAT minInfluence );
```

These functions allow us to get and set the minimum weight thresholds used to determine how much a bone matrix will contribute towards the transformation of one of its attached vertices. For example, if we set this value to 0.2 and then called UpdateSkinnedMesh, any matrices that influence a vertex with a weight less than 0.2 will not be used in the vertex blend. This might be useful if you know that you have some bones mapped to vertices with very small weights which do not influence the vertex position to any noticeable degree. You could set this threshold value so that these matrices will be ignored when transforming that vertex, speeding up the software transformation process. You will only rarely need to use this functionality (we will not use it at all in our lab projects).

```
HRESULT GetMaxFaceInfluences(LPDIRECT3DINDEXBUFFER9 pIB,
                             DWORD NumFaces, DWORD *maxFaceInfluences );
```

This function returns the maximum number of bones that affect a single triangle in the mesh. We pass in the index buffer of the mesh we are testing as the first parameter and the number of triangles in the buffer as the second parameter. The third parameter is the address of a DWORD which on function return will store the value of the maximum number of matrices that affect a single triangle in the mesh.

When performing software skinning, this information is of little significance since we are not limited to only using a few matrices per face. But when we discuss hardware skinning later in the chapter we will see that things are very different. For example, a given graphics card might only allow the setting of 6 bone matrices on the device at any given time, even though it is possible that each vertex in a triangle may be influenced by as many as 4 bones. This means that a single triangle could be influenced by 12 unique matrices and to be correctly transformed and rendered by the 3D pipeline we would need the ability to set those 12 matrices. This cannot be done on the hardware in our example so we would have to place the device in software vertex processing mode where the limitation is removed (we must have a software or mixed mode device to be able to do this). Note that the pipeline will still perform the vertex blending for us, but it will be done by the DirectX software transformation module. So we would lose the advantages of hardware T&L for that mesh. Please note that this is not the same as software skinning (which we are currently discussing) where the pipeline will not have the vertex blending render state enabled at all. In other words, when performing software skinning, the pipeline does not multi-matrix transform (i.e., vertex blend) our vertices. We are instead using a function (UpdateSkinnedMesh) to do our vertex blending outside of the pipeline. We will discuss pipeline vertex blending capabilities and hardware skinning later in the lesson.

```
HRESULT UpdateSkinnedMesh
(
    CONST D3DXMATRIX *pBoneTransforms,
    CONST D3DXMATRIX *pBoneInvTransposeTransforms,
    PVOID pVerticesSrc,
    PVOID pVerticesDst
);
```

This is the function that performs vertex blending when using software skinning. It transforms the model space vertices in the source mesh into vertex blended world space vertices in the destination mesh.

This function is called during the render loop to update the skinned mesh vertices whenever any of its bones have been animated or changed. The first parameter is an array of bone matrices (the absolute/world space frame matrices) and the second parameter is an array containing the corresponding bone offset matrices. The third parameter is the vertex buffer from the source mesh which contains the model space vertices of the skin in its reference pose (as passed into the CreateMeshContainer function by D3DXLoadMeshHierarchyFromX). The fourth parameter is the vertex buffer of the destination mesh that will receive the world space vertices and will be used to render the mesh in its current position and orientation. This function first combines each bone matrix in the pBoneTransforms array with the corresponding bone offset matrix in the pBoneInvTransposeTransforms array to generate the final world space matrix for each bone. It then multiplies each vertex with the bone matrices that influence that vertex to generate the blended vertex for the final vertex buffer. If the vertex format contains a normal, then the normals will also be blended in the same way, but without the translation portion of the matrix being used.

Recall that in our code we will allocate a third (global) matrix array called pCombinedBoneMatrices to store the combined bone matrices prior to passing them to this function. We do this because our mesh container stores an array of pointers to the bone matrices and not an array of the bone matrices themselves. In order to pass the bone matrices into this function, we would first need to copy them into a temporary array. Since we are looping through each bone anyway for copying purposes, we might as well just do the multiplication ourselves and store the result in the pCombinedBoneMatrices array. Since this global array will now hold the combined bone matrices, we can simply pass this array in as the first parameter to UpdateSkinnedMesh and set the second parameter to NULL. The function will still work perfectly; it will simply skip the matrix concatenation step that we just performed (thus making our matrix copy a cost-free operation).

11.7.3 Manual Skin Creation

It is possible to create an empty ID3DXSkinInfo and populate it programmatically or with skinning information stored in a custom file format. For example, you might have a mesh object that was not originally intended as a skin (or perhaps it was, but it was not provided in skin format). You can programmatically build your own frame hierarchy to represent the bones of the skeleton and then write some code that maps that skeleton to the mesh. Alternatively you might start with a skeleton and then procedurally build a skin to fit around it. Once done, you could create an empty ID3DXSkinInfo and populate it with the information for each bone, such as its name in the hierarchy, which vertices are influenced by that bone, and the bone weights. You would also need to calculate the bone offset matrix for each bone (which we learned how to do earlier) and store those as well.

The ID3DXSkinInfo interface has three 'Set..' functions which can be used to populate an empty D3DXSkinInfo object. Before we look at these, let us first talk about the global D3DX function that can be used to create an empty D3DXSkinInfo object. Although you will not need to use these functions when you are loading your data from X files, they are extremely useful if you are building your skinned meshes by hand. While we will not spend time in this chapter doing this, it is an important technique to learn. So in the next chapter, we will spend a good deal of time examining how to construct a skinned mesh manually to create some interesting animating trees for our outdoor environments. For now, we will just get an overview of the functionality involved.

```
HRESULT D3DXCreateSkinInfoFVF(DWORD numVertices, DWORD FVF,
                              DWORD numBones,
                              LPD3DXSKININFO* ppSkinInfo );
```

Although ID3DXSkinInfo does not store the actual vertex data (this is stored in a separate ID3DXMesh), the first parameter should contain a value describing the number of vertices in the mesh that we intend to use as the skin and the second parameter should be the FVF flags for the vertex structure we intend to use. This is important, because the UpdateSkinnedMesh function will need to know if the vertex contains a normal so that the normal is also blended when the vertex is transformed. The third parameter is the number of bones that this skin will need to be mapped to (i.e. the number of bones in the hierarchy for which we intend to attach a vertex). The D3DXCreateSkinInfoFVF function will use this number to allocate an internal bone name array and a bone offset matrix array of the correct size. The fourth parameter is the address of an ID3DXSkinInfo interface pointer which on successful function return will point to a valid interface to an empty D3DXSkinInfo object.

Once we have created an empty ID3DXSkinInfo object we need to populate it with data -- filling in the name of each bone, the vertex indices and weights for that bone and the bone offset matrix for that bone.

```
HRESULT SetBoneName( DWORD BoneNumber, LPCSTR BoneName );
```

This function is used to set the name of a bone. The first parameter is the index of the bone we wish to set the name for. For a newly created object, this will start off at 0 and increase as we add each bone's information. This index should never be greater than or equal to the numBones parameter passed into

the D3DXCreateSkinInfoFVF function. The BoneName we pass in should also match the name of one of the bones in the hierarchy.

```
HRESULT SetBoneInfluence(DWORD Bone, DWORD numInfluences,
                         CONST DWORD *vertices, CONST FLOAT *weights);
```

Once you have set the bone name, you have to tell ID3DXSkinInfo which vertices in the skin mesh are attached to this bone and the weight at which this bone should be used to influence each of them. The first parameter is the index of the bone we are setting the vertex mapping for. This should be followed by a DWORD parameter describing how many vertices in total will be influenced by this bone. As the third parameter we pass in an array of DWORDs where each element in the array describes the index of a vertex in the skin that will be influenced by this bone to some degree. The fourth parameter is where we store the matching weights for each vertex index specified in the previous parameter.

```
RESULT SetBoneOffsetMatrix( DWORD Bone,LPD3DXMATRIX pBoneTransform );
```

This function allows us to set the bone offset matrix for each bone. This matrix can be calculated by traversing the reference pose hierarchy (concatenating as we go) to the bone in question and then taking the inverse of the concatenated matrix.

At this point we have a through enough understanding of what the ID3DXSkinInfo interface contains and how to extract that data to store it in the mesh container to move forward. We also know how to manually create and populate an ID3DXSkinInfo if we need to fill it with some other non-X file data. Finally, it is worth remembering that, in the software skinning case at least, once we have extracted this information we do not just want to release the ID3DXSkinInfo interface. Instead we want to store it in the mesh container because we will use its UpdateSkinnedMesh function to transform the vertices of the skin into world space.

Let us now see how all of this theory can be put into practice by looking at a simple CreateMeshContainer implementation.

11.7.4 The CreateMeshContainer Function

In Chapter Nine we learned how to derive a class from the ID3DXAllocateHierarchy interface and implement its CreateMeshContainer function. This function will be called for each mesh contained in the X file. If the mesh is a skinned mesh, then the function will be passed an ID3DXMesh containing the skin (this is just a regular mesh) and an ID3DXSkinInfo interface that will contain the bone to vertex mapping information. Our function will need to store the mesh and the ID3DXSkinInfo interface pointer in the mesh container and will need to extract the bone offset matrices and store them as well. Our other responsibility is to find the matching bone matrices in the hierarchy and store pointers to them in our mesh container. Let us now have a look at the code to a typical function that would do all of this.

In this next example we will not show the processing of the material or texture data since we already know how to do this. The more complete function is of course fully implemented in the source code that accompanies this chapter. It is important to note that this implementation of the CreateMeshContainer function is for the software skinning case only. We will look at how this function will need to be implemented for the hardware skinning cases later (in our lab projects we will write a single function that handles all cases).

The function starts by allocating a new mesh container structure and getting a pointer to the ID3DXMesh passed into the function. This mesh will contain the skin in its model space reference pose.

```
HRESULT CAllocateHierarchy::CreateMeshContainer
       ( LPCTSTR Name, LPD3DXMESHDATA pMeshData, LPD3DXMATERIAL pMaterials,
         LPD3DXEFFECTINSTANCE pEffectInstances, DWORD NumMaterials,
         DWORD *pAdjacency,
         LPD3DXSKININFO pSkinInfo, LPD3DXMESHCONTAINER *ppNewMeshContainer )
{
    D3DXMESHCONTAINER_DERIVED *pMeshContainer = NULL;
    UINT iBone, cBones;
    LPDIRECT3DDEVICE9 pd3dDevice = NULL;
    LPD3DXMESH pDestinationMesh = NULL;
    *ppNewMeshContainer = NULL;

    // Get a pointer to the mesh of the skin we have been passed
    pDestinationMesh = pMeshData->pMesh;

    // Allocate a mesh container to hold the passed data.
    // This will be returned from the function
    // where it will be attached to the hierarchy by D3DX.
    pMeshContainer = new D3DXMESHCONTAINER_DERIVED;
    memset(pMeshContainer, 0, sizeof( D3DXMESHCONTAINER_DERIVED ));
```

Next we copy over the name of the mesh passed into the function and store it in the mesh container. We also get a pointer to the device object to which the mesh belongs as we will need it in a moment.

```
    // If this mesh has a name then copy that into the mesh container too.
    if ( Name ) pMeshContainer->Name = _tcsdup( Name );

    pDestinationMesh->GetDevice(&pd3dDevice);
```

The next section of code is optional; it is not specific to skinned meshes and applies to meshes of any kind. It is shown here for completeness. It tests to see if the input mesh has vertex normals defined. If not, then in this example we will assume that they are desired and clone the mesh to create a new skin that has room for vertex normals. We store the cloned result in the mesh container's MeshData member. After cloning, we create normals using the very handy D3DXComputeNormals helper function.

```
    // if no normals exist in the mesh, add them ( we might need to use lighting )
    if (!(pDestinationMesh->GetFVF() & D3DFVF_NORMAL))
    {
        pMeshContainer->MeshData.Type = D3DXMESHTYPE_MESH;

        // Clone the mesh to make room for the normals
        pDestinationMesh->CloneMeshFVF( pMesh->GetOptions(),
```

```
                                        pMesh->GetFVF() | D3DFVF_NORMAL,
                                        pd3dDevice,
                                        &pMeshContainer->MeshData.pMesh );

         pDestinationMesh = pMeshContainer->MeshData.pMesh;

        // Now generate the normals for the pmesh
        D3DXComputeNormals( pDestinationMesh, NULL );
    }
```

In the above code, we clone the mesh and divert the pDestinationMesh pointer to point at the newly created mesh interface. Remember, this originally pointed at the mesh passed into the function by D3DX which will no longer be used (because it did not have normals). We did not increment the reference count of the mesh when we assigned this pointer and thus do not need to release it here (it was a temporary pointer assignment). When this function returns, D3DX will release its hold on the original mesh interface causing it to be unloaded from memory. This is exactly what we want since we will prefer to use the newly cloned mesh instead.

If the mesh already contained normals, then we will use this mesh as is and simply store the passed mesh in the mesh container's MeshData member. We are careful to increment the mesh's reference count so that it is not unloaded from memory on function return when D3DX releases its claim on the object.

```
    else  // if normals already exist, just add a reference
    {
        pMeshContainer->MeshData.pMesh = pDesinationMesh;
        pMeshContainer->MeshData.Type = D3DXMESHTYPE_MESH;
        pDestinationMesh->AddRef();
    }
```

At this point in the function the mesh has been copied into the mesh container and contains vertex normals -- so far we have done nothing that we would not do for a standard mesh.

The next section of code is where we identify whether or not this is a skinned mesh. If the pSkinInfo parameter is not NULL, then this is indeed a skinned mesh and we will need to fill out the new members of our mesh container structure. Before we do this, we would probably store the textures and materials as shown in previous lessons, but we will skip that step for this example to keep things simple.

If this is a skinned mesh then we will copy the passed ID3DXSkinInfo interface pointer into the mesh container and make sure that we increment the reference count (we do not want the object prematurely destroyed when the function returns).

```
    // If there is skinning information, save off the required data
    // and then set up for skinning because this is a skinned mesh.
    if (pSkinInfo != NULL)
    {
        // first save off the SkinInfo and original mesh data
        pMeshContainer->pSkinInfo = pSkinInfo;
        pSkinInfo->AddRef();
```

The next step is to find out how many bones this skin is influenced by, using the ID3DXSkinInfo interface GetNumBones function. Once we have this value we know how large to make the mesh container's bone offset matrix array. After we allocate the bone offset matrix array, we loop through each bone and extract its bone offset matrix using the ID3DXSkinInfo::GetBoneOffsetMatrix member function and store the matrix in the mesh container's array.

```
        // We now know how many bones this mesh has
        // so we will allocate the mesh containers
        // bone offset matrix array and populate it.
        NumBones = pSkinInfo->GetNumBones();
        pMeshContainer->pBoneOffsetMatrices = new D3DXMATRIX  [NumBones];

        // Get each of the bone offset matrices so that
        // we don't need to get them later
        for (iBone = 0; iBone < NumBones; iBone++)
        {
             pMeshContainer->pBoneOffsetMatrices[iBone] =
           *(pMeshContainer->pSkinInfo->GetBoneOffsetMatrix(iBone));
        }
```

You might assume that we should now set up the mesh container's ppBoneMatrixPtrs array so that we can store all of the pointers to the absolute bone matrices in the hierarchy. However, at this point the hierarchy has not yet been fully created, so this is something that we will have to do after we have loaded the entire hierarchy and the D3DXLoadMeshHierarchyFromX function has returned program flow back to our application.

What we can do now though is check how large our temporary global combined matrix array is going to be because it needs to be able to hold enough matrices to accommodate the skinned mesh that uses the largest number of bones. So we check the current size of this global array (which will initially be allocated to a small default size) and if it is too small to contain the number of bones used by the mesh we are loading, we have found a new largest bone count and we resize the array. After all skinned meshes have been loaded, this array will be large enough to hold the bones of any skinned mesh in the scene. Recall that this global array is used by our application as a scratch pad prior to transforming a skinned mesh. It will be used to hold an array of concatenated bone and bone offset matrices for the mesh which will be passed into the ID3DXSkinInfo::UpdateSkinned Mesh function and used to multi-matrix transform the vertices.

```
       // Resize the global scratch array if this mesh
       // has more bones then any others previously loaded
       if ( gblMaxNumBones < NumBones)
        {
            gblMaxNumBones = NumBones;

            // Allocate space for blend matrices
            delete [] pgbl_CombinedBoneMatrices;
            pgbl_CombinedBoneMatrices  = new D3DXMATRIX [ NumBoneMatricesMax ];
        }
```

At this point our mesh container stores the model space reference pose mesh, the ID3DXSkinInfo interface, and all of the bone offset matrices. As discussed earlier, our preference will be to use the

MeshData member of the mesh container to store our destination mesh (i.e., the render-ready world space mesh), but right now it currently contains the original model space vertex data (i.e., the source mesh). So we will clone the mesh and store a pointer to the clone in the pOriginalMesh member that we added to our mesh container. Unlike its MeshData sibling, this mesh will never be overwritten and will always contain the model space mesh reference pose. This is the mesh whose vertex buffer will be passed into UpdateSkinnedMesh as the source vertex buffer. The transformed vertices will be copied into the destination mesh stored in the MeshData member of the mesh container for later rendering.

```
       // Finally clone the mesh so that we now
       // have a copy of it stored in the 'OriginalMesh' member
       // of the mesh container.
      // This is the mesh that will be the source mesh in transformation
       pDestinationMesh->CloneMeshFVF( D3DXMESH_MANAGED,
                                       pMeshContainer->MeshData.pMesh->GetFVF(),
                                       m_pd3dDevice,
                                      &pMeshContainer->pOriginalMesh );
  }
```

As it turns out, these are the only steps we will need to take in our CreateMeshContainer function when we are creating a mesh for software skinning.

Finally, we assign the passed mesh container pointer to point at our newly created mesh container so that when the function returns, D3DXLoadMeshHierarchyFromX will have access to it and will be able to attach it to the hierarchy.

```
    // Return the transformation
    *ppNewMeshContainer = (D3DXMESHCONTAINER *)pMeshContainer;
    pMeshContainer = NULL;

    pd3dDevice->release();
    return D3D_OK;
}
```

11.7.5 Fetching the Bone Matrix Pointers

After we have loaded our scene using D3DXLoadMeshHierarchyFromX, any skinned meshes that were contained inside the X file are now in their respective mesh containers in the hierarchy. However, our mesh container also has a new member called ppBoneMatrixPtrs which stores pointers to each absolute bone matrix for easy access after hierarchy changes. After we have finished loading the hierarchy, our next task will be to allocate this array so that we can populate it with the relevant matrix pointers. Our scene initialization code will usually look something like the code shown next. Note that this code assumes that CAllocateHierarchy is the name of our ID3DXAllocateHierarchy derived class and that pDevice is a pointer to a valid Direct3D device object.

```
D3DXFRAME  pFrameRoot;
ID3DXAnimationController *pAnimController;
CAllocateHierarchy Alloc;
D3DXLoadMeshHierarchyFromX("MyFile.x", D3DXMESH_MANAGED,
```

```
                              pDevice, &Alloc, NULL, &pFrameRoot,
                             &m_pAnimController);

SetupBoneMatrixPointers ( pFrameRoot , pFrameRoot );
```

The SetupBoneMatrixPointers function will be a simple recursive function that we write to finalize our mesh container data. In our actual code for this lesson we will store each loaded hierarchy inside a separate CActor class, for ease of data management. So if we loaded three X files, each one containing a separate skinned mesh, we would have three CActor objects in our application -- each representing a different character with its own root frame and its own animation controller. We will also make the SetupBoneMatrixPointers function we are about to discuss a member function, but for now we will forget about this encapsulation and just look at the techniques involved. We will call the following function for each skeletal hierarchy that we load:

```
HRESULT SetupBoneMatrixPointers(LPD3DXFRAME pFrame , LPD3DXFRAME pRoot)
{
    if (pFrame->pMeshContainer != NULL)
         SetupBoneMatrixPointersOnMesh ( pFrame->pMeshContainer, pRoot );

    if (pFrame->pFrameSibling != NULL)
         SetupBoneMatrixPointers ( pFrame->pFrameSibling , pRoot  ) ;

    if (pFrame->pFrameFirstChild != NULL)
         SetupBoneMatrixPointers ( pFrame->pFrameFirstChild , pRoot );

    return S_OK;
}
```

This function recursively traverses each frame (bone) in the hierarchy and tests to see if the frame has a mesh container attached to it. If it does, then it calls the SetupBoneMatrixPointersOnMesh function to set up the matrix pointers in the mesh container. We will look at that function in a moment. After SetupBoneMatrixPointers has returned control back to the caller, all of the mesh containers which store skins will have had their ppBoneMatrixPtrs array allocated and populated with pointers to each absolute bone matrix in the hierarchy. Notice that SetupBoneMatrixPointers passes the root frame pointer down the tree as well so that it is accessible in the SetupBoneMatrixPointersOnMesh function. This allows us to search the hierarchy starting at the root for a specific bone.

Let us now examine the SetupBoneMatrixPointersOnMesh function.

```
HRESULT SetupBoneMatrixPointersOnMesh( LPD3DXMESHCONTAINER pMeshContainerBase ,
                                       D3DXFRAME *pRootFrame  )
{
    UINT iBone, NumBones;
    D3DXBone *pFrame;

    D3DXMESHCONTAINERDERIVED *pMeshContainer =
                                    (D3DXMESHCONTAINER_DERIVED*)pMeshContainerBase;

    // If this is a skinned mesh then setup its bone matrix pointers
```

```
    if (pMeshContainer->pSkinInfo != NULL)
    {
        NumBones = pMeshContainer->pSkinInfo->GetNumBones();
        pMeshContainer->ppBoneMatrixPtrs = new D3DXMATRIX*[cBones];

        for (iBone = 0; iBone < NumBones; iBone++)
        {
            pFrame = (D3DXBone*)D3DXFrameFind( pRootFrame,
                                pMeshContainer->pSkinInfo->GetBoneName(iBone));

            pMeshContainer->ppBoneMatrixPtrs[iBone] = &pFrame->mtxCombined;
        }
    }

    return S_OK;
}
```

The first thing this function does after casting the mesh container to our derived D3DXMESHCONTAINER_DERIVED structure is test to see if the ID3DXSkinInfo pointer is set to NULL in the mesh container. If not, then this mesh container contains a skin and we retrieve the number of bones that the mesh uses (just as we did in CreateMeshContainer). This value is used to allocate the container's ppBoneMatrixPtrs array to hold that many matrix pointers. Next, we loop through each bone stored in the ID3DXSkinInfo object and retrieve its name so that we can use the D3DXFrameFind function to search the hierarchy (starting at the root) for a frame with a matching name. Once we have a pointer to this frame, we store a pointer to its absolute matrix in the corresponding element in the ppBoneMatrixPtrs array. Remember, these absolute matrices will be rebuilt every time the hierarchy is updated. So this array provides fast access to the matrices after modifications have been made without have to perform a traversal of the tree.

We now have the absolute bone matrix pointers stored in the mesh container in exactly the same order that the bone offset matrices were stored in ID3DXSkinInfo. This provides a one-to-one mapping between pBoneOffsetMatrices and ppBoneMatrixPtrs in the mesh container for easy access later on.

11.7.6 Animating the Skeletal Hierarchy

Skeletal hierarchy animation will be no different from the animation techniques we studied in Chapter Ten. We simply use the animation controller interface to set and activate mixer track animation sets and then call the AdvanceTime method to run the process. After the relative matrices of the hierarchy (i.e. the skeleton) have been updated by the controller, we will build the absolute matrices in the hierarchy by traversing through the structure, combining relative matrices as we go. When our traversal is complete, each bone in the skeleton will have its absolute world space position and orientation stored in its mtxCombined member. If the frame is being used as a bone for a skin, a pointer to this combined matrix will be stored in the mesh container's ppBoneMatrixPtrs array.

The following code shows how a function could be called to update the animation of the bone hierarchy, which is immediately followed by the call to UpdateFrameHierarchy (which traverses the hierarchy and calculates the combined frame matrices).

```
void UpdateAnimation ( D3DXMATRIX matWorld, float m_fElapsedTime )
{
     if ( m_pAnimController != NULL )
          m_pAnimController->AdvanceTime(m_fElapsedTime);

     UpdateFrameMatrices(m_pFrameRoot, &matWorld);
}
```

You can see that there is nothing new here at all. We pass in the world matrix that we will use to position and orient the bone hierarchy and the updated time in seconds that is used to update the animation controller's internal timer. We will actually have a function like this as part of our CActor class so that we can individually update each skinned mesh in our scene. Nevertheless, do not forget that it is possible for multiple skinned meshes to be stored in a single hierarchy. In that case, we would be updating the animation and position of the entire hierarchy stored in a specific actor using the above code.

11.7.7 Transforming and Rendering the Skin

After we have applied skeletal animation and updated the absolute matrix for every bone in the hierarchy, we are ready to traverse the hierarchy and render any meshes that it contains. The hierarchy traversal is no different from the previous lessons -- we simply traverse the hierarchy and render any mesh containers we find (visibility testing preferably included). However, before we render a mesh container, we will want to see if it is a skinned mesh or not. If it is not, then we will render the mesh just as we did before. However if the mesh is a skinned mesh, then we will need to call ID3DXSkinInfo::UpdateSkinnedMesh to transform and blend the vertices from the source mesh into world space and store them in the destination mesh for rendering.

We will not bother showing the code that traverses the hierarchy and searches for mesh containers to render since we covered this in earlier lessons and it remains unchanged. The function we will look at is the one that renders each mesh container, called during hierarchy traversal for every mesh container found in the hierarchy. The function in this example is passed a pointer to the mesh container to be rendered and a pointer to the frame which owns the mesh container. The owner frame is important if this is not a skinned mesh because this frame's combined matrix will be the matrix we wish to use as the world matrix to render the mesh.

The first thing this function should do is check the mesh container's ID3DXSkinInfo interface pointer to see if it is NULL, because this informs the function whether the stored mesh is to be used as a skin. If not, then the mesh can be rendered normally. If it is a skin then additional steps must be taken.

```
void DrawMeshContainer(  LPD3DXMESHCONTAINER pMeshContainerBase ,
                         D3DXFRAME pFrameBase  )
{

    D3DXSkinContainer* pMeshContainer = ( D3DXSkinContainer* ) pMeshContainerBase;
    D3DXBone *pFrame = (D3DXBone*)pFrameBase;

    // first check for skinning
```

```
    if (pMeshContainer->pSkinInfo != NULL){
```

If we get into this code block then the mesh container stores a skin. When this is the case, the first thing we do will be to set the world matrix to an identity matrix, since we will not require the pipeline to transform our vertices into world space. We will do this manually using software vertex blending. We also get the number of bones used by the mesh.

```
            D3DXMATRIX  Identity;
            DWORD          NumBones  = pMeshContainer->pSkinInfo->GetNumBones();
            DWORD          i;
            PBYTE            pbVerticesSrc;
            PBYTE            pbVerticesDest;

            // set world transform
            D3DXMatrixIdentity(&Identity);
            m_pd3dDevice->SetTransform(D3DTS_WORLD, &Identity);
```

Now we need to loop and combine each absolute bone matrix used by this mesh with its corresponding bone offset matrix. We will store the concatenated result in our global temporary matrix array.

```
           // set up bone transforms
            for ( i = 0; i < NumBones; ++i)
            {
                D3DXMatrixMultiply
                (
                    &pgbl_CombinedBoneMatrices[i],
                    &pMeshContainer->pBoneOffsetMatrices[i],
                    pMeshContainer->ppBoneMatrixPtrs[i]
               );
       }
```

We now have an array of matrices to use for transforming the vertices from the source mesh into the destination mesh. Thus, we lock the vertex buffers in both the source and destination meshes for access to the memory.

```
       pMeshContainer->pOriginalMesh->LockVertexBuffer(D3DLOCK_READONLY,
                                                       (LPVOID*)&pbVerticesSrc);
       pMeshContainer->MeshData.pMesh->LockVertexBuffer(0,
                                                       (LPVOID*)&pbVerticesDest);
```

We now pass the pointers for both vertex buffers into the UpdateSkinnedMesh function. We also pass in the combined Bone/BoneOffset matrices we just stored in the temporary global array. When the function returns, the destination mesh in the mesh container will store the new world space blended vertex data for the skin in its current position (based on its current skeleton).

```
     // generate skinned mesh
     pMeshContainer->pSkinInfo->UpdateSkinnedMesh( pgbl_CombinedBoneMatrices, NULL,
                                                   pbVerticesSrc, pbVerticesDest);
```

Note that the second parameter to the above function is supposed to be a pointer to an array of bone offset matrices, but we passed in NULL. As discussed earlier, we decided to combine the matrices

ourselves in order to handle the matrix copy that would have been necessary if we wanted to pass the matrix arrays in separately (because our mesh container stores matrix pointers, not matrices). UpdateSkinnedMesh will recognize that the bone offset array parameter is NULL and will therefore skip the concatenation process that we just performed ourselves.

We can now unlock the two vertex buffers.

```
            pMeshContainer->pOrigMesh->UnlockVertexBuffer();
            pMeshContainer->MeshData.pMesh->UnlockVertexBuffer();
```

At this point, the mesh container now has the updated world space vertex data for the skin stored in the MeshData member (our destination mesh) so we can proceed to render this mesh as we would any other mesh. Below we see a call to a function called DrawMesh, which we can imagine would just loop through each of the mesh subsets, set any relevant textures and materials, and then call the DrawSubset function until the mesh was rendered in its entirety. The destination mesh is just a regular mesh after all and can be rendered using all of the standard techniques.

```
            / / render the mesh
            DrawMesh ( pMeshContainer->MeshData.pMesh )
    }
```

If this mesh container did not store a skinned mesh, then we will just set the world matrix to the combined matrix of its owner frame and render it (as discussed in previous lessons).

```
    else
    {
          IDirect3DDevice9 * pDevice;
          pMeshContainer->MeshData.pMesh->GetDevice(&pDevice);
          pDevice->SetTransform(D3DTS_WORLD, &pFrame->mtxCombined);
          DrawMesh(pMeshContainer->MeshData.pMesh)
          pDevice->Release();

    }  // end if this is not skinned mesh

} // end function
```

11.7.8 Software Skinning Summary

When we break it down into its separate parts, software skinning is really quite simple. We have seen that we can load a skeleton from an X file using the familiar D3DXLoadMeshHierarchyFromX and we now know that the skeleton is simply a standard frame hierarchy, where each frame is considered to be a bone. We also know how to modify our CreateMeshContainer function to support the loading of skinned mesh data from an X file. We saw that this function is passed a standard mesh containing the model space vertices of the mesh in its reference pose and an ID3DXSkinInfo interface which tells us which frames in the hierarchy are used by the mesh as bones. Animation was also quickly taken care of since the skeleton is treated in exactly the same way as any normal frame hierarchy.

Finally, we saw that skinned mesh rendering requires a few additional steps, but is also straightforward enough. We use the ID3DXSkinInfo::UpdateSkinnedMesh function to convert the model space skin vertex data into world space vertex data using vertex blending. We pass this function an array of bone and bone offset matrices along with our source mesh vertices and a destination vertex buffer that will receive the transformation results. The ID3DXSkinInfo object will manage the entire transformation process using the bone weights stored internally. It can do this because the ID3DXSkinInfo object contains all the vertex weights for each influential bone that was stored in the X file. As discussed earlier, these weights are used to scale the contribution of bones on one of its assigned vertices.

Once we have the world space vertex data in the destination mesh, we can simply set the world matrix of the device to an identity matrix and draw the mesh subsets as we normally would.

In the workbook that accompanies this chapter you will see that code similar to the sample code shown in this textbook has been implemented inside our CActor class. We will implement both software skinning and two different types of hardware skinning techniques in the code, so be sure to focus on the software skinning technique for now. We will begin to tackle the hardware techniques in the next section.

Software Skinning Advantages

- Very easy to understand and implement.
- Requires no hardware support and will therefore work on any system.
- There is no limit to how many bones a single vertex can be attached to because all of the bone/weight information is stored in the ID3DXSkinInfo object. The only limits we face are more practical: the memory taken up by the bone/vertex mapping information and the speed at which the vertices can be transformed by the CPU.
- Because the transformation is done in software, software skinning does not affect the way we batch render our primitives. This allows us to continue to batch by states such as textures and materials for optimal performance. This is not true for hardware skinning; we will be forced to batch by bone contributions as the primary key (discussed later).

Software Skinning Disadvantages

- Often considerably slower than hardware skinning techniques because vertices are transformed in software inside the UpdateSkinnedMesh method of the ID3DXSkinInfo interface. With dedicated hardware skinning, the vertices are multi-matrix transformed in the DirectX pipeline (by the GPU on a T&L card). As we will see however, non-indexed hardware skinning (unfortunately, the more commonly supported hardware skinning technique) can often suffer a performance hit as well due to less than ideal batching requirements.

11.8 DirectX Skinning II: Non-Indexed Skinning

The DirectX fixed-function pipeline provides two skinning methods that can take advantage of available 3D hardware support for vertex blending. It is worthy of note that the software skinning technique we have just discussed is not one of these techniques, since it was not performed in the DirectX pipeline. Software skinning simply sent a regular mesh to be transformed and rendered by the pipeline in the usual way; the fact that this mesh was being used as a skin was of no significance to the pipeline. This was because we transformed the vertices into world space manually with the help of the ID3DXSkinInfo interface. When it came time to render the skin, we simply handed it off to the pipeline as a regular mesh (albeit containing world space vertices). The pipeline was not aware that the vertices were transformed according to some skeletal pose or how they ended up in the destination mesh. So it is very important to remember, as we move forward, that the software skinning technique previously discussed was *not* performed in the T&L pipeline.

There are two geometry blending techniques that are integral to the pipeline. They can be invoked as an alternative to software skinning to accelerate the skinning process in hardware. These techniques are referred to as **non-indexed skinning** and **indexed skinning**. The latter is the more efficient of the two, but support is not as widely available, especially on older T&L graphics hardware. However, even if hardware support is not available for either of these techniques, we can still use the pipeline's skinning techniques by rendering the mesh using software vertex processing. This will of course mean that the vertex blending is carried out in the software module of the vertex transformation pipeline and thus is not going to be as fast. But the important point is that both techniques will work on all systems even when no hardware support is available. The software vertex blending module of the DirectX pipeline is still quite efficient, so this is a good fallback for us even in commercial applications.

You should note the distinction between software skinning as discussed previously and the pipeline skinning techniques performed using software vertex processing. As mentioned, in software skinning the pipeline plays no part in the generation of the world space vertex transformations for the skin. But when using either indexed or non-indexed pipeline skinning, we do not have to transform the vertices of the skin from model to world space ourselves. We simply pass the skin to the pipeline as model space vertex data and the pipeline will multi-matrix blend the vertices into world space for us. If hardware support is available, then the GPU will be utilized to perform this geometry blending with great speed and efficiency. If hardware support is not available, the pipeline can still perform the blending transformations for us using its own software transformation module.

If we intend to utilize the pipeline's vertex blending module on a system that does not support hardware acceleration, we will need to place the device into software vertex processing mode prior to rendering the skin so that the software module can be utilized by the pipeline. This also means that the mesh that contains the skin will need to be created with the D3DXMESH_SOFTWAREPROCESSING flag so that the software module of the pipeline can be allowed to work with its vertices. This brings other considerations to the fore. We know from our discussions in Chapter Three that in order for the pipeline to be able to perform software vertex processing, we must either create a software device or a mixed-mode device. This contrasts with the kind of device we would usually be striving for -- either a hardware device or the even more efficient PURE device. We cannot use software vertex processing with the latter two device types, so it should be obvious that if we intend to use the pipeline skinning techniques

and we want our application to work on an end user system that does not have hardware support for vertex blending, ideally we will want to create a mixed-mode device. This will allow us to render of all our regular geometry with the device set to hardware processing mode (so that the vertex data is transformed and lit by the GPU) and then switch to software processing mode for our chosen pipeline skinning technique. Although the default state of a mixed-mode device is hardware vertex processing mode, if the device had previously been placed into software vertex processing mode, we would want to place it back into hardware mode prior to rendering our regular meshes for maximum speed. To do so we would use the following function call:

```
pDevice->SetSoftwareVertexProcessing(FALSE);
```

When the time comes to render our skinned meshes (and no hardware support exists), we can place the mixed mode device into software mode as follows:

```
pDevice->SetSoftwareVertexProcessing(TRUE);
```

Anything we render from this point on will use the DirectX software transformation pipeline. While performance will not be as good, we have given ourselves the option of using the pipeline skinning techniques even when hardware support for vertex blending is absent on the current system

Of course, in order to switch between hardware and software vertex processing techniques you will need to have created a mixed-mode device. If you had created a hardware device or a PURE device, then software vertex processing could not be invoked and the pipeline would fail to render the skin on a device that had no hardware support.

> **Note:** Be careful not to set the vertex processing mode to software for all of your rendering (even on a mixed-mode device). Once software vertex processing is enabled, any T&L acceleration that the 3D card has to offer will be ignored and all vertices rendered from that point on (until software vertex processing is disabled) will be transformed and lit in software. This will incur a significant performance penalty if you use it to render your entire scene rather than just the meshes that require software emulation to account for the lack of hardware support.

11.8.1 Why use software skinning at all?

If the DirectX pipeline can perform the vertex blending in software when no hardware support is available, then why would we ever need to use the software skinning technique we discussed in the previous section? The answer will become clearer as we discuss the semantics of the DirectX transformation pipeline with respect to vertex blending, but for starters, we know that with software skinning, we are not limited by how many bones are allowed to influence a single vertex. This is because the weights for each vertex for a given bone are stored inside the ID3DXSkinInfo object and are used when we manually transform the mesh using UpdateSkinnedMesh. However, when using the pipeline to perform vertex blending, we do not have the luxury of storing elements such as vertex weights in external data objects like ID3DXSkinInfo. Once we call DrawPrimitive, the model space vertices of the skin are sent off into the pipeline and from that point forward things are pretty much out of our hands. When the pipeline is performing vertex blending, we have to pass the weights in the vertex

structure itself. This is how the pipeline (and hopefully the GPU, if hardware support is available) is informed as to how strongly each currently set world matrix is to influence the vertex being transformed.

In a few moments we will look at how to store the weight values in the mesh vertices as well as how to set multiple world matrices (bone matrices) on the device. The important point right now is that there is a limit on how many weights can be stored in a vertex. This is because vertices need to be compact packets of information that can be passed over the bus at a reliably decent speed and stored efficiently in either local or non-local video memory. Therefore, DirectX limits the number of weights that we can store and use in a vertex to 3 in the non-indexed skinning technique. This will mean that a single vertex can, at most, be influenced by four matrices. Why four? As it happens, the pipeline expects the combined weights stored in the vertices to always add up to 1.0, so if we have three weights stored in a vertex, the pipeline can calculate the fourth weight by summing the first three and subtracting from 1.0. This clever design decreases the memory footprint of vertices in precious video memory and lowers the amount of subsequent bus traffic.

Weight4 = 1.0 – (Weight1 + Weight2 + Weight3)

Although four weights per vertex might not sound like much, it is generally more than adequate given how most skinned meshes are constructed and animated. Unfortunately, the situation is quite a good deal worse when we use non-indexed vertex blending. You will see in a moment how we can set up to four world (i.e. bone) matrices on the device. That is, before a vertex is sent to the pipeline, we will need to set the bone matrices that influence it. The weights in the vertices match a corresponding matrix; the pipeline will use the first weight defined in the vertex to weight the contribution of the first currently set world matrix, the second weight will be used to weight the contribution of the second currently set world matrix, and so on.

However, we know that the vertex blending pipeline is invoked after we have called the DrawPrimitive function (or the DrawSubset wrapper function), so the smallest entity we will be rendering will be at least one triangle. We do not render one vertex at a time, but rather one triangle at a time, so it is only between DrawPrimitive calls that we can change states -- like setting different world matrices. As a result, when using non-indexed blending, not only are we are limited to a maximum of four matrices per vertex, but consequently, we are limited to four matrices *per subset*.

This last point has a real impact on our ability to batch render effectively. Since we can only change matrices between draw calls, our ability to batch render triangles has been greatly reduced. We will now need to attribute sort our mesh not only by textures and materials, but primarily by bone (matrix) contributions. This implies re-ordering the mesh triangles such that all triangles that use the same four bones will belong to the same subset. This can greatly reduce the number of triangles that can exist in a single subset and therefore greatly reduce the number of triangles in the skinned mesh that we can render with a single call to DrawPrimitive. For example, a typical non-skin mesh might have 20 triangles that use the same texture and material and usually we would attribute sort the mesh such that all of these triangles would belong to a single subset. However, in a skin mesh, each one of these triangles might be attached to a different combination of 4 bones. While this is probably an extreme example, the point is that it would cause not one, but twenty subsets to be created, each with a single triangle and each requiring its own DrawPrimitive call. Again, we have to batch by bone because we will need to set the bone matrices on the device before we render a given subset.

As if things do not sound bad enough, three weights (four matrices) is the maximum that the DirectX pipeline supports, so we will be able to use all three weights if we are using software vertex processing. However, if we want the pipeline to take advantage of hardware support for vertex blending, then we may hit another wall -- the graphics hardware might not support all four matrix blends. In some cases only two or three matrix blends are supported. When this is the case, the mesh will have to be modified so that only the supported number of weights is used in each vertex. This would usually involve having to step through the weight/bone information, removing less influential bones from attached vertices. The result is that the skin might not animate as nicely as the artist had intended. If a given vertex was assigned to four bones by the artist, but the current hardware only supports two bones, two bones would need to be detached from this vertex and not used. The vertex would now store only one weight value to blend the two matrices we would use to transform it.

You may be thinking that the thought of loading a mesh and determining how many bones the hardware supports and having to convert that data into a hardware friendly mesh, batched into subsets based on bone contributions, sounds like a complete nightmare. However, you will be glad to know that support is available. When the mesh is first loaded inside the CreateMeshContainer function, we can use the ID3DXSkinInfo::ConvertToBlendedMesh function to perform all of these steps for us. We will look at this function in more detail later, but for now just know that we will pass this function the regular ID3DXMesh containing the skin that is passed into our CreateMeshContainer function. ConvertToBlendedMesh will automatically clone the mesh into a format that contains the correct number of vertex weights in each vertex and will attribute sort the mesh so that triangles are batched primarily by bone combinations. This means that all of the triangles that use one set of up to four matrices will belong in one subset; all the triangles that use another combination of four matrices will belong in another subset; and so on. Subsets are then further subdivided so that a single subset will contain only triangles that share the same material and texture. As you can imagine, this means we can end up with subsets that are quite small, even in typical cases.

For example, the skinned mesh contained in ‘Tiny.x’ which ships with the DirectX SDK uses only a single texture and material. This is something we try to target when working with skinned meshes, for obvious reasons. If we were to register Tiny as a regular mesh, it would have only one subset and we could render it with a single draw call. However, when Tiny is converted into a skin that is compatible with the non-indexed skinning technique, the new mesh will have been broken up into over 30 different subsets (and that is assuming that four matrix blends are available on the hardware). So even though each subset uses the same texture and material, the triangles in each subset use different combinations of 4 bone matrices which need to be set on the device before we issue each draw call. This batching problems stems not from only being able to have four bone influences per vertex, but from the implied one-to-one mapping between vertex weights and matrix slots on the device. As there are at most four weights, they always map to the first four matrices set on the device.

We can check how many blend weights the mesh returned from the ConvertToBlendedMesh function needs to use and make some decisions of our own. If this value is beyond the limits of the hardware, we can choose to invoke software vertex processing at this point (device type permitting).

When it comes time to render the mesh, we will loop through each subset, set the world (bone) matrices that the triangles in that subset are influenced by (which ID3DXSkinInfo tells us), and then render that

subset with vertex blending enabled, using the D3DRS_VERTEXBLEND renderstate that we will take a look at shortly.

In this section we will discuss non-indexed blending. This is the skinning technique which is most commonly supported by hardware (even on older T&L cards) but has the disadvantages just described. Later in this lesson we will discuss the second hardware accelerated skinning technique called indexed blending, where we are no longer limited to only four influences per subset. This will allow for much more efficient batching.

11.8.2 Setting Multiple World Matrices

In order for the DirectX pipeline to do a multi-matrix blend of the vertices in our skinned mesh, we need a way to bind more than one world matrix to the device at a time. When using non-indexed blending, a vertex can have up to three weights, so it will require the pipeline to transform it using up to four world matrices. Whereas in the software skinning case we simply passed our entire array of bone matrices into the UpdateSkinnedMesh function, now we will need to send the device only the bone matrices that the subset we are about to render will use.

As it turns out, the software skinning code we used to extract the bone offset matrices from ID3DXSkinInfo and store them in the mesh container can be reused. This part of the system will not change -- we will continue to use the ID3DXSKinInfo object passed into the CreateMeshContainer function to retrieve the bone offset matrices and store them in the mesh container. We will similarly traverse the hierarchy to find the matching absolute bone matrices so that we can store those in the mesh container as well. Therefore, when it comes time to render, our mesh container will store an array of bone offset matrices and a matching array of absolute bone matrix pointers just as it did in the software skinning case.

The difference now is that we will not simply combine all bone matrices with their corresponding bone offset matrices into the global matrix buffer and run the update (although we will still need to perform the concatenation). Instead, we will first need to determine which bones in our bone array are needed by the subset we are about to render. This is because these are the bones that the weights defined in the subset vertices are relative to. When we examine our modified CreateMeshContainer function a bit later in the lesson, we will see how to convert the skin into a mesh that contains the vertex weights. We will be able to subsequently retrieve the mesh in the desired vertex format along with something called a *bone combination table*. The bone combination table will be an array of structures, where each element in the array will contain the bone indices used by a given subset. Before we render skin subset N, we will check element N in our bone combination table to determine which bones are relevant. This structure in the table will store an array of bones indices which we can use to locate the needed world matrices in the mesh container. Because we stored our bone matrix pointers inside the mesh container in the same order that the bone offset matrices were stored in the ID3DXSkinInfo object, these bone combination table indices will directly index into our array of bone matrix pointers and bone offset matrices stored in the mesh container.

As an example, let us imagine that we are about to render subset 5 of a mesh, and element 5 in our bone combination table tells us that this subset uses bones 6 and 20. We know that we must combine each absolute bone matrix with its bone offset matrix stored in the corresponding mesh container arrays before we set them on the device as a world transformation matrix:

```
D3DXMatrixMultiply(&Matrix1,
                   &pMeshContainer->pBoneOffsetMatrices[6],
                    pMeshContainer->ppBoneMatrixPtrs[6] );

D3DXMatrixMultiply(&Matrix2,
                   &pMeshContainer->pBoneOffsetMatrices[20],
                    pMeshContainer->ppBoneMatrixPtrs[20] );
```

As you can see, the two bones that influence the subset we are about to render have been combined with their corresponding bone offset matrices such that we now have two temporary combined matrices which we can bind to the device as world matrix 1 and world matrix 2. For each vertex in this subset, its first weight will determine how influential Matrix1 (bone 6) will be and the second weight will determine how influential Matrix2 (bone 20) will be.

For the time being, do not worry about how we find out which bones affect which subset; we will see this all later when we take a detailed look at the ConvertToBlendedMesh function. The bigger point here is that in the above example we have created two combined matrices which we now need to set on the device so that the pipeline can access them. So how do we set more than one world matrix on the device?

The World Matrix Palette

A Direct3D device actually has the ability to store 511 matrices. When we call the SetTransform device method and pass in a transform state such as D3DTS_VIEW to set the view matrix, this transform state actually equates to an index into a larger palette of matrices which places the view matrix at the index in this matrix palette where the device expects it to be stored. The first 256 matrix positions (transform states 0 – 255) are used by the pipeline to store the view matrix, the projection matrix, the viewport matrix, and other matrices such as the texture matrices for each texture stage. We will not normally place matrices into these positions using raw matrix indices. Rather, we use transform states such as D3DTS_VIEW and D3DTS_PROJECTION to map to matrix palette indices somewhere in the 0 – 255 range. However, transform states 256 – 511 are reserved to hold up to 256 world matrices. Up until now, we have only used one of these world matrices so you might have assumed that there was only one world matrix slot on the device. As it happens, when we set a world matrix like so:

```
pDevice->SetTransform ( D3DTS_WORLD , &mat );
```

we are actually setting this matrix in the device matrix palette at index 256 (the first palette position where world matrices begin). That is, D3DTS_WORLD is defined in the DirectX header files with a value of 256. When we are not using vertex blending, we only need to use this first world matrix position. But we now see that we have the ability to set many more world matrices simply by passing in

the index of the matrix we wish to set. For example, if we wanted to set three world matrices, we could do the following:

```
pDevice->SetTransform ( 256 , &mat1 );
pDevice->SetTransform ( 257 , &mat2 );
pDevice->SetTransform ( 258 , &mat3 );
```

Bear in mind however that setting the matrices does not mean that the transformation pipeline will use them -- we have to enable vertex blending for that to happen. If the vertex blending render state has not been set to TRUE, then only the first world matrix (256 or D3DTS_WORLD) will be used to transform vertices. Since it is not very intuitive to set the world matrices using raw index numbers, DirectX supplies us with a macro that maps indices 0-255 into the 256-511 range. This is useful because if we know we have to set four bone matrices to render a given subset, we tend to think of these as being matrices 0-4 and not matrices 256-259. Therefore, when setting world matrices we will use the D3DTS_WORLDMATRIX macro, defined in the DirectX header files as:

```
#define D3DTS_WORLDMATRIX(index) (D3DTRANSFORMSTATETYPE)(index + 256)
```

As you can see, this simple macro just adds 256 to the passed index. Thus, we would rewrite the above example code as:

```
pDevice->SetTransform ( D3DTS_WORLDMATRIX ( 0 ) , &mat1 );
pDevice->SetTransform ( D3DTS_WORLDMATRIX ( 1 ) , &mat2 );
pDevice->SetTransform ( D3DTS_WORLDMATRIX ( 2 ) , &mat3 );
```

Although the result is the same, it is much more intuitive to read. We can see that matrix (0) maps to weight (0) in the vertex, matrix (1) maps to weight (1) in the vertex, and so on. In this example where only three matrices are being used, you should keep in mind that the weight for matrix (2) would not be stored in the vertex since the pipeline will automatically calculate it by doing 1.0 – (weight0 + weight1). If a maximum of N matrices are being used, there should be N-1 weights in the vertex structure. Weight N is always calculated by the pipeline.

You may be wondering why 256 world matrix slots have been allocated when we know that a maximum of four matrices is supported. After all, in the current version of DirectX, only three weights can be defined in the FVF format of the vertex (the fourth weight is calculated on the fly) and these are paired up with the corresponding matrices that are set on the device. Since there is an implicit mapping between weight positions in the vertex and matrix indices on the device, it must follow then that given the restriction of four weights, only four of the possible 256 matrices will ever be used during blending. The other 252 matrices would appear to be wasted space. As it turns out, when performing non-indexed blending, this is absolutely the case. At most, we will only ever use the first four world matrix slots on the device (Fig 11.20). It is because of this limitation that the non-indexed skinning technique suffers such inefficient batching (all of the triangles in a given subset must use the same four bone matrices in order to be rendered together).

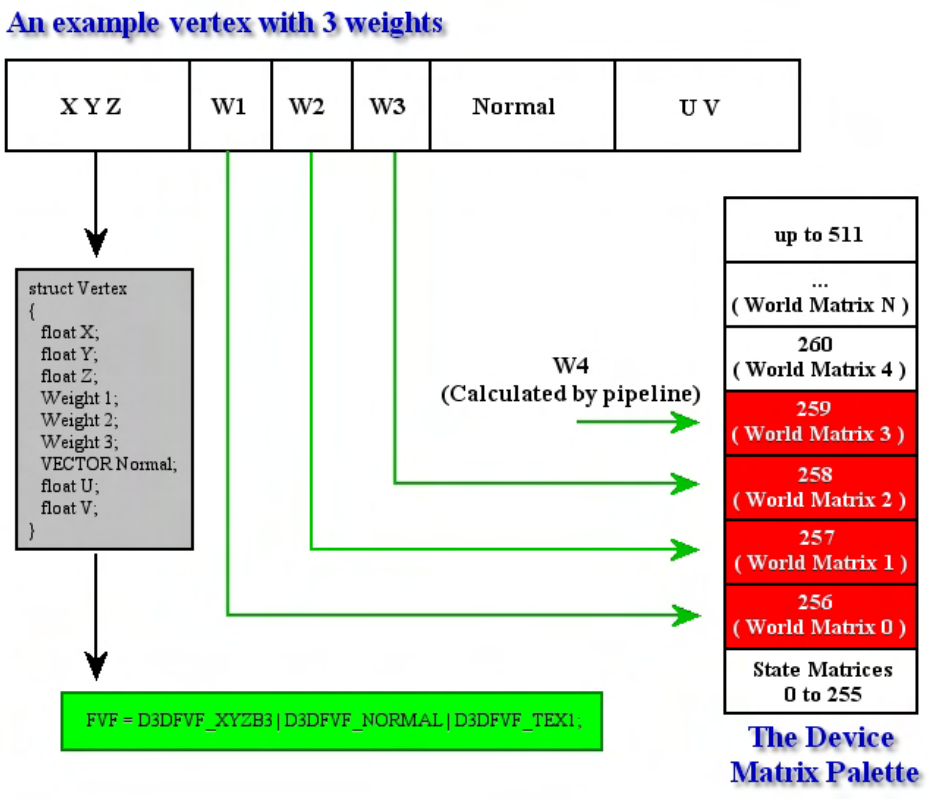

Figure 11.20

In Fig 11.20 we see an example of a vertex format that contains three weights, which gives us access to the first four world matrices on the device. Notice the FVF flags in the green box that we use to define the vertex format for the vertex buffer that would contain these weighted vertices. The D3DFVF_XYZB3 flag is an FVF flag we have not encountered yet in this series. It is used in place of the typical D3DFVF_XYZ to specify that each vertex will have three blend weights defined. As you might imagine, there are other flags for defining vertices with different blending weights (one, two, three, four, or five weights as it turns out):

Additional FVF blending flags:
D3DFVF_XYZB1
D3DFVF_XYZB2
D3DFVF_XYZB3
D3DFVF_XYZB4 // not currently supported
D3DFVF_XYZB5 // not currently supported

These FVF flags are mutually exclusive since they each define a vertex as having untransformed X, Y, and Z components along with some specified number of weights. Fig 11.20 also shows us that the weights should be defined immediately after the XYZ position component in the vertex structure. The number of float weights you place in your vertex must match the FVF flags that you intend to use.

We will not actually need to create a vertex buffer ourselves using the flags listed above because the ConvertToBlendedMesh function will create the mesh (and therefore its vertex buffer) for us in the correct format. However, you are certainly permitted to use the pipeline's vertex blending features

without having used this particular function to set up the mesh on your behalf. In such cases you would need to create the vertex buffer yourself with the appropriate FVF flags and vertex weight values.

Later in the lesson we will discuss the second pipeline skinning technique called indexed blending. It is much more efficient, but unfortunately not as widely supported in hardware. Using this technique, each vertex can contain up to 3 weights as in the non-indexed case, but can also contain 4 indices using a packed DWORD. These indices allow the vertex to specify not only the weights themselves, but exactly which bone matrix in the device matrix palette that each weight applies to -- up to 256 now allowed. Consequently, subsets will be much larger and even a single triangle could be influenced by 12 unique bone matrices. Since a subset could contain many triangles all influenced by different bones somewhere in the 256 matrix palette, this makes a significant difference. We mentioned the case of Tiny.x earlier and saw that over 30 skin subsets were created when using non-indexed blending (each of which could only access four matrices at a time). In the indexed case, the mesh contains only a single subset and can be rendered with a single draw call. This is because we can set all of the bone matrices on the device for the character simultaneously before we render the mesh. The vertices of the mesh accurately describe to the pipeline (using their stored indices), which of the currently set matrices its weights are defined for.

For the time being, let us not get distracted by indexed vertex blending, for we still have a ways to go in our examination of non-indexed blending. Like it or not, non-indexed blending will often be the only hardware accelerated vertex blending technique supported on an end user's system, so you will definitely want to accommodate it in your skinned mesh implementation.

11.8.3 Enabling Vertex Blending

To enable vertex blending on the device we use the D3DRS_VERTEXBLEND render state:

```
pDevice->SetRenderState ( D3DRS_VERTEXBLEND , D3DVERTEXBLENDFLAGS );
```

The second parameter should be a member of the D3DVERTEXBLENDFLAGS enumerated type. The default state for this render state is D3DVBF_DISABLE, which means the pipeline will perform no vertex blending and a single world matrix (stored at index 256) will be used for vertex transformations. This is the mode we have used in all our demos up until this point where a single world matrix was needed.

```
typedef enum
_D3DVERTEXBLENDFLAGS
{
        D3DVBF_DISABLE = 0,
        D3DVBF_1WEIGHTS = 1,
        D3DVBF_2WEIGHTS = 2,
        D3DVBF_3WEIGHTS = 3,
        D3DVBF_TWEENING = 255,
        D3DVBF_0WEIGHTS = 256
} D3DVERTEXBLENDFLAGS;
```

Before rendering the mesh, we will tell the device how many matrices we wish to use per vertex. One point that needs to be clear is that if we pass D3DVBF_2WEIGHTS for example, then the vertices in our mesh must have *at least* two weight components defined in the FVF. However, keep in mind that every vertex in the mesh must have the same number of weights because all vertices in a mesh vertex buffer must be of the same format.

We will use the ConvertToBlendedMesh function to convert our initial skin mesh into one that has the correct number of weights. This function essentially informs the pipeline of the number of weights defined in each vertex, which will be equal to the maximum number of bone influences for a single vertex in the mesh (minus 1 because the last weight is never stored, it is calculated on-the-fly).

If our mesh had all of its vertices influenced by only two bones, but one vertex in the mesh happened to be influenced by four bones, then every vertex in the mesh would have three weights defined and we would use the D3DVBF_3WEIGHTS flag before rendering this mesh. Any vertices that are only influenced by two bones (and would normally only need one weight) will still have three weights -- the two additional weights are added to pad the vertex structure. They will be assigned weights of 0.0 so that they do not affect the vertex transformation.

Although these 'padding' weights will not affect the final transformation results for the vertex, it is necessary to note that they will still be used to blend matrices, even though the result will be a no-op because it is scaled to zero. We will see later how we can introduce a possible optimization during rendering in the non-indexed case. Essentially, before rendering a subset, we will find out the maximum number of matrices used by that subset and adjust the D3DRS_VERTEXBLEND render state to this amount. This will allow us to make sure that the additional (padding) weights are not used to needlessly blend matrices that will have no effect on the final vertex position. Using our previous example, where the mesh vertices have been padded to three weights and most of the subsets are influenced by only two matrices, we would determine before we render a subset which of the two categories it falls into. If it is influenced by two matrices then we can set the D3DRS_VERTEXBLEND to D3DVBF_1WEIGHTS so that the additional padded weights (weights 2 and 3 in this example) and their respective matrices are not needlessly included in the vertex transformation.

Therefore, the second parameter to this function describes not the total number of weights defined in the vertices, but the number we wish to use for transformations (which may be less). Let us examine the possible values the D3DRS_VERTEXBLEND render state can be set to and see what they mean when used.

D3DVBF_0WEIGHTS

This value informs the device that the vertices we are about to render do not contain any weights and therefore will be transformed by only one matrix with an assumed weight of 1.0. This might sound like a very strange flag to be able to set because surely a vertex that uses one matrix with a weight of 1.0 is a vertex that is not being blended. Indeed it would seem that this flag would have the same effect as using the D3DVBF_DISABLE flag. As it turns out, this is actually true in the case of non-indexed blending and in fact, there will be no need to use this flag under those circumstances. However, in the indexed blending case, we might have a triangle where each of its three vertices will need to use different world matrices. Therefore, while vertex blending is not taking place, it is still possible that we might have a mesh where every vertex is only attached to one bone, but the vertices belonging to the same triangles/subsets might not all use that same bone for transformation. While no actual blending is taking place, three matrices could still be used to transform a single triangle (e.g., one matrix for each vertex). This would not be possible using only the single world matrix that is available using the D3DVBF_DISABLE flag. This will all make more sense when we discuss indexed skinning later in the lesson.

D3DVBF_1WEIGHTS
This flag informs the device that we wish to render our triangles using vertex blending where each vertex will have a single weight. Remember that if the vertex has one weight, then this means it is influenced by two bones and will be blended using two matrices. The second weight is calculated by the pipeline as Weight2 = 1.0 – Weight1. After setting this state, any triangles that you render must have at least one vertex weight defined or behavior will be undefined.

D3DVBF_2WEIGHTS
This flag informs the pipeline that we wish to render our triangles such that they will be transformed using three world matrices. After this state has been set, any triangles we render must have a vertex format that contains at least two weights. When this state is set the vertex will be transformed using the first three world matrices on the device. The weight of the third matrix is calculated as Weight3 = 1.0 – (Weight1 + Weight2).

D3DVBF_3WEIGHTS
This flag informs the pipeline that we wish to render some triangles such that they will be transformed using four world matrices. After this state has been set, any triangles we render must have a vertex format that contains at least three weights. When this state is set, the vertex will be transform using the first four world matrices on the device. The weight of the fourth matrix is calculated by the pipeline using the calculation: Weight3 = 1.0 – (Weight1 + Weight2 + Weight3).

D3DVBF_TWEENING
We will not be using vertex tweening in this lesson and therefore we will not require this flag. However you already have a good high level understanding about how tweening works, so you should be able to use the SDK documentation to fill in the gaps if you would like to use this technique in your applications. (Recall that tweening was an interpolation technique between two pre-defined sets of mesh vertices in different key animation poses.)

D3DVBF_DISABLE
This flag will disable vertex blending and set the device back to its default mode of using a single world matrix to transform vertices.

We have now covered all of the theory involved in the non-indexed skinning technique, so it is time to discuss some implementation details. We will need to examine what our CreateMeshContainer function will now look like for the non-indexed skinning case. We will also want to have a discussion about the very important ID3DXSkinInfo::ConvertToBlendedMesh function, since it will do so much of the setup work for us.

11.8.4 Storing the Skinned Mesh

Whether we are using software skinning, non-indexed skinning, or indexed skinning, our application loads the skinned mesh and bone hierarchy in exactly the same way: using the D3DXLoadMeshHierarchyFromX function. It is in the CreateMeshContainer function of our ID3DXAllocateHierarchy derived class that we are passed a regular mesh and an ID3DXSkinInfo interface. Our job will be to use the tools available to create a mesh that is capable of being vertex

blended by the pipeline. Therefore, we will skip straight to the CreateMeshContainer function and the mesh container structure we will need to store the required information.

Our mesh container will need a few additional members when we perform skinning in the pipeline. Also, when performing indexed or non-indexed skinning we will no longer need our temporary global matrix array as we did when performing software skinning. This is because this array was used to store the resulting matrices of combining the bone matrices with their corresponding bone offset matrices before sending them to UpdateSkinnedMesh. We will no longer need this temporary matrix buffer because we will be setting the matrices (a maximum of a four at a time in the current case) directly on the device. The new mesh container will accommodate the CreateMeshContainer function for a non-indexed skinned mesh and is defined next.

```
struct D3DXMESHCONTAINER_DERIVED : public D3DXMESHCONTAINER

{
    DWORD           NumAttributeGroups;
    DWORD           NumInfl;
    LPD3DXBUFFER    pBoneCombinationBuf;
    D3DXMATRIX**    ppBoneMatrixPtrs;
    D3DXMATRIX*     pBoneOffsetMatrices;
    DWORD           iAttributeSW;
};
```

Four new data members have been added to this structure and one has been removed. We no longer need to store the original mesh since the concept of a source and destination mesh is no longer valid. We will now store a single model space mesh in the MeshData member of the base structure and it is this mesh that will be transformed and rendered by the pipeline. Notice that the two matrix arrays remain. As before, the ppBoneMatrixPtrs array will contain pointers to all of the absolute bone matrices in the hierarchy that affect this mesh and we also maintain the corresponding bone offset matrix array. Most of the new members are used to store information that is returned from the ConvertToBlendedMesh function, which we will look at shortly.

DWORD NumAttributeGroups

When ID3DXSkinInfo::ConvertToBlendedMesh is called, our mesh will be cloned into a new format where the vertices contain the correct number of weights. But this function also does a lot more than simply clone the mesh into a different vertex format. Most importantly, it also breaks the mesh into different subsets so that no individual subset is influenced by any more than four matrices (or perhaps less depending on the hardware), since this is all we have available with the non-indexed skinning technique. This is likely to create many more subsets/attribute groups than the original mesh had and we will need to know how many subsets the new mesh has been divided into because there will be exactly this many elements in our bone combination buffer (also returned from the ConvertToBlendedMesh function and stored in the mesh container). Each element in the bone combination buffer will represent a subset in the mesh and will contain information such as the matrix indices into our bone/bone offset arrays which we will need in order to render that subset. We will look at the bone contribution table in a moment.

The NumAttributeGroups DWORD describes how many subsets the blended mesh has and is the number we will need to loop against in order to set the matrices for each subset and render it.

DWORD NumInfl

This member will store a value that will be returned from ConvertToBlendedMesh that describes the maximum number of influences that a single vertex has in the resulting mesh. Subtracting one from this value will tell us exactly how many weights we have in the vertex structure of the converted mesh.

If this value is set to 4 then it means that there is at least one vertex in the mesh that is influenced by four matrices (and will therefore need to have 3 weights stored for it). In that case, every vertex in the mesh will have three weights. Any vertices that are influenced by fewer than 3 weights will have padding weights set to 0.0 as needed.

LPD3DXBUFFER pBoneCombinationBuf

This member stores a pointer to an ID3DXBuffer interface. The interface to this buffer is returned from the ConvertToBlendedMesh function and is stored in the mesh container for use during rendering. The buffer will contain the bone combination table for this mesh -- an array of D3DXBONECOMBINATION structures. Each structure in the array contains information for a single subset in the converted mesh. This means that the array will contain NumAttributeGroups D3DXBONECOMBINATION structures.

When rendering the mesh, we will loop through each of its subsets/attribute groups and fetch its D3DXBONECOMBINATION structure from this buffer. This structure will tell us which texture and material to use, which vertex and index ranges in the vertex and index buffers belong to this subset, and of course, which bone matrices need to be set on the device.

The D3DXBONECOMBINATION structure is defined as follows:

```
typedef struct _D3DXBONECOMBINATION
{
    DWORD AttribId;
    DWORD FaceStart;
    DWORD FaceCount;
    DWORD VertexStart;
    DWORD VertexCount;
    DWORD *BoneId;
} D3DXBONECOMBINATION, *LPD3DXBONECOMBINATION;
```

This is a very important structure for a number of reasons. First, it is our only link between subsets in the converted mesh and their relationship to the bones in our mesh container. It is also our only link between the textures and materials that these new subsets use. Remember that although we are passed the D3DXMATERIAL buffer (in CreateMeshContainer) which describes the texture and material to use for each subset in the original mesh, after we have converted the mesh using the ConvertToBlendedMesh function, the subsets will have been completely rearranged and subdivided.

> **Note:** The bone combination buffer is calculated automatically during ConvertToBlendedMesh, so we will not have to figure out these values ourselves.

Before continuing our mesh container examination, let us take some time to discuss the members of this new structure. Keep in mind that there will be one of these structures in the buffer for each subset in the converted mesh.

DWORD AttribId
This value is our means of indexing into the original D3DXMATERIAL buffer passed into the CreateMeshContainer function. It will describe the texture and material that should be used to render this subset. Remember that the converted mesh will have had its subsets completely recalculated, so there is no longer have a 1:1 mapping with the D3DXMATERIAL buffer. That is why this link between the new subset and old D3DXMATERIAL array is needed.

DWORD FaceStart
DWORD FaceCount
These two members describe the range of triangles in the index buffer of the converted mesh which are considered to be part of this subset. When the ConvertToBlendedMesh function executes, each new subset it generates will have its triangles stored together in the index buffer. FaceStart describes the index of the first triangle in the index buffer that belongs to this subset and FaceCount describes how many triangles (starting at FaceStart) are included in this subset.

DWORD VertexStart
WORD VertexCount
These two members describe the range of vertices in the vertex buffer that belong to this subset. When the ConvertToBlendedMesh function executes, each new subset it generates will have its vertices stored together in the vertex buffer. VertexStart describes the index of the first vertex in the vertex buffer that belongs to triangles in this subset. VertexCount describes how many vertices (starting at VertexStart) are used by triangles in this subset.

DWORD *BoneId
This member is an array of DWORD indices describing which matrices in our mesh container matrix arrays are used by this subset. This tells us which matrices need to be set on the device in order to render this subset. The size of this array will always be equal to the maximum number of influences on a single vertex in the mesh -- which is equal to the NumInfl value we added to our mesh container. As an example, let us imagine once again the case where a mesh might have been converted such that each vertex has three weights. This means that, at most, a vertex will be blended using four matrices. In this instance, the BoneId array of every subset will have four elements in it. These four elements are the indices of the four matrices that the vertices in this subset need to have sent to the device before they are rendered. If the current subset being processed only uses two matrices out of the possible four, then the last two bone indices in the subsets BoneId array will be set to UINT_MAX and their corresponding weights in each vertex will be set to zero.

To better illustrate what BoneId contains, let us imagine that the current subset we wish to render has a BoneId array containing the values {4, 3, 1, UINT_MAX}. Since the vertices in this subset are influenced by only three of the possible four matrices we can set, we would need to set the following matrices on the device before rendering this subset:

```
D3DXMatrixMultiply(&Matrix0,
                   &pMeshContainer->pBoneOffsetMatrices[4],
                   pMeshContainer->ppBoneMatrixPtrs[4] );

D3DXMatrixMultiply(&Matrix1,
                   &pMeshContainer->pBoneOffsetMatrices[3],
                   pMeshContainer->ppBoneMatrixPtrs[3] );
```

```
D3DXMatrixMultiply(&Matrix2,
                   &pMeshContainer->pBoneOffsetMatrices[1],
                   pMeshContainer->ppBoneMatrixPtrs[1] );

pDevice->SetTransform ( D3DTS_WORLDMATRIX ( 0 ) , &matrix0 );
pDevice->SetTransform ( D3DTS_WORLDMATRIX ( 1 ) , &matrix1 );
pDevice->SetTransform ( D3DTS_WORLDMATRIX ( 2 ) , &matrix2 );
```

We now see that the values stored in the BoneId array for each subset directly index into our mesh container matrix arrays. This is made possible by the way we store our bone pointers in the same order they are listed in the ID3DXSkinInfo object. We saw how to store the matrices in the mesh container in this order during our software skinning discussion and this process is unchanged.

Of course, for the above code to function properly we will need to enable vertex blending before we render the subset. Since we know that each vertex in our example mesh will have three weights defined and that any unused weights will be set to zero, we can safely set the vertex blend mode as follows and render all subsets of our mesh with this single setting:

```
pDevice->SetRenderState ( D3DRS_VERTEXBLEND , D3DVBF_3WEIGHTS );
```

This will work properly because all of our subset vertices will have three weights defined. This is true even if the subset we are about to render only uses three matrices (two of its three weights) as is the case in the above example where the last element in the BoneId array is set to UINT_MAX. Since the last weight will be set 0.0, any matrix set in the fourth matrix slot on the device will have its contribution scaled to 0.0 and will not effect the position of the transformed vertex. You will notice in the above code example that we only set three of the four possible matrices because the subset only uses three matrices (as described by the BoneId array). The contents of the fourth device matrix are insignificant; even if it is not set to an identity matrix and just contains garbage data, its contribution is reduced to zero by the pipeline so it will have no effect.

The BoneId array allows us to perform a rendering optimization in the non-indexed skinning case. For example, we know that if a subset has a BoneId array of {4, 10, UINT_MAX, UINT_MAX} then we only need to set two matrices, even though the vertex will have three weights. The last two weights will be set to zero, so we do not have to bother setting the third and fourth device matrices as just discussed. This is wasteful however, since every vertex in this subset will still be blended with all four matrices even though the final two matrix multiplies will have no effect on the outcome. Therefore, rather than just setting the D3DRS_VERTEXBLEND renderstate to the number of weights per vertex in the mesh (3 in our example) and rely on the zero weights of the vertex to cancel out the contributions from unused matrix slots, we can check the BoneId array to find out exactly how many matrices will really be needed by this subset. Once we find out this information, we could set the D3DRS_VERTEXBLEND render state to process only this number of vertex weights/matrices.

So in the example subset above, although the vertices contain three weights (because some other subset must have needed to use this many) this particular subset only needs to use two weights for its three matrix contributions. If we set the D3DRS_VERTEXBLEND state to D3DVBF_2WEIGHTS before rendering this subset, we can avoid the overhead of unnecessary per-vertex matrix multiplication. Since

only two of the three defined weights will be used by the pipeline, the fourth matrix slot on the device will be completely ignored.

The following code snippet demonstrates how to test the BoneId array of the current subset we are about to render to see how many matrices will be needed. We then use this value to set the D3DRS_VERTEXBLEND render state so that non-contributing matrices and weights are ignored.

```
      pBoneComb = (LPD3DXBONECOMBINATION)
                        (pMeshContainer->pBoneCombinationBuf->GetBufferPointer());

      // Render each subset
      for (iAttrib = 0; iAttrib < pMeshContainer->NumAttributeGroups; iAttrib++)
      {
            NumBlend = 0;
            for (DWORD i = 0; i < pMeshContainer->NumInfl; ++i)
            {
                  if (pBoneComb[iAttrib].BoneId[i] != UINT_MAX)
                  {
                        NumBlend = i;
                  }
            }

            // Use only relevant matrices / weights
            pDevice->SetRenderState(D3DRS_VERTEXBLEND,  NumBlend);

            // Set matrices and render subset here
       }
```

Now that we know what the bone contribute table in our mesh container will contain, we can continue our discussion of the new members added to our mesh container.

DWORD iAttributeSW

This value will store the zero-based index of the first subset in the mesh that needs to be rendered with software vertex processing enabled. For example, if this value is set to 5, it means that the first five subsets can be rendered with hardware vertex processing and that the remaining subsets (starting from index iAttributeSW up to NumAttributeGroups) need to be rendered with software vertex processing. This is because some of the subsets in that range will need to use more vertex blends than the hardware can support. In software vertex processing mode, we know the pipeline will always have the capability to blend up to four matrices, and the converted mesh will never have any more than three weights defined, so all is fine. However, the hardware may not support all four matrix blends and may instead support only two for example. So if we have a mesh where some of the subsets require more matrix blends than the hardware supports, we will need to render those subsets using software vertex processing.

ConvertToBlendedMesh will try to intelligently arrange the mesh based on the hardware capabilities of the device. For example, if the hardware supports only two weights (three matrix influences) but the original bone/vertex mapping describes one or more vertices as being influenced by more bones than three (four or more), then the function will try to return a mesh that only has three weights defined

without severely compromising the skin/bone relationship. In that case, means we can render the entire mesh using hardware vertex processing.

However, if the device supports a maximum of only two influences per vertex (i.e. one weight) then the function may not be able to approximate the mesh down to this level without severely compromising the relationship between the skin and bones. Therefore some of the subsets in the returned mesh may still require more matrix blends than the device can handle in hardware. It is in this instance that we will use the iAttributeSW flag to distinguish these subsets so that we can optimize the rendering of the mesh using two passes. In the first pass we will render all of the subsets that are influenced by no more than two bones using hardware vertex processing. In the second pass we will enable software vertex processing and render the remaining subsets that have three or more influences. Because we have the index of the first subset that is non-hardware compliant, we do not have to loop through and test all subsets again from the beginning during the second pass. Instead we can start checking subsets from this index.

After we call the ConvertToBlendedMesh function to create the new skinned mesh (in our CreateMeshContainer function), our first job will be to check how many matrix blends the hardware supports. We do this by querying the **MaxVertexBlendMatrices** member of the D3DCAPS9 structure as shown below.

```
D3DCAPS9 d3dcaps;
pDevice->GetDeviceCaps ( &d3dcaps );
DWORD MaxNumberBlends = d3dcaps.MaxVertexBlendMatrices;
```

Once we have this value, we will loop through each subset in the D3DXBONECOMBINATION buffer and search each BoneId array to see if that subset requires more matrix influences than the hardware supports. Once we find the first subset in the buffer that exceeds the hardware capabilities, we will set the iAttributeSW member to this index. Now we can render the mesh using the two pass approach just discussed. In the first pass we will render all subsets in hardware using this logic.

```
for ( int I = 0 ; I < NumSubsets; I++ )
{
     if ( Subset[I] can be rendered in hardware )  RenderSubset[I];
}
```

In this first pass we have looped through every subset and only render subsets that are not influenced by more matrices than the hardware supports. In the next pass, we will do the same again only this time with software vertex processing enabled. However, because we have stored the index of the first non-hardware compliant subset, we do not have to start testing from the beginning. We can start from this index because we know that no subsets exist before this index that cannot be rendered in hardware.

```
pDevice->SetSoftwareVertexProcessing ( TRUE );

for ( int I = iAttributeSoftware ; I < NumSubsets; I++ )
{
      if ( Subset[I] can NOT be rendered in hardware )  RenderSubset[I];
}
```

Fortunately, virtually all recent video cards support more than two matrix blends in hardware, so this will only be an issue on fairly old graphics cards.

11.8.5 ID3DXSkinInfo::ConvertToBlendedMesh

Before we look at our new CreateMeshContainer function for non-indexed skinning, we will examine the ID3DXSkinInfo::ConvertToBlendedMesh function. This function that will take the regular mesh we are passed to our CreateMeshContainer callback function and output a new mesh that has the correct number of weights in the vertices. This function will never return a mesh with more than three weights (four influences) defined for each vertex even if the bone to vertex data stored inside the ID3DXSkinInfo object has vertices that are mapped to more than four bones. In this case, the function will approximate the mesh as best as it can so that it meets this requirement. It will also try to take the current hardware into account so that it will return a mesh that is within the maximum matrix blend capabilities of the device. This was discussed in the previous section.

ConvertToBlendedMesh will be called from inside our CreateMeshContainer function. We will pass in the interface to the standard mesh that we were passed by D3DXLoadMeshHierarchyFromX. This function will use the ID3DXSkinInfo's internal bone and weight information to clone a new mesh into a format that can be vertex blended by the pipeline. The new mesh will still contain all of the old input mesh data such as vertex position, vertex normals, texture coordinates, etc., but now it will have additional information that allows it to use multiple device matrices for blending.

The parameter list might seem pretty overwhelming at first, but most of them are actually output parameters that we can store in our mesh container and use to render the mesh later. We have already covered most of them in the context of the mesh container structure earlier in the lesson.

```
HRESULT ID3DXSKinInfo::ConvertToBlendedMesh
(
    LPD3DXMESH      pMesh,
    DWORD           Options,
    CONST LPDWORD   pAdjacencyIn,
    LPDWORD         pAdjacencyOut,
    DWORD           *pFaceRemap,
    LPD3DXBUFFER    *ppVertexRemap,
    DWORD           *pMaxVertexInfl,
    DWORD           *pNumBoneCombinations,
    LPD3DXBUFFER    *ppBoneCombinationTable,
    LPD3DXMESH      *ppMesh
);
```

LPD3DXMESH pMesh

This first parameter is a pointer to the source mesh interface passed into our CreateMeshContainer method by the D3DX loading function. This mesh is a standard ID3DXMesh that contains the skin geometry and it will be cloned into a blend-enabled mesh by this function. When this function returns and the mesh has been cloned, this mesh will no longer be needed and its interface can be released.

DWORD Options

This parameter is like the options flags used in the other mesh creation and cloning functions we have studied previously. It can be a combination of D3DXMESH flags and D3DXMESHOPT flags. Recall that the D3DXMESH flags allow us to choose properties such as which resource pool the vertex and index buffers of the mesh will be created in and whether or not this mesh should have the capability to be rendered with software vertex processing. The D3DXMESHOPT allows us to specify which optimizations should be applied to the vertex and index data of the cloned mesh. For example, the following flag combination would inform the function to create the vertex buffer and index buffer of the cloned mesh in the managed resource pool with vertex cache optimization. We know from previous lessons that this optimization actually performs the compact optimization, the attribute sort optimization, and will optimize the mesh to achieve better vertex cache coherency where possible.

```
D3DXMESH_MANAGED | D3DXMESHOPT_VERTEXCACHE
```

The optimizations will not be as effective as those applied to a regular mesh because now the triangles will also need to be batched into subsets based on bone contribution. We may have ten triangles which all share the same texture and material and, under normal circumstances, they would all end up in a single subset. But if these triangles do not all use the same N bones, they will be batched into additional subsets based on shared bones.

CONST LPDWORD pAdjacencyIn

This is a DWORD pointer that contains the adjacency information for the source mesh. We do not need to calculate this information ourselves since our CreateMeshContainer function will be passed the adjacency information of the source mesh by D3DXLoadMeshHierarchyFromX.

LPDWORD pAdjacencyOut [output]

Although we can pass NULL as this parameter, if we are interested in the adjacency information of the resulting mesh then we can pass in a pre-allocated DWORD array large enough to hold three DWORDs for every triangle in the source mesh. When the function returns, this array will be populated with the adjacency information of the newly cloned mesh. If you do pass NULL as this parameter, you can always generate the adjacency information for the output mesh at a later time using the ID3DXMesh::GenerateAdjacency method.

DWORD *pFaceRemap [output]

The pFaceRemap parameter should be large enough to hold one DWORD for every face in the source mesh. When the function returns, each element in the array will describe how the index of a face in the source mesh has been mapped to an index in the output mesh. If pFaceMap[5]=10 for example, this means that the 6^{th} face in the original index buffer of the source mesh has now been moved to the 11^{th} face slot in the index buffer of the output mesh. This gives us a chance to update any external structures that we may be maintaining that are linked to the original faces by index. You can set this pointer to NULL if you do not require the re-map information.

LPD3DXBUFFER *ppVertexRemap [output]

The ppVertexRemap parameter points to the address of an ID3DXBuffer interface which on function return will contain an array of DWORDs for each vertex in the source mesh describing how the vertex has been moved in the vertex buffer of the output mesh. The function will create this buffer during the call so we will not pre-allocate it. If you do not need this information then you can set this parameter to NULL.

DWORD *pMaxVertexInfl [output]

For this parameter we pass in the address of a DWORD which on function return will tell us the maximum number of bones that influence a single vertex in the mesh. This is the value that we will store in the NumInfl member of our mesh container. It is significant because subtracting one from this value will tell us how many weights each vertex has defined (we subtract one because the weight for the last influence is always calculated on the fly). If this value returns 4 for example, then it means the vertex structure of this mesh will have three weights defined and there will be at least one subset that needs access to all four matrices on the device. As mentioned previously, this does not mean that all vertices in the mesh need to use four matrices even though they will all store three weights. Any weights in the vertex that are not used will be set to 0.0 so that the corresponding matrix will not contribute.

This value is also significant because it tells us how large each BoneId array is in the D3DXBONECONBINATION structure for each subset in our bone combination table. If this value is 3 for example, then we know that for every element in the bone combination table, each D3DXBONECOMBINATION structure will contain a BoneId array with three elements. Not all elements in the BoneId array for a given subset are necessarily used. If a given subset only needs to use two matrices, its BoneId array would still have 3 elements (in our current example) but the value of the third element would be set to UINT_MAX instead of a valid bone matrix index. This allows us to perform a rendering optimization by only setting the matrices that are used and setting the D3DRS_VERTEXBLEND render state appropriately so that no-op vertex matrix transformations are not carried out.

DWORD *pNumBoneCombinations [output]

There will be one D3DXBONECOMBINATION structure in this buffer for each subset in the output mesh. The bone combination buffer itself will be calculated by this function and returned to us so that we can store it away in our mesh container. This parameter is the address of a DWORD which on function return will tell us how many D3DXBONECOMBINATION structures are stored in the returned ID3DXBuffer (next parameter). Since there will be one D3DXBONECOMBINATION structure for each subset in the output mesh, this value will also tell us how many subsets exist in the output mesh, which we will need to know during rendering.

The value stored in this DWORD will be copied into the NumAttributeGroups member of our mesh container and will be used during rendering to loop through each subset that needs to be rendered.

LPD3DXBUFFER *ppBoneCombinationTable [output]

This parameter is the address of an ID3DXBuffer interface pointer. The function will allocate the ID3DXBuffer and on function return it will store the entire bone combination table for the mesh. For each subset in the output mesh (described by the previous parameter pNumBoneCombinations) there will be a D3DXBONECOMBINATION structure describing exactly which bones need to be set on the device in order to render that subset. These indices are stored inside each structure’s BoneId array and they reference directly into the ppBoneMatrixPtrs and pBoneOffsetMatrices arrays in our mesh container. Each D3DXBONECOMBINATION structure also contains the ranges of vertices and indices in the output mesh vertex and index buffers which belong to a particular subset. The D3DXBONECOMBINATION table also stores an AttributeId which indexes into the D3DXMATERIAL buffer that was passed into CreateMeshContainer.

LPD3DXMESH *ppMesh [output]
The final parameter to this method is the address of an ID3DXMesh interface pointer. On function return, it will point to a mesh that will have pMaxVertexInfl weights defined in each vertex, where each weight will have been assigned its correct value. This is the mesh that we will use for rendering, and as such, the source (input) mesh can be released since it will no longer be needed.

11.8.6 The CreateMeshContainer Function

The first part of the mesh container creation function is completely unchanged from the software skinning version, so we will not need to explore it in much detail here. The following code stores the passed mesh pointer in a newly allocated mesh container (temporary, as this will be replaced with the converted blended mesh) and also copies the name of the mesh passed into the function. Once again, our example will assume that we will need vertex normals in our mesh so that it can be correctly lit by the pipeline. If normals are not present, then we clone the mesh to make space for vertex normals and then calculate them thereafter.

```
HRESULT CAllocateHierarchy::CreateMeshContainer
       ( LPCTSTR Name, LPD3DXMESHDATA pMeshData, LPD3DXMATERIAL pMaterials,
         LPD3DXEFFECTINSTANCE pEffectInstances, DWORD NumMaterials,
         DWORD *pAdjacency,
         LPD3DXSKININFO pSkinInfo, LPD3DXMESHCONTAINER *ppNewMeshContainer )
{
    D3DXMESHCONTAINER_DERIVED *pMeshContainer = NULL;
    UINT iBone, cBones;
    LPDIRECT3DDEVICE9 pd3dDevice = NULL;
    LPD3DXMESH pDestinationMesh = NULL;
    *ppNewMeshContainer = NULL;

    // Get a pointer to the mesh of the skin we have been passed
    pDestinationMesh = pMeshData->pMesh;

    // Allocate a mesh container to hold the passed data.
    // This will be returned from the function
    // where it will be attached to the hierarchy.
    pMeshContainer = new D3DXMESHCONTAINER_DERIVED;
    memset(pMeshContainer, 0, sizeof( D3DXMESHCONTAINER_DERIVED ));

    // If this mesh has a name then copy that into the mesh container too.
    if ( Name ) pMeshContainer->Name = _tcsdup( Name );

    // Get a pointer to the d3d device
    pDestinationMesh->GetDevice(&pd3dDevice);

    // if no normals exist in the mesh, add them ( we might need to use lighting )
    if (!(pDestinationMesh->GetFVF() & D3DFVF_NORMAL))
    {
        pMeshContainer->MeshData.Type = D3DXMESHTYPE_MESH;

        // Clone the mesh to make room for the normals
        pDestinationMesh->CloneMeshFVF( pMesh->GetOptions(),
                                        pMesh->GetFVF() | D3DFVF_NORMAL,
```

```
                                        pd3dDevice,
                                       &pMeshContainer->MeshData.pMesh );

         pDestinationMesh = pMeshContainer->MeshData.pMesh;

        // Now generate the normals for the pmesh
        D3DXComputeNormals( pDestinationMesh, NULL );
    }
   else  // if normals already exist, just add a reference
    {
        pMeshContainer->MeshData.pMesh = pDesinationMesh;
        pMeshContainer->MeshData.Type = D3DXMESHTYPE_MESH;
        pDestinationMesh->AddRef();
    }
```

We now have a regular mesh stored in the mesh container (which is correct because we must remember that the same X file could contain skinned meshes and regular meshes) and at this point we would usually parse the passed texture and material information and store it in some meaningful way. We have already covered how to do this in previous lessons so will not show it here. You can check the accompanying workbook for this lesson for more details.

If we have been passed a valid ID3DXSkinInfo interface, then it means that the passed mesh is to be used to skin the hierarchy (or a section of it) and we will need to convert the passed mesh into a mesh that includes bone weights.

The first section of the code that is executed when we have been passed a skinned mesh is also unchanged -- we store the ID3DXSkinInfo pointer in our mesh container for later use since we will need it after the hierarchy is loaded to map bone offset matrices to absolute bone matrices. We then increase the reference count because we have made a copy of the interface, and we retrieve the bone offset matrices and store them in the mesh container. All of this is unchanged from the software skinning case.

```
    // If there is skinning information,
    // save off the required data and then set up for skinning
    if (pSkinInfo != NULL)
    {
        // first save off the SkinInfo and original mesh data
        pMeshContainer->pSkinInfo = pSkinInfo;
        pSkinInfo->AddRef();

        // We now know how many bones this mesh has
        // so we will allocate the mesh containers
        // bone offset matrix array and populate it.
        NumBones = pSkinInfo->GetNumBones();
        pMeshContainer->pBoneOffsetMatrices = new D3DXMATRIX  [NumBones];

        // Get each of the bone offset matrices so that
        // we don't need to get them later
        for (iBone = 0; iBone < NumBones; iBone++)
        {
             pMeshContainer->pBoneOffsetMatrices[iBone] =
           *(pMeshContainer->pSkinInfo->GetBoneOffsetMatrix(iBone));
        }
```

The next section is where things change compared to software skinning. It is time to convert the mesh that we were passed into a blend-enabled mesh using ID3DXSkinInfo::ConvertToBlendedMesh. We currently have the source mesh stored in the MeshData member of the mesh container. This is where we want the resulting mesh to be stored, so we copy the source mesh pointer to a temporary SourceMesh pointer.

```
    ID3DXMesh * pSourceMesh = pMeshContainer->MeshData.pMesh;
    pMeshContainer->MeshData.pMesh=NULL;

    pMeshContainer->pSkinInfo->ConvertToBlendedMesh
                                (
                                    pSourceMesh,
                                    D3DXMESH_MANAGED|D3DXMESHOPT_VERTEXCACHE,
                                    pAdjacency,
                                    NULL, NULL, NULL,
                                    &pMeshContainer->NumInfl,
                                    &pMeshContainer->NumAttributeGroups,
                                    &pMeshContainer->pBoneCombinationBuf,
                                    &pMeshContainer->MeshData.pMesh
                                );

    pSourceMesh->Release ();
```

We pass in the source mesh and request that the resulting mesh be created as a managed resource which has the vertex cache optimization applied to it. We also pass in the adjacency information that was passed to CreateMeshContainer function and pass NULL for the following three parameters (we will have no need for the adjacency, vertex re-map, or face re-map information that this function generates for the output mesh). In the mesh container's NumInfl member will be stored the maximum number of bones that influence a single vertex in the mesh (which also tells us indirectly how many weights are stored in each vertex) and in the NumAttributeGroups member we store the number of subsets in the output mesh. The bone combination buffer is stored in the mesh container's pBoneCombinationBuf member and the converted output mesh is stored in the mesh container's MeshData.pMesh member.

Finally, we release the source mesh; we will be using the new mesh to render from this point forward because it contains the bone weight information the vertex blending module of the transformation pipeline needs for proper transformations.

At this point we have a mesh that contains the correct number of weights, but it is possible that some subsets in the output mesh may require the use of more matrices than is supported by the hardware. Recall that when the device is in software vertex processing mode we will always be able to render using up to four matrix influences. So taking this into account, before we return from the CreateMeshContainer function, we will loop through each subset in the output mesh and examine each subset's bone combination table. For each subset, we will examine the BoneId array of its D3DXBONECOMBINATION structure to count how many bone influences affect it. As soon as we find a subset that has more bone influences than the hardware supports, we will store the index of this subset in the mesh container's iAttributeSoftware member. All subsets up to this index can be rendered using hardware vertex processing and all subsets after that index (itself included) *may* have to be rendered with software vertex processing.

We start by getting a pointer to the mesh container's bone combination table which is stored inside an ID3DXBuffer:

```
LPD3DXBONECOMBINATION rgBoneCombinations  =
  (LPD3DXBONECOMBINATION)(pMeshContainer->pBoneCombinationBuf->GetBufferPointer());
```

We will now loop through each subset in the mesh:

```
 for (pMeshContainer->iAttributeSW = 0;
      pMeshContainer->iAttributeSW < pMeshContainer->NumAttributeGroups;
      pMeshContainer->iAttributeSW++ )
     {
```

For each subset we will loop through each element of its BoneId array which contains bone matrix indices that are used by this subset. If for example, the NumInfl member returned by the ConvertToBlendedMesh equals 4, then it means that the BoneId array will be 4 elements long (i.e., large enough to hold four matrix indices). If a particular subset only uses two bone matrices, the third and fourth elements will be set to UINT_MAX to indicate that they are unused. We can use this fact to count how many matrix blends the pipeline will need to perform to render this subset, as shown below.

```
            DWORD cInfl   = 0;
            for (DWORD iInfl = 0; iInfl < pMeshContainer->NumInfl; iInfl++)
            {
                if (rgBoneCombinations[pMeshContainer->iAttributeSW].BoneId[iInfl]
                   != UINT_MAX)
                {
                    ++cInfl;
                }
            }
```

At this point in the code, the DWORD local variable cInfl will tell us how many matrix blends the current subset we are checking will require. If this is larger than the maximum number of matrix blends supported by the hardware then we will break from the loop since we have just found the first subset that the hardware will not support. The index of this subset will be stored in the mesh container's iAttributeSoftware member because this was used as the loop variable to iterate through each subset.

```
            if (cInfl > m_d3dCaps.MaxVertexBlendMatrices)
            {
                break;
            }
        }
```

The iAttributeSoftware variable will now contain either the index of the first subset that cannot be rendered using hardware vertex processing or it will be equal to the number of subsets in the mesh if a non-hardware compliant subset was not found and the loop continued to completion. So if iAttributeSoftware is not equal to the number of subsets in the mesh then it means that part of this mesh will need to be rendered using software vertex processing.

Note however that the current mesh cannot be rendered using software vertex processing because when we create a mesh which we intend to use with software vertex processing on a mixed-mode device, we

must use the D3DXMESH_SOFTWAREPROCESSING mesh creation flag (which we did not do previously). Therefore, if this mesh needs to be software vertex processed, we will need to clone the mesh using this flag so that the resulting mesh can be properly rendered.

```
if (pMeshContainer->iAttributeSW < pMeshContainer->NumAttributeGroups)
{
   LPD3DXMESH pMeshTmp;
   pMeshContainer->MeshData.pMesh->CloneMeshFVF
   (
       D3DXMESH_SOFTWAREPROCESSING|pMeshContainer->MeshData.pMesh->GetOptions(),
       pMeshContainer->MeshData.pMesh->GetFVF(),
       m_pd3dDevice,
       &pMeshTmp
   );

   pMeshContainer->MeshData.pMesh->Release();
   pMeshContainer->MeshData.pMesh = pMeshTmp;
   pMeshTmp = NULL;
  }
 } // end if ID3DXSkinInfo!=NULL
} // End Function
```

The code clones the mesh into a temporary mesh and then releases the old mesh before assigning the newly cloned software processing enabled mesh to the mesh container's MeshData.pMesh member.

That brings us to the end of our non-indexed version of the CreateMeshContainer function. When D3DXLoadMeshHierarchyFromX returns control back to our application, the hierarchy will be loaded and all of our skinned meshes will be stored in their respective mesh containers along with their bone combination tables. Notice how the CreateMeshContainer function no longer requires the code that was used in the software skinning case that allocated (and resized) the temporary global matrix array. That array was only used to pass matrices into the UpdateSkinnedMesh function, which is not used when performing hardware skinning.

Do not forget that after D3DXLoadMeshHierarchyFromX returns control back to your program, you will still need to traverse the hierarchy and store the absolute bone matrices of each frame in the mesh container's ppBoneMatrixPtrs array, just as we did in the software skinning technique. You will recall that we wrote a function to do this called SetupBoneMatrixPointers and this function is unchanged regardless of the skinning technique used.

We have now seen everything there is to see with regards to setting up the hierarchy and storing the skinned meshes in a format which can be used by the non-indexed vertex blending module of the pipeline.

11.8.7 Transforming and Rendering the Skin

Animating the hierarchy is no different from the software skinning case (or in fact any animation of the frame hierarchy) -- we use the animation controller's AdvanceTime method to apply the animation data to the relative bone matrices of the hierarchy and then perform a pass through the hierarchy to recalculate the absolute matrix for each frame. So the next and final stage of the non-indexed skinning technique we need to look at is the code that would be used to actually render the mesh. We already know how to recursively traverse the hierarchy and call the DrawMeshContainer function for each mesh container found, so we will focus on this DrawMeshContainer function, just as we did in the software skinning technique.

Our drawing function in this example is passed a pointer to the mesh container to be rendered and a pointer to the owner frame. This frame is important if this is not a skinned mesh because this frame's combined matrix will be the matrix we wish to use as the world matrix to render the mesh.

The first thing this function does is cast the passed mesh container and frame to our derived class types.

```
void DrawMeshContainer (LPD3DXMESHCONTAINER pMeshContainerBase,
                        LPD3DXFRAME pFrameBase)
{

    D3DXMESHCONTAINER_DERIVED*pMeshContainer =
                                  (D3DXMESHCONTAINER_DERIVED*)pMeshContainerBase;

    D3DXFRAME_MATRIX *pFrame = (D3DXFRAME_MATRIX*)pFrameBase;

    UINT NumBlend;
    UINT iAttrib;
    LPD3DXBONECOMBINATION pBoneComb;
    UINT iMatrixIndex;
    D3DXMATRIXA16 matTemp;
    IDirect3DDevice9 * pDevice;

    pMeshContainer->MeshData.pMesh->GetDevice(&pDevice);
```

This function can be called for both skinned meshes and regular meshes so we will need to make sure (as we did in the software skinning version of this function) that we cater to both types. Because we are covering each of the skinning techniques in isolation for the purpose of clarity, in this version of the code we are assuming that if the ID3DXSkinInfo pointer stored in the mesh container is not NULL, then the mesh stored here is setup to be used with the non-indexed skinning technique.

The first thing we do is fetch the bone combination table of the mesh container so that we can get the matrix indices needed to render each subset.

```
    // first check if this is a skinned mesh or just a regular mesh
    if (pMeshContainer->pSkinInfo != NULL)
    {
```

```
        pBoneComb = ( LPD3DXBONECOMBINATION )
                    ( pMeshContainer->pBoneCombinationBuf->GetBufferPointer() );
```

Our next task will be very similar to the code we used to calulate the index of the iAttributeSoftware flag. For each subset we will first count how many matrices it requires for rendering. We will consider this the first pass over the mesh where we draw all subsets that can be rendered using hardware vertex processing.

```
        // Draw all subsets that can be rendered with Hardware Processing First
        for (iAttrib = 0; iAttrib < pMeshContainer->NumAttributeGroups; iAttrib++)
        {
               NumBlend = 0;
               for (DWORD i = 0; i < pMeshContainer->NumInfl; ++i)
               {
                   if (pBoneComb[iAttrib].BoneId[i] != UINT_MAX)
                   {
                       NumBlend = i;
                   }
                }
```

For each subset we will check to see whether or not the number of matrices that influence the subset (stored in the NumBlend local variable) is within the capabilities of the hardware. If so, we will fetch the matrix indices from this subset's BoneId array and use them to fetch the corresponding bone matrix and bone offset matrix stored in the mesh container. We will combine these two matrices to create a single world matrix and set that matrix in the relevant position in the device matrix palette (indices 0 through 3). The position of the index in the BoneId array describes which of the four matrix slots on the device the matrix should be bound to, as shown below.

```
               // Can we render this subset in hardware?
               if (m_d3dCaps.MaxVertexBlendMatrices >= NumBlend + 1)
               {
                   // Fetch each bone matrix for this subset.
                   // Combine with its offset matrix, and set it
                   for (DWORD i = 0; i < pMeshContainer->NumInfl; ++i)
                   {
                       iMatrixIndex = pBoneComb[iAttrib].BoneId[i];
                       if (iMatrixIndex != UINT_MAX)
                       {
                           D3DXMatrixMultiply( &matTemp,
                              &pMeshContainer->pBoneOffsetMatrices[iMatrixIndex],
                               pMeshContainer->ppBoneMatrixPtrs[iMatrixIndex] );

                           pDevice->SetTransform( D3DTS_WORLDMATRIX( i ),
                                                  &matTemp );
                       }
                  } // End for each matrix influence
```

At this point, the matrices are correctly set on the device for the current subset we are about to render and the local NumBlend variable tells us how many matrices have been set for this subset. This allows us to optimize the rendering by setting the D3DRS_VERTEXBLEND to process only the required number of matrices, instead of wastefully processing every weight defined in the vertex. We finally render the current subset (and repeat for every subset in the mesh).

```
                    pDevice->SetRenderState(D3DRS_VERTEXBLEND, NumBlend );

                    // lookup the material used for this subset of faces
                    Set Textures and Materials Here ( Not Shown )

                    pMeshContainer->MeshData.pMesh->DrawSubset(iAttrib);

                } // End can be rendered in hardware

            } // End for each attribute
```

At this point we will have looped through each subset and will have rendered all subsets that can be rendered using hardware vertex processing. However, some subsets may not have been rendered in the above loop if they required more matrix blends than the hardware supported. Therefore, we will now loop through the subsets and basically do what the above code did all over again. This time however, we will enable software vertex processing and render only the subsets that have more bone influences than the hardware supports. This is the second pass we discussed earlier in the lesson. Because we have stored (in the mesh container's iAttributeSoftware member) the index of the first subset that exceeds the hardware capabilities, we do not have to loop through every subset this time -- we just have to start from this index.

```
    // If necessary draw any subsets that the hardware could not handle
    if (pMeshContainer->iAttributeSW < pMeshContainer->NumAttributeGroups)
    {
       pDevice->SetSoftwareVertexProcessing(TRUE);

         for ( iAttrib = pMeshContainer->iAttributeSW;
               iAttrib < pMeshContainer->NumAttributeGroups;
               iAttrib++)
         {
               NumBlend = 0;
               for (DWORD i = 0; i < pMeshContainer->NumInfl; ++i)
               {
                   if (pBoneComb[iAttrib].BoneId[i] != UINT_MAX)
                   {
                        NumBlend = i;
                   }
               }

               if (m_d3dCaps.MaxVertexBlendMatrices < NumBlend + 1)
               {
                   // Fetch each bone matrix for this matrix.
                   // Combine with its offset matrix. And set it
                   for (DWORD i = 0; i < pMeshContainer->NumInfl; ++i)
                   {
                       iMatrixIndex = pBoneComb[iAttrib].BoneId[i];
                       if (iMatrixIndex != UINT_MAX)
                       {
                           D3DXMatrixMultiply( &matTemp,
                                &pMeshContainer->pBoneOffsetMatrices[iMatrixIndex],
                                 pMeshContainer->ppBoneMatrixPtrs[iMatrixIndex] );

                           pDevice->SetTransform( D3DTS_WORLDMATRIX( i ),
```

```
                                                &matTemp );
                        }
                    }

                    m_pd3dDevice->SetRenderState(D3DRS_VERTEXBLEND, NumBlend );

                    // Set Textures and Materials for the current Subset  Here

                    // draw the subset -- correct material/matrices are loaded
                    pMeshContainer->MeshData.pMesh->DrawSubset(iAttrib);

                } // end if can be rendered in hardware

            }  // end for each subset

            pDevice->SetSoftwareVertexProcessing(FALSE);

    } // end if software vertex processing subsets exist in this mesh
```

Finally, we disable vertex blending just in case any other objects in our scene need to be rendered.

```
                pDevice->SetRenderState(D3DRS_VERTEXBLEND, 0);
    } // end if this is a skinned mesh
```

If this was not a skinned mesh, then we render the mesh normally as shown below.

```
    else  // this is just a regular mesh so draw normally
    {
            pDevice->SetTransform(D3DTS_WORLD, &pFrame->mtxCombined);
            DrawMesh ( pMeshContainer->MeshData.pMesh )
    }
            pDevice->Release();

} // end function
```

And that is all there is to hardware non-indexed skinning. Although the code is fairly long, this is only because we repeat a lot of it to handle the two separate passes.

11.8.8 Non-Indexed Skinning Summary

Non-indexed Skinning: Advantages

- Vertex blending is performed in hardware by the GPU, making it faster than software skinning.
- We have the ability to optimize rendering of a subset by setting the D3DRS_VERTEXBLEND renderstate so that only the influential matrices are used. This

avoids the need for the pipeline to factor in matrix calculations that have zero weights which would not contribute towards the final world space position of the vertex.

- This form of hardware skinning is very well supported even on older T&L graphics hardware, although some hardware may not support all four possible matrix blends. Even if you do decide to support indexed skinning (discussed next) you should always implement this skinning technique as a fallback option because indexed skinning is not as widely supported in hardware.
- This skinning method can be used even if hardware support is not available as long as we create either a software or mixed-mode device. In this case, the vertex blending will be done in the software vertex blending component of the pipeline. This means that we can implement just this technique and have it work even when no hardware support is available for vertex blending.

Non-indexed Skinning: Disadvantages

- Only four bone influences per vertex (although this is usually more than enough).
- Because there is no information within each vertex specifying how each weight in the vertex maps to matrices in the device matrix palette, an implicit mapping is used where each of the four weights map to the first four matrices in the palette. This means that we can only use four out of the 256 matrix slots on the device. This results in the mesh being broken into many more subsets because each subset can only contain triangles that are influenced by the same four bone matrices.
- Only four bone influences per subset.
- Batch rendering severely compromised.

11.9 DirectX Skinning III: Indexed Skinning

The final skinning technique we will cover in this chapter is indexed skinning. Just like the non-indexed skinning technique, the geometry blending mechanism used is integral to the DirectX transformation pipeline. Indexed skinning is the most desirable skinning technique because it inherits the best aspects from both software skinning and pipeline skinning without the limitations of the non-indexed approach. Unfortunately, indexed skinning is not as widely supported in older hardware, but because it is part of the DirectX transformation pipeline, even if hardware support is not available, we can still perform this skinning technique with software vertex processing (assuming we have created a device for which software vertex processing is applicable).

On the bright side, indexed skinning works almost identically to its non-indexed cousin as far as implementation details go. So we will only have to cover a few changes to add indexed skinning support to our current code base.

In the previous section we learned that one of the biggest disadvantages of using non-indexed skinning was that we can only use four out of the 256 possible device palette world matrix slots. This was because each vertex in the blend-enabled mesh contains a number of weights, but no information describing which matrix slots on the device those weights are applicable to. The result was that a one to one mapping is implied, such that weights 0 – 3 in the vertex are always used to weight the contributions of world matrices 0 – 3 on the device (actual indices = 256 – 259). So even though the device supports 256 world matrices, any subset that we render could only consist of vertices that used the first four. One undesirable side effect was that batching was seriously compromised. Even if the entire mesh used only a single texture and material (which would usually cause all faces to be grouped into a single subset), the mesh would still have to be broken into multiple subsets, where each subset contained only the triangles that share the same four bone matrices.

When we think about the non-indexed case for a moment and lament the wasted matrices in the device matrix palette, we soon realize that our problems could all be solved if we had the ability to store matrix indices in each vertex. For example, if a vertex has N weights, then we would need to store N+1 matrix indices (because we recall that the N+1 weight is calculated on the fly in the pipeline). If we could do this, then when the pipeline transforms a vertex, it can examine each weight and its corresponding matrix index (the index would be a value between 0 and 255 describing which matrix in the device matrix palette the weight is defined for) and use the correct matrix to transform the vertex. If we had a mesh with 50 bones where all faces used the same texture, we could have a single subset because we would then have the ability to set all 50 bone matrices in the matrix palette simultaneously before rendering the mesh. Thus our batching optimizations are left intact. And if, practically speaking, each subset was no longer limited by how many matrices it can use and we consider that a vertex can still have four bone influences, then any given triangle could actually be manipulated by up to 12 unique bone matrices.

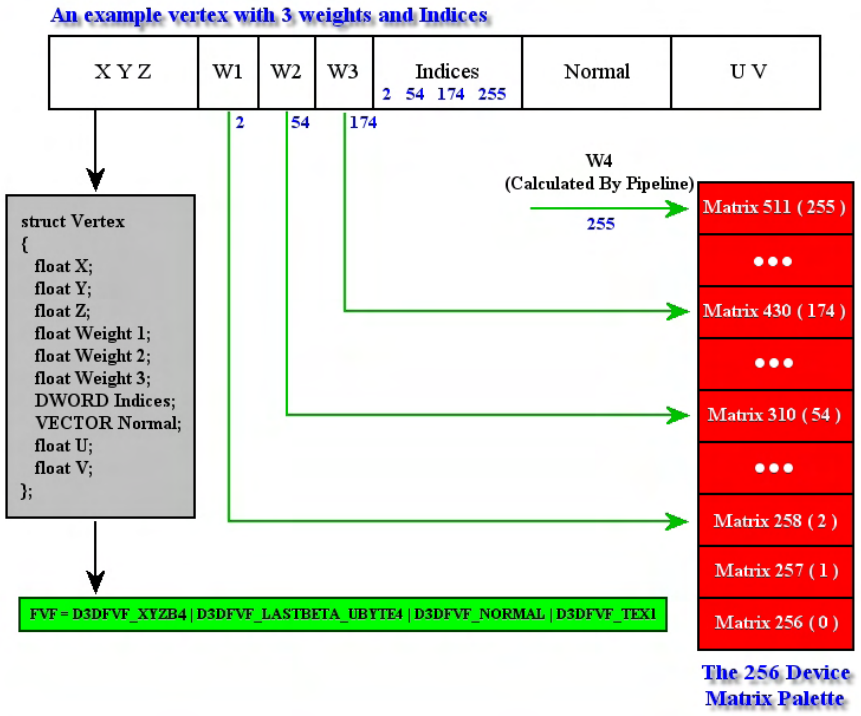

Figure 11.21

It just so happens that there is an FVF flag that allows us to place up to four matrix indices in our vertex structure in addition to the vertex weights. In Fig 11.21, the vertex has three weights (i.e. four bone influences) along with a new DWORD member called Indices. In each of the four bytes of the DWORD the index of one of the weights is stored. This tells the pipeline which matrix in the palette should be used with a given weight in the vertex to transform the mesh. In the example above, you can see that the vertex is to be transformed by the matrices stored in world matrix slots {2, 54, 174, 255}. These are the matrices used to transform this vertex for weights 1 through 4 respectively. We can imagine how another vertex in the same triangle might have a completely different set of indices, and this would hold true for every other vertex within the subset. Before rendering a subset, we just need to set all of the matrices that will be used by it (possibly even the entire bone hierarchy) in their respective matrix slots and then draw it.

11.9.1 Storing Matrix Palette Indices

Before continuing, we will take a look at the FVF flags that must be used to describe a vertex structure that includes both bone weights and matrix palette indices. These indices will take the form of the four individual bytes of a single DWORD. You would normally need to know these FVF flags when creating the vertex buffer that will store the indexed skin, but as it happens we can use a method of the ID3DXSkinInfo interface to work this out on our behalf. Like the ConvertToBlendedMesh function that we studied previously, which clones a normal mesh into one that includes weights, there is a second method that we will use for indexed skinning called ConvertToIndexedBlendedMesh. It does virtually the same thing as its sibling, only this time returns a mesh that has weights and indices defined in each vertex. Therefore, setting up the mesh for the indexed skinning technique is essentially identical to the non-indexed case. The exception is that we will call ConvertToIndexedBlendedMesh in our CreateMeshContainer function instead of the non-indexed version. Nevertheless, we will still look at the correct FVF flags that would be needed to create a vertex buffer that supports both weights and matrix palette indices just in case you need to build the buffer by hand.

Just for review, a vertex structure that would allow for three weights (four bone influences) is shown below along with the accompanying FVF flags.

```
struct NonIndexVertex
{
   D3DXVECTOR3 Pos;
   float Weight1;
   float Weight2;
   float Weight3;
   D3DXVECTOR3 Normal;
};

FVF = D3DFVF_XYZB3 | D3DFVF_NORMAL;
```

Recall that D3DFVF_XYZB3 informs the pipeline that the vertex will have an untransformed XYZ position and three float weights defined. Following the weights in this example we have also defined a vertex normal.

If we want to use the same basic structure, but include a matrix index for each weight then we have:

```
struct IndexVertex
{
   D3DXVECTOR3 Pos;
   float Weight1;
   float Weight2;
   float Weight3;
   DWORD Indices;
   D3DXVECTOR3 Normal;
};
```

The FVF for this structure is slightly less intuitive. There is a new FVF flag being used along with a change to one of the others.

```
FVF = D3DFVF_XYZB4 | D3DFVF_LASTBETA_UBYTE4 | D3DFVF_NORMAL;
```

The first thing you will notice is that we are now describing the vertex structure as containing four weights instead of three (D3DFVF_XYZB4). Technically this is not true of course since we only used three weights, but there is a catch. Since a DWORD and a FLOAT are both four bytes each in size, the above vertex data structure could be rewritten as:

```
struct IndexVertex
{
   D3DXVECTOR3 Pos;
   float Weight1;
   float Weight2;
   float Weight3;
   float Indices;
   D3DXVECTOR3 Normal;
};
```

Or we could even write the structure like so:

```
struct IndexVertex
{
   D3DXVECTOR3 Pos;
   float Weights[4];
   D3DXVECTOR3 Normal;
};
```

So we can see that while we might *define* the indices member as a DWORD (in the first structure) following the three weights to increase programmer readability, as far as the pipeline is concerned we are just passing it another four bytes. Therefore, our structure now has *space* for four weights defined.

Note that since a vertex cannot be influenced by more than four matrices, defining four weights would actually break this rule because it says it is influenced by five matrices. So our example flag would not actually work at all in the non-indexed case. The secret to the whole process is in the use of the second FVF flag shown above: D3DFVF_LASTBETA_UBYTE4. This flag tells the pipeline that the last weight (a weight is also sometimes called a *beta*) will be treated differently. It informs the pipeline that if it has been instructed to blend using N blend weights in the vertex, the Nth blend weight should not be used as a blend weight, but instead should be used as a four byte matrix palette index container.

So our FVF set above works with the vertex type we saw in Fig 11.21 -- a vertex with three actual blend weights (four bone contributions) and an additional four byte area containing the indices of up to four matrices in the device palette.

However, it must be made absolutely clear that D3DFVF_LASTBETA_UBYTE4 does not say that the last weight *defined in the vertex* will be the weight that will be used as an index container. Instead it says that the last weight that the pipeline has been instructed to process during vertex blending will be used as the index container. In other words, the last weight (last beta) is determined by the D3DRS_VERTEXBLEND render state and not by the number of weights defined in the vertex format. For example, if the D3DRS_VERTEXBLEND renderstate is set to D3DVBF_2WEIGHTS so that the pipeline will only process two weights for the vertex (three bone influences), the last beta in this example would be the third weight defined in the vertex (weight[2]). This weight would be treated as a DWORD with 4-byte indices. This is true even if the vertex contained four weights. So it would not be correct in our example, where the index data would be stored in the fourth weight, not the third.

We can see then that the D3DRS_VERTEXBLEND render state will also have to be set appropriately before rendering the mesh so that the correct weights are used for blending and the correct weight is used to feed matrix index data to the pipeline. Thus, we can no longer use the optimization that we did in the non-indexed case where we toggled the D3DRS_VERTEXBLEND render state between subsets to rid ourselves of zero weight matrix contributions. If we store our indices in the fourth weight for example, we will need this to be interpreted as the Indices member for all vertices that we render as defined by our vertex structure, regardless of the fact that there may be no-ops that result. The loss of this optimization is more than made up for however by the massive gains made from having much larger subsets.

Here is another example of a structure that will be indexed blended using three bone contributions (i.e. two weights).

```
struct IndexVertex
{
   D3DXVECTOR3 Pos;
   float Weight1;
   float Weight2;
   DWORD Indices;
   D3DXVECTOR3 Normal;
};

FVF = D3DFVF_XYZB3 | D3DFVF_LASTBETA_UBYTE4 | D3DFVF_NORMAL;
```

Our final example is an indexed vertex that has two bone contributions (1 weight) and its corresponding flags.

```
struct IndexVertex
{
   D3DXVECTOR3 Pos;
   float Weight1;
   DWORD Indices;
   D3DXVECTOR3 Normal;
};

FVF = D3DFVF_XYZB2 | D3DFVF_LASTBETA_UBYTE4 | D3DFVF_NORMAL;
```

11.9.2 Determining Support for Indexed Skinning

Before creating our mesh to use indexed skinning, we will need to determine what level of support the hardware provides. If the device is in software vertex processing mode, then indexed skinning will always be supported and we will be able to access all 256 world matrices on the device. But when using hardware vertex processing, things are not so simple.

First, if the device supports indexed blending at all, it may only support a subset of the 256 possible matrices. For example, a hardware device might support indexed vertex blending but only use the first 64 world matrix device slots. This is information we will need to know because it affects the way ConvertToIndexedBlendedMesh calculates the skinned mesh. If only 64 matrix palette entries are available, then the mesh will need to be adjusted to work with this limitation. This will typically involve breaking the mesh into separate subsets so that no single subset requires more than 64 matrices to be set simultaneously in order to render it. Therefore, when we call the ConvertToIndexedBlendedMesh function from our CreateMeshContainer function to convert our mesh into an indexed skinning compliant mesh, we will also pass in the number of matrices that the current device can support so that the function can make the appropriate adjustments.

We can query the device indexed skinning support by checking the MaxVertexBlendMatrixIndex flag in the D3DCAPS9 structure.

```
D3DDCAPS9 caps;
pDevice->GetCaps ( &caps );
DWORD MaxMatIndex = caps.MaxVertexBlendMatrixIndex;
if ( MaxMatIndex == 0)
{
    //No Hardware Support Available, Enable Software Processing
}
```

The MaxVertexBlendMatrixIndex member contains the value of the maximum index into the matrix palette that the device supports. For example, if this value is set to 63 then it means that this device does support hardware skinning but the pipeline can only use world matrices 0 through 63. Therefore, a single subset in the mesh can be influenced by no more than 64 matrices. In this example, the ConvertToIndexedBlendedMesh function would create a skinned mesh in which every subset uses no more than the first 64 matrices. This might result in more subsets than would otherwise be needed.

If MaxVertexBlendMatrixIndex is set to 0, then indexed geometry blending is not supported by the hardware at all. In this case we can choose to either fallback to software vertex processing or use the non-indexed skinning technique discussed earlier.

11.9.3 Storing the Skinned Mesh

Let us now look at how we might declare our mesh container structure to store the information needed to perform indexed skinning. Note that the frame hierarchy is stored in exactly the same way as we saw with the previous skinning techniques; it is only the way we create and render the mesh that has changed.

```
struct D3DXMESHCONTAINER_DERIVED: public D3DXMESHCONTAINER
{

    DWORD               NumAttributeGroups;
    DWORD               NumInfl;
    LPD3DXBUFFER        pBoneCombinationBuf;
    D3DXMATRIX**        ppBoneMatrixPtrs;
    D3DXMATRIX*         pBoneOffsetMatrices;
    DWORD               NumPaletteEntries;
    bool                UseSoftwareVP;
 };
```

There are two new members in our mesh container; the rest of the members have the same meaning they had in the non-indexed case.

DWORD NumPaletteEntries

This DWORD will store the size of the device matrix palette that is available for skinning. We will calculate this ourselves by querying the D3DCAPS9::MaxVertexBlendMatrixIndex. We will also have to factor in whether or not the mesh has vertex normals. As it happens, if the mesh does have vertex normals, then the number of matrices that the device can use is cut in half. If a device supports 200 matrices (MaxVertexBlendMatrixIndex = 199) then we can only use 100 of these matrices when the mesh has vertex normals because the normals will also have to be transformed. Therefore, if our mesh has normals, we will divide the MaxVertexBlendMatrixIndex value by two before passing it into ConvertToIndexedBlendedMesh. The ConvertToIndexedBlendedMesh function needs to know how many matrices are available for indexed skinning (i.e. the palette size) so that it can force the output mesh to use no more than this many matrices per subset. As discussed previously, if a subset needs to use more matrices than the device currently supports, the mesh will be subdivided into smaller subsets where each subset only uses the number of matrices available.

bool UseSoftwareVP

We will use this simple Boolean to indicate whether the device supports indexed skinning. If not, then we will have to place the device into software vertex processing mode in order to render it using the indexed skinning technique. When software vertex processing is used, the device will always support 256 world matrices (128 if the mesh has vertex normals).

11.9.4 The CreateMeshContainer Function

The first section of our updated CreateMeshContainer function is completely unchanged. We allocate the mesh container, copy the name of the mesh and, in this example, clone the source mesh if it does not contain vertex normals. This is not a requirement for skinning, but since we intend to use the DirectX lighting pipeline in our code, we will get this step out of the way now.

```
HRESULT CAllocateHierarchy::CreateMeshContainer
       ( LPCTSTR Name, LPD3DXMESHDATA pMeshData, LPD3DXMATERIAL pMaterials,
         LPD3DXEFFECTINSTANCE pEffectInstances, DWORD NumMaterials,
         DWORD *pAdjacency,
         LPD3DXSKININFO pSkinInfo, LPD3DXMESHCONTAINER *ppNewMeshContainer )
{
    D3DXMESHCONTAINER_DERIVED *pMeshContainer = NULL;
    UINT iBone, cBones;
    LPDIRECT3DDEVICE9 pd3dDevice = NULL;
    LPD3DXMESH pDestinationMesh = NULL;
    *ppNewMeshContainer = NULL;

    // Get a pointer to the mesh of the skin we have been passed
    pDestinationMesh = pMeshData->pMesh;

    // Allocate a mesh container to hold the passed data.
    // This will be returned from the function
    // where it will be attached to the hierarchy.
    pMeshContainer = new D3DXMESHCONTAINER_DERIVED;
    memset(pMeshContainer, 0, sizeof( D3DXMESHCONTAINER_DERIVED ));

    // If this mesh has a name then copy that into the mesh container too.
    if ( Name ) pMeshContainer->Name = _tcsdup( Name );

    // Get a pointer to the d3d device.
    pDestinationMesh->GetDevice(&pd3dDevice);

    // if no normals exist in the mesh, add them ( we might need to use lighting )
    if (!(pDestinationMesh->GetFVF() & D3DFVF_NORMAL))
    {
        pMeshContainer->MeshData.Type = D3DXMESHTYPE_MESH;

        // Clone the mesh to make room for the normals
        pDestinationMesh->CloneMeshFVF( pMesh->GetOptions(),
                                        pMesh->GetFVF() | D3DFVF_NORMAL,
                                        pd3dDevice,
                                       &pMeshContainer->MeshData.pMesh );

         pDestinationMesh = pMeshContainer->MeshData.pMesh;

        // Now generate the normals for the pmesh
        D3DXComputeNormals( pDestinationMesh, NULL );
    }
    else  // if normals already exist, just add a reference
    {
        pMeshContainer->MeshData.pMesh = pDesinationMesh;
```

```
        pMeshContainer->MeshData.Type = D3DXMESHTYPE_MESH;
        pDestinationMesh->AddRef();
    }
```

We now have a regular mesh stored in the mesh container, so it is time to check to see if we have been passed skinning information. When this is the case, we will start off with the same approach as in the previous version of the function -- we will store the ID3DXSkinInfo interface and bone offset matrices in our mesh container.

```
    // If there is skinning information, save off the required data
    // and then set up for skinning
    if (pSkinInfo != NULL)
    {
        // first save off the SkinInfo and original mesh data
        pMeshContainer->pSkinInfo = pSkinInfo;
        pSkinInfo->AddRef();

        // We now know how many bones this mesh has
        // so we will allocate the mesh containers
        // bone offset matrix array and populate it.
        NumBones = pSkinInfo->GetNumBones();
        pMeshContainer->pBoneOffsetMatrices = new D3DXMATRIX  [NumBones];

        // Get each of the bone offset matrices so that
        // we don't need to get them later
        for (iBone = 0; iBone < NumBones; iBone++)
        {
             pMeshContainer->pBoneOffsetMatrices[iBone] =
                 *(pMeshContainer->pSkinInfo->GetBoneOffsetMatrix(iBone));
        }
```

Now things will start to get a little different. We need to know if the current hardware can perform indexed skinning as well as any matrix limitations that may exist. If the device does not support enough matrices for this mesh, then software vertex processing will have to be invoked later to render it. Imagine a device that supports only six matrices to use for indexing. At first, this might not seem like a problem because we know that a single vertex can only be influenced by four matrices at most. However, our DrawPrimitive rendering units in this case are triangles, not single vertices. So the smallest item we can batch contains three vertices. If each of these three vertices used different matrices, then that triangle would need access to 12 matrices in order to be transformed. This would be beyond the capabilities of our example device so we would have to use software vertex processing.

How do we know if a single triangle in this mesh uses more matrices than the hardware has to offer? It just so happens that ID3DXSkinInfo has a method that calculates the maximum number of bones that influence a single triangle in the mesh. This function is called GetMaxFaceInfluences and is shown next.

```
HRESULT GetMaxFaceInfluences
(
    LPDIRECT3DINDEXBUFFER9 pIB,
    DWORD NumFaces,
    DWORD *maxFaceInfluences
);
```

Because ID3DXSkinInfo only contains the bone-to-vertex information, it has no idea how those vertices are arranged into faces in the mesh. So we must pass in the index buffer followed by the number of triangles in the buffer so that this can all be worked out internally. The third parameter is the address of a DWORD which on function return will contain the maximum number of bones that influence a single triangle in the mesh. We can use this value to determine whether the current hardware can cope with this mesh.

The code that calls this function to fetch the maximum face influence of the mesh follows:

```
        DWORD NumMaxFaceInfl;
        DWORD Flags = D3DXMESHOPT_VERTEXCACHE;
        LPDIRECT3DINDEXBUFFER9 pIB;
        pMeshContainer->MeshData.pMesh->GetIndexBuffer(&pIB);
        pMeshContainer->pSkinInfo->GetMaxFaceInfluences(
                                   pIB,
                                   pMeshContainer->MeshData.pMesh->GetNumFaces(),
                                   &NumMaxFaceInfl);
        pIB->Release();
```

As long as we have 12 matrices in the device matrix palette, we have enough to render any triangle and thus the mesh can be rendered in hardware. If the above function returned more than twelve (unlikely), then ConvertToIndexedBlendedMesh will be able to approximate the mesh to fit. Therefore, we take either the value returned from the previous function or the value of 12 (whichever is less) and check that the hardware supports it. If not, then we will set the D3DXMESH_SOFTWAREPROCESSING flag when we create the skinned mesh and set the mesh container's UseSoftwareVP Boolean to TRUE so that we know we will need to enable software vertex processing during rendering.

In software vertex processing mode we will always have 256 matrices available, so we also calculate the palette entries we will need on the device. Remember that we will feed this value into the ConvertToIndexedBlendedMesh function and it will subdivide the mesh so that no subset uses more matrices than the NumPaletteEntries we specify. Of course, we want this palette size to be a large as possible (no larger than 256 though) so that the mesh can be grouped into larger subsets.

In the following code we calculate this by taking the minimum of 256 and the number of bones in the mesh. This means that if there are more bones in the mesh than 256, then the mesh will need to be subdivided to some degree so that no subset uses more than this amount. If however, the number of bones is less than 256 then these are all the palette entries we need. For example, if there are 128 bones in the mesh, then we will only need at most 128 matrix palette entries to achieve maximum batching efficiency (forgetting about the vertex normals issue for the moment). The number of palette entries is also stored in the mesh container's NumPaletteEntries member because we will need this later during rendering to know how many elements will be in every subset's BoneId array.

```
        NumMaxFaceInfl = min(NumMaxFaceInfl, 12);

        if (m_d3dCaps.MaxVertexBlendMatrixIndex + 1 < NumMaxFaceInfl){
            // HW does not support indexed vertex blending. Use SW instead
            pMeshContainer->NumPaletteEntries = min( 256,
                                        pMeshContainer->pSkinInfo->GetNumBones());
            pMeshContainer->UseSoftwareVP = true;
            Flags |= D3DXMESH_SOFTWAREPROCESSING;
        }
```

The code above shows what happens when the device cannot support the maximum number of matrices that influence a single triangle in the mesh. The result is that we will need to switch over to software vertex processing at the appropriate time.

The following code demonstrates what happens when the hardware can support enough matrices to make sure that at least every triangle is rendered. Notice that in the hardware case we calculate the number of matrix palette entries we are going to use differently from the software case. This time we set the number of entries to either the number of bones in the mesh, or half the number of matrices the hardware can handle, whichever is less. The reason we divide the number of matrices the device can support by two is because we are assuming that the skin has normals. When the *hardware* is performing indexed skinning and the mesh has normals, half of the available matrix slots are reserved for vertex normal transformations. If the number of bones in the mesh is less than half the number of matrices supported by the device, then we can use this value since there is adequate space in the palette. If you are setting up a skin that does not contain normals, then the division by two will not be necessary and you will be able to use all of the matrix slots available on the device.

```
        else{
            pMeshContainer->NumPaletteEntries =
                                min((m_d3dCaps.MaxVertexBlendMatrixIndex + 1) /2,
                                pMeshContainer->pSkinInfo->GetNumBones() );
            pMeshContainer->UseSoftwareVP = false;
            Flags |= D3DXMESH_MANAGED;
        }
```

At this point, we have everything we need to create the indexed blended mesh. The following code shows the call to ConvertToIndexedBlendedMesh which creates a skinned mesh that has both weights and indices stored at the vertex level. It also returns the bone combination table describing which subsets use which matrices.

```
        ID3DXMesh * pSourceMesh = pMeshContainer->MeshData.pMesh;
        pMeshContainer->MeshData.pMesh=NULL;
        pMeshContainer->pSkinInfo->ConvertToIndexedBlendedMesh
                                            (
                                             pSourceMesh,
                                             Flags,
                                             pMeshContainer->NumPaletteEntries,
                                             pMeshContainer->pAdjacency,
                                             NULL, NULL, NULL,
                                            &pMeshContainer->NumInfl,
                                            &pMeshContainer->NumAttributeGroups,
                                            &pMeshContainer->pBoneCombinationBuf,
                                            &pMeshContainer->MeshData.pMesh
                                            );
       pSourceMesh->Release();
    } // end if skin
} //end function
```

When this function returns, we will have a mesh stored in our hierarchy that is ready to be rendered using the pipeline indexed skinning techniques discussed previously.

11.9.5 ID3DXSkinInfo::ConvertToIndexedBlendedMesh

Let us finish off our discussion on creating indexed skinned meshes by looking at the ConvertToIndexedBlendedMesh method of the ID3DXSkinInfo object. This function is very similar to the ConvertToBlendedMesh function used to create the non-indexed skinned mesh in the previous section. The exception is one extra parameter where we specify to the function the number of matrix palette entries we have available for our device. This allows the function to manipulate the mesh such that no single subset uses more matrix influences than this.

```
HRESULT ConvertToIndexedBlendedMesh(

    LPD3DXMESH       pMesh,
    DWORD            Options,
    DWORD            paletteSize,
    CONST LPDWORD    pAdjacencyIn,
    LPDWORD          pAdjacencyOut,
    DWORD           *pFaceRemap,
    LPD3DXBUFFER    *ppVertexRemap,
    DWORD           *pMaxVertexInfl,
    DWORD           *pNumBoneCombinations,
    LPD3DXBUFFER    *ppBoneCombinationTable,
    LPD3DXMESH      *ppMesh
);
```

All of the parameters are the same as the ConvertToBlendedMesh call with the exception of the third parameter (paletteSize). Please refer back to our earlier discussions if you need a refresher on these other parameters.

DWORD paletteSize
This is the number of world matrices that are available for use on the current device. If we were to pass in a value of 64 for this parameter, then this function would subdivide the mesh into different subsets such that no single subset needs to be rendered using more than 64 matrices.

We have now covered everything needed to load and store the indexed skinned mesh. With the exception of one or two places, the code did not change much from the non-indexed case. When D3DXLoadMeshHierarchyFromX returns, the hierarchy will be loaded and will contain all of our indexed skinned meshes in their respective mesh containers.

Once again you are reminded that animating the hierarchy is identical in all of the skinning cases we have covered. We will call the animation controller's AdvanceTime method and then traverse the hierarchy to build the absolute bone matrices for each frame.

11.9.6 Transforming and Rendering the Skin

When we are ready to render our indexed skinned mesh we take the same approach as always – we traverse the hierarchy looking for mesh containers and call their drawing functions as they are encountered. This part is no different than what we have seen in the previous sections. So let us now look at what the DrawMeshContainer method would look like in the indexed skinning technique and then our work is done. This version of DrawMeshContainer is actually the smallest of all the techniques studied.

The first thing that this function does is cast the passed mesh container and frame to our derived class formats.

```
void DrawMeshContainer (LPD3DXMESHCONTAINER pMeshContainerBase,
                        LPD3DXFRAME pFrameBase)
{
    D3DXMESHCONTAINER_DERIVED*pMeshContainer=
                                (D3DXMESHCONTAINER_DERIVED*)pMeshContainerBase;

    D3DXFRAME_MATRIX *pFrame = (D3DXFRAME_MATRIX*)pFrameBase;

    UINT NumBlend;
    UINT iAttrib;
    LPD3DXBONECOMBINATION pBoneComb;
    UINT iMatrixIndex;
    D3DXMATRIXA16 matTemp;
    IDirect3DDevice9 * pDevice;
    pMeshContainer->MeshData.pMesh->GetDevice(&pDevice);
```

After retrieving a copy of our device, we check to see if the mesh stored in this mesh container is a skinned mesh. If so, then we check to see if the mesh needs to be rendered using software vertex processing and enable it if necessary.

```
    if (pMeshContainer->pSkinInfo != NULL)
    {
            if (pMeshContainer->UseSoftwareVP)
            {
                pDevice->SetSoftwareVertexProcessing(TRUE);
            }
```

Next we will set the D3DRS_VERTEXBLEND render state so that we inform the pipeline about how many weights our vertices will have. This tells the pipeline that the N+1 weight in our vertex structure is where the matrix indices are stored. We have this information stored in our mesh container's NumInfl member because it was returned by ConvertToIndexedBlendedMesh. If NumInfl is set to 1 then it means that although we wish to perform indexed blending, there are no weights in the vertices. In this case each vertex will be influenced by one matrix with an assumed weight of 1.0. Every vertex in a subset may still be influenced by a different matrix in the palette, even in this case when the vertex does not have weights (although it would still have the weight being used as matrix indices); we are still performing

indexed matrix transformations and a given triangle could be transformed by up to three matrices (one per vertex).

```
      if (pMeshContainer->NumInfl == 1)
          pDevice->SetRenderState(D3DRS_VERTEXBLEND, D3DVBF_0WEIGHTS);
```

If NumInfl is not 1 then we can just subtract one from it to tell us the number of weights that our vertices use (remember that the number of weights is always one less than the number of influences). So for any cases other than NumInfl = 1 we can use this fact to map directly to the enumerated type for vertex blending.

```
      else
          pDevice->SetRenderState(D3DRS_VERTEXBLEND, pMeshContainer->NumInfl - 1);
```

As a reminder, the flags of the D3DVERTEXBLENDFLAGS enumerated type are assigned the following values:

```
D3DVBF_DISABLE = 0,
D3DVBF_1WEIGHTS = 1,
D3DVBF_2WEIGHTS = 2,
D3DVBF_3WEIGHTS = 3,
D3DVBF_TWEENING = 255,
D3DVBF_0WEIGHTS = 256
```

Having set the D3DRS_VERTEXBLEND render state to correctly describe our vertex format and the weights we wish to use for blending, our next job is to inform the pipeline that we wish to perform indexed vertex blending instead of the standard non-indexed blending. We do this using a device render state that we have not yet seen, called D3DRS_INDEXEDVERTEXBLENDENABLE. It will be set to TRUE or FALSE to enable or disable indexed vertex blending, respectively. So before we render our skin, we must enable it:

```
     pDevice->SetRenderState(D3DRS_INDEXEDVERTEXBLENDENABLE, TRUE);
```

Next, we get a pointer to the mesh container's bone combination table which will contain all of the bone indices used by each subset.

```
     pBoneComb = ( LPD3DXBONECOMBINATION)
                 (pMeshContainer->pBoneCombinationBuf->GetBufferPointer());
```

For each subset we loop through the BoneId array of its bone combination structure. We have stored in the mesh container the size of the matrix palette being used by this mesh, so this is exactly how large the BoneId array of each subset will be. We fetch each matrix index from the subset's BoneId array and, assuming it does not contain UINT_MAX, this is a matrix slot that will be used by this subset. We use the index to fetch the bone matrix from the mesh container and combine it with its corresponding bone offset matrix and set the resulting matrix at its correct slot in the device matrix palette.

```
      for (iAttrib = 0; iAttrib < pMeshContainer->NumAttributeGroups; iAttrib++)
      {
         for ( iPaletteEntry = 0;
```

```
                iPaletteEntry < pMeshContainer->NumPaletteEntries;
            ++iPaletteEntry  )
        {
             iMatrixIndex = pBoneComb[iAttrib].BoneId[iPaletteEntry];
             if (iMatrixIndex != UINT_MAX)
             {
                 D3DXMatrixMultiply( &matTemp,
                              &pMeshContainer->pBoneOffsetMatrices[iMatrixIndex],
                               pMeshContainer->ppBoneMatrixPtrs[iMatrixIndex] );

                 pDevice->SetTransform( D3DTS_WORLDMATRIX( iPaletteEntry ),
                                        &matTemp );
             }
        }
```

By the time we have exited the iPaletteEntry loop above, we will have set all of the matrices used by the current subset in their proper device palette slots. This might be only two matrices or might be over two hundred depending on how many triangles are in the subset and how many matrices need to be used to transform them.

We can now set the textures and material used by the subset (not shown here for simplicity).

```
       //Set Textures and Material of subset here
```

Finally, we render the current subset with the correct palette of matrices that we have just set up.

```
        pMeshContainer->MeshData.pMesh->DrawSubset( iAttrib );

    } // end current attribute 'iAttrib'

  } // end If skin Info != NULL

  else // this is just a regular mesh so draw normally
  {
       pDevice->SetTransform(D3DTS_WORLD, &pFrame->mtxCombined);
       DrawMesh ( pMeshContainer->MeshData.pMesh)
  }

  pDevice->Release();

} // end function
```

As with all other versions of this function, the last section of code is executed if the mesh stored in this mesh container is not a skinned mesh. In that case it is rendered normally, as discussed in previous lessons.

11.9.7 Indexed Skinning Summary

Indexed Skinning Advantages

- Significantly faster than all other skinning techniques because effective batch rendering is maintained when the hardware has a sizable matrix palette.
- Supported in software vertex processing mode if no hardware support exists.
- Possible 256 matrix influences per subset and 12 influences per triangle.

Indexed Skinning Disadvantages

- Not as widely supported as non-indexed, even on fairly recent 3D hardware.
- Still limited to a maximum of 4 matrix influences per vertex, whereas the software skinning technique has no limitation.

Conclusion

We have now covered all three skinning techniques in isolation and have even looked at a lot of basic code to implement them. For a complete implementation description you should now turn to your workbook that accompanies this lesson. It will integrate all three skinning methods into a single mesh class that will make for a nice plug-in to our application framework.

We are not quite finished with our skinning discussions just yet. Our focus in this lesson was almost entirely on how to load and store skins that were pre-generated and stored in X files. In the next chapter, we will use many of the ideas we learned about in this lesson to do things a little differently -- we will create skins, skeletons, and even animations all procedurally. The result will be a solid understanding of how the entire process works, and from a practical perspective, a nice tree class that we can use to liven up our outdoor scenes. Make sure you are comfortable with all of the code we cover in the workbook for this chapter as it will be expected that you understand it when you work on the lab projects in the next chapter.

Workbook Eleven: Skinned Meshes and Skeletal Animation I

Introduction

In the previous lab project we extended our CActor class so that it was possible for an application to use its interface to apply animations to the frame hierarchy. Furthermore, we implemented a system such that these animated actors hierarchies could be efficiently instanced. In this lab project, we will extend CActor to provide automated transformation and rendering support for skinned meshes. Lab Project 11.1 will concentrate on extending the CActor code to support the loading and rendering of skinned meshes using vertex blending and these changes will be demonstrated in an updated viewer application. This will demonstrate our CActor object's ability to play back pre-animated scene hierarchies comprising of both static and skinned meshes. That is, both static and skinned mesh types existing together in a single frame hierarchy.

Lab Project 11.1 – Adding Skinning Support to CActor

You might assume that in order to upgrade our actor code to support the loading and rendering of skinned mesh data, we would need to create a new class; an addition to CActor that is used in special cases for handling skinned mesh data. After all, skinned meshes are processed quite differently from the regular meshes stored in a multi-mesh X file. This is certainly true in the case of actually rendering these entities. However, there is no reason why we cannot extend our actor class elegantly to support both skinned and static mesh hierarchies. This would allow our application to use a single interface for handling both types of mesh data, making the separate tasks usually performed to load and render these two different mesh types invisible to the application.

If you think about how our actor currently works, you should recognize that the changes to the code will not need to be so dramatic. Our actor currently handles the loading and rendering of single or multi mesh (non-skinned) hierarchies. With such a hierarchy, the X file will contain a frame hierarchy which in turn will contain one or more static mesh containers. Each mesh container will contain the data for a single static mesh and will be attached to a single frame in that hierarchy. When this data is loaded from the X file, the data is laid out in the same way inside the actor as we have seen in the previous lab projects.

We know that before we render our actor we must first apply any animations to the relative frame matrices of the hierarchy and then perform a traversal of the hierarchy to update the absolute matrices for each frame. At that point, we are ready to render all the meshes in that hierarchy. The current rendering strategy of our actor similarly involves another traversal of the hierarchy. Currently, when we render our actor, we start at the root frame and traverse the entire hierarchy looking for mesh containers. Whenever we find a frame with a mesh container structure attached, we know that this frame owns a mesh. At this point, we set the frame's absolute matrix as the current world matrix for the D3D device and render the mesh stored there. After we have traversed the hierarchy, all meshes managed by the actor will have been rendered.

So, what needs to be changed in order to render skinned meshes stored in a hierarchy? The first obvious difference is that the absolute frame matrix alone no longer describes the position and orientation of the

skinned mesh within the hierarchy (or world). Instead, the mesh container will contain an ID3DXSkinInfo object which will tell us the connection between vertices in the skin and frames/bones in the hierarchy. More specifically, it will tell us which matrices in the hierarchy should be used to multi-matrix transform (vertex blend) the vertices of each subset of the mesh. Before rendering each subset, we must find the absolute matrices of the frames that influence that subset. We then set these matrices on the device, enable vertex blending, and then render the triangles in that subset. The frames of our hierarchy which influence the transformation of subsets in our skinned mesh are often referred to as the 'bones' of the mesh. The absolute matrices for these frames are referred to as the bone matrices. While this often sounds a bit scary to the uninitiated, we are quite used to working with bones. They are, after all, just frame matrices going by a different name.

At first, it seems that the rendering method of the actor would need to be able to maintain two modes. If it is an actor that contains skinned meshes we should render using the slightly more complex multi-matrix blending method; if not, we render using the single matrix method that our actor has supported for the last few lessons. However, this is not quite the way we want our actor to work. We do not want our actor to be in either one mode or another because it is possible (and not at all uncommon) that we might load an X file (or procedurally build a hierarchy) that contains both static and skinned meshes all within a single hierarchy.

It may be difficult at first not to visualize a hierarchy that contains a skinned mesh, as always being limited to defining the bones (skeletal structure) of a single character or object. It is more intuitive for us to picture an actor as containing a single character bone hierarchy containing a single skinned mesh for which the the hierarchy forms its skeleton. If we were to extend our actor to only work in this way, then we would indeed be able to have an actor that works in one of two modes. However, we would find this extremely limiting and it would actually fail to correctly manage and render a large number of X files and scene configurations which contain both skinned and regular meshes all within the same frame hierarchy.

For example, in lab project 11.1, we show how an X file is loaded into our new viewer application. It is worth remembering that the X file could actually contain an entire scene and not just a single skinned mesh. That is to say, it could contain the static geometry for lots of buildings and multiple skinned meshes (for example). The X file could also contain pre-recorded animation data that when played, make the characters walk about within that scene. This is a single X file, which means it would be managed and rendered by a **single actor**. The actor will have a frame hierarchy that contains not only the frames to position the static meshes in the scene (the rooms, buildings, and tables, etc.) but also, sub-sections of that hierarchy will contain the complete skeletons for two or more character meshes (the skins). While translation keyframes are applied to the skeletons of each character to make them move around the scene independently from each other, they are still attached to the root frame of the scene and share the same frame hierarchy with other static meshes. The character skeletons are now just sub-sections of that entire scene hierarchy. The animation controller defined for this scene would only apply animations to the frames of the hierarchy that comprise the character skeletons. Therefore, the static and skinned meshes are all connected and the entire pre-recorded scene (including the character meshes) could be repositioned somewhere else in world space simply by applying a new world matrix to the actor's root frame.

One thing should be clear from the above discussion. We need to allow our actor's hierarchy to manage both skinned and static meshes and allow them to harmoniously co-exist within the same actor hierarchy. The actor's rendering logic should be extended such that it can recognize and render both types of mesh when doing a render traversal. For example, when traversing the hierarchy during a render pass, it will search for all frames that have a mesh container attached. For each one that is found, it will need to determine whether or not this mesh container stores a skinned or regular mesh and choose a suitable rendering strategy for each case.

As discussed in the textbook, when a frame hierarchy is being loaded and mesh data is attached to a frame (a relationship defined in the X file), the ID3DXAllocateHierarchy::CreateMeshContainer call-back function will be called. This function accepts an ID3DXSkinInfo interface pointer, which we have thus far ignored in previous lab projects. If this pointer is NULL, then it means the mesh currently being loaded is a static mesh and we load it in the same way we have in all previous projects. If this interface pointer is not NULL, then it means there is also skinning information defined for this mesh in the X file. Since the D3DXMESHCONTAINER structure contains an ID3DXSkinInfo pointer member, we can store this ID3DXSkinInfo interface pointer in the mesh container during the hierarchy loading/creation process. We will need it later anyway to figure out which frame matrices in the hierarchy must be used to transform its various subsets. The upshot of this is, during the rendering traversal of the hierarchy, whenever we find a mesh container, we can simply test to see if its ID3DXSkinInfo pointer member is set to NULL. If it is, then it is not a skinned mesh and should be transformed and rendered in the regular way (by simply setting the absolute matrix of the current frame as the device world matrix prior to rendering that mesh). If it is not NULL, then we know we have a skinned mesh and can deploy an entirely new rendering strategy for that mesh. With the latter case, we would use the ID3DXSkinInfo object to determine which matrices to set simultaneously on the device prior to rendering each subset of the skin.

With this type of logic in place, our application can use a single CActor to load any type of scene without having to worry about what that scene contains; it will not have to perform any special processing in the skinned case. The application may use the actor to load an X file which contains a single skinned mesh character (where the hierarchy represents a single character skeleton) for example, or it may use the actor to load an entire scene of static meshes. The actor could also be used to load an X file that contains both a mix of regular and skinned meshes. In every case, the application has no logic to perform; it simply calls CActor::LoadActorFromX and lets the actor handle the details of both loading and rendering that geometry.

An example of a scene that might contain multiple static and skinned meshes might be a forest scene. The basic hills, valleys and buildings comprising the the scene would be arranged hierarchically and would be constructed as static meshes. However, it may also contain a few trees that sway in the wind. We might decide that the trees themselves will be represented as skinned meshes and frames will be added to the hierarchy inside the tree branches to act as the branch bones. The artist might then build animations to rotate and translate those bones in a random pattern so that the branches appear to be swaying in the wind. The actor will handle this automatically and the application will use the actor in exactly the same way as it has in previous projects. The actor will still have a single frame hierarchy and will still apply animations (via its animation controller) to certain frames in that hierarchy. The fact that some of those frames (the ones being animated) are actually being skinned by branch meshes, does not effect the hierarchy representation or the way animations are applied to that hierarchy.

For example, consider a simple example of a winter tree that has a tree trunk and four branches stored in an X file.

Figure 11.1

While this might look like a single tree mesh, assume it consists of five separate meshes. The tree trunk would be one mesh and each of the four branches shooting off of the main trunk might also each be individual meshes. The artist might decide when building this tree that the branches should sway in the wind and therefore might decide to place some frames/bones inside the branches. We will imagine for now that the root frame has been placed inside the trunk. The artist could build subtle animations that would be applied to the branch frames to make them move by some small amount as a result of wind being applied. We might decide however that as the trunk of the tree itself would never actually move, we will not make it a skinned mesh like the four branch meshes. This decision might be made in an attempt to aid rendering performance as rendering a skinned mesh is more computationally expensive. Now, this is a slightly odd example because normally you would make the entire tree a single skinned mesh so that no cracks or gaps appear between the branch meshes and the trunk, but bear with us for the purposes of this example.

We know that when the above tree was exported, we would have an X file that contained a frame hierarchy. In that hierarchy there would exist five meshes -- one static mesh (the tree trunk) and four skinned meshes (the tree branches). Therefore, while the hierarchy described by the X file would essentially contain the bones of the entire tree, not all meshes contained in the hierarchy would need to be multi-matrix transformed when rendered. For the sake of this example, let us imagine the frame hierarchy for the tree was defined as shown below in Figure 11.2.

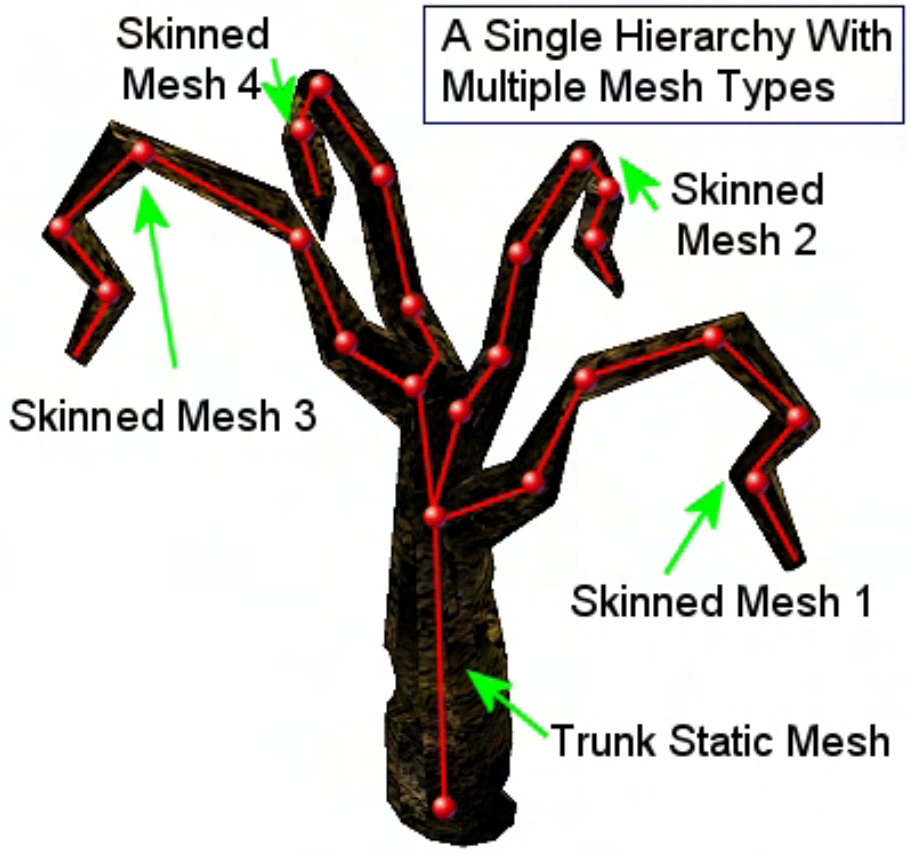

Figure 11.2

The bone (red sphere) at the bottom of the tree trunk is assumed to be the root frame in this diagram and its absolute matrix would be used to directly position the static trunk mesh prior to rendering. We might say then, that this is not a bone at all in the traditional sense. The rest of the frames in the hierarchy are bones as these will be mapped to vertices in the branches such that, when animation data rotates or translates these bones matrices, the branches of the tree will be animated. The root frame however is not a bone in the traditional sense as its absolute matrix is not used directly to transform and render any of the vertices in the branch meshes. That is, we will never set the root frame's absolute matrix while rendering the skins; we only do this when we render the trunk mesh (in which case it will be the only matrix set on the device). However, the root frame is certainly a bone in another sense as any rotations or translations applied to this bone will alter the positions and orientations of all the other bones in the tree also.

Figure 11.3 shows how a tree might be represented as a hierarchy in the X file and inside our actor. Figure 11.3 is not an accurate depiction of the bones used in 11.2, but will serve for the purpose of this example.

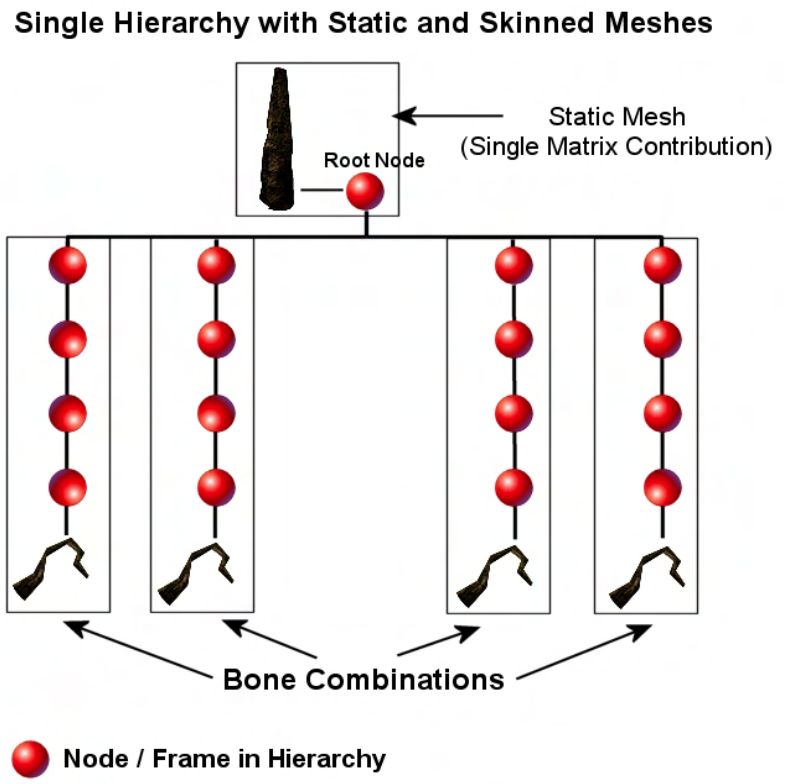

Figure 11.3

In Figure 11.3 we can see how the hierarchy looks with both its static trunk mesh and its four branch skins. In this example, the trunk mesh is in a mesh container attached to the root node. Since this is a static mesh, the absolute matrix of the root node will be used as the world matrix for rendering this static mesh. As children of the root node, there are several frames that will be used as the bones of the branch meshes. The block boxes indicate the frames in the hierarchy that influence each mesh.

Looking at this example, we can see that our actor is using a combination of static and skinned meshes. Let us walk through the rendering strategy, assuming that all animations have been applied and the absolute matrix of each frame has been updated and is now ready for the rendering traversal pass.

Our actor's rendering function would start at the root frame. It would find that there is a mesh container there, but would also discover that this mesh container contains no skinning information. This means it is a static mesh and the absolute matrix stored in the root is the actual world matrix that should be set on the device to correctly transform and render the mesh. So the matrix would be set as the current world matrix on the device and the mesh would be rendered.

We would now discover that this frame has children, so we would then traverse into each of these little sub-hierarchies. We will step through the traversal of the left-most sub-hierarchy first. We would get the first child frame and discover that no mesh container is stored there, so there is nothing to render. We would then step down into its child where the same discovery would be made again. There is still nothing to do so we would step down into the third level of this sub-hierarchy where once again, there is

no mesh data attached and nothing to render. Finally, we would step down into the fourth frame of this sub-hierarchy where the skin (i.e., branch mesh) is actually stored in a mesh container.

At this point we would test to see if this mesh container had skinning information loaded for it and would find that it does indeed have a valid pointer to an ID3DXSkinInfo interface. This means this is a skinned mesh. We would now have to loop through each subset in the mesh and set all the matrices that influence that subset in the device's matrix palette. With all the matrices that influence the subset now bound to the device, we would enable vertex blending and render the subset. In this example, the four matrices that share the black box with the branch mesh (Figure 11.3) would be sent to the device (combined with their respective bone offset matrices) and used to multi-matrix transform the vertices of the subset into world space. For both regular and skinned meshes, we must render every subset. Unlike in the regular case however, when rendering a skinned mesh, each subset may require a different set of bone matrices to be sent to the device before it is rendered. Therefore, when rendering the skinned mesh, we are no longer just concerned with batch rendering by texture and material. We must now also make sure that we also set the correct matrices for each subset that we render, giving us yet another batching key to worry about for efficient rendering.

You will see when we cover the upgraded code for CActor, that each mesh container that stores a skinned mesh will also store a bone combination table. This will be calculated at hierarchy load time (inside the ID3DXAllocateHierarchy::CreateMeshContainer method) and will contain information describing, for each subset in the skin, which matrices must be set on the device in order to render it.

So we now know that our actor should have the ability to render a hierarchy that may contain skinned and regular meshes and we should place no burden on the application to provide any support for this. We want CActor to encapsulate the hierarchy loading, animation, transformation, and rendering just like it always has, including handling the cases of skinned meshes in our scene.

For another more complex example, an X file might contain multiple tree representations like the one previously described. The skeletal structures for each tree could be combined in a single hierarchy as shown in Figure 11.4. In this example the X file contains two trees. Each tree has a static trunk mesh and four branch skins. In this example, each trunk mesh is a child of the root. This shows an example of an X file/hierarcy that contains both multiple static and skinned mesh types.

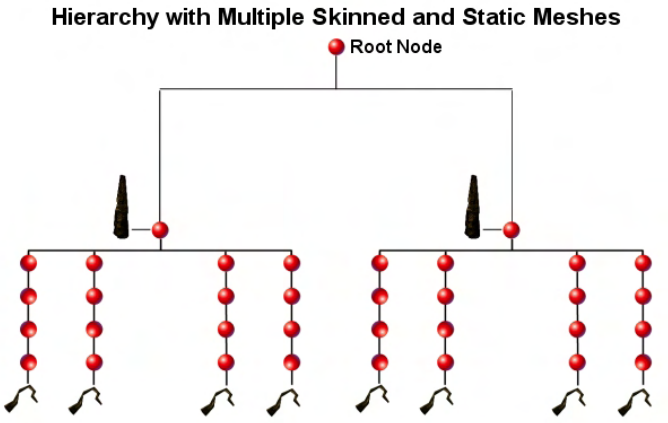

Figure 11.4

Not only should CActor handle skinned mesh support behind the scenes without burdening the application with any significant additional work, it should also support a number of different skinning techniques. We learned in the accompanying textbook that there are three types of skinning techniques we can use when performing character skinning.

We would like our actor to be able to support software skinning. While this is the slowest technique available to us (because the hardware is not utilized for purposes of transformation), it is also the only technique that imposes no limitations on the number of bones which can influence a single vertex, triangle or subset. Therefore, we may sometimes find that if we wish to accurately render a skinned mesh with an extremely complex skeletal structure and maintain its integrity to the best of our ability, we may sacrifice speed for the ability to render an object which has many bone contributions per vertex. When using hardware techniques, we can never have more than four bone influences per vertex, so software skinning support within CActor may come in handy. While it is extremely rare in real-time work that you would ever need to render geometry that uses more than four bones contributions per vertex, let us not shy away from providing that ability. We never know when we might need it.

We will also want CActor to support two types of hardware skinning that is available on most DirectX 9 graphics cards on the market today. Non-indexed skinning is usually the least desirable of the hardware techniques available because, while the hardware is utilized for the multi-matrix vertex transformations, this speed savings can be offset (sometimes) by the fact that we can only set four matrices on the device at any one time. This usually results in the source mesh being divided into many small subsets such that no single subset is influenced by more than four bones (even if the triangles share the same texture and material). This is a shame, since we know that we could usually render all triangles that share the same textures and material with single draw call. This need to render based on bone contribution creates smaller subsets and can reduce batch rendering performance.

One of the saving graces of the non-indexed case is that we can at least optimize the rendering a little by making sure that when we render a subset, we only use the weights and matrices that the subset actually needs. For example, if we render subset A which has four bone contributions, we can set the D3DRS_VERTEXBLEND renderstate such that the three weights (the fourth is created on the fly by the pipeline) are used to weight the contributions of the matrices in matrix slots 1-4 on the device. However, if subset B is only influenced by two matrices, we can adjust the D3DRS_VERTEXBLEND render state so that only one weight (the second weight is generated on the fly) is used to weight the matrix contributions of matrices in device slots 1-2 only. This way we do not waste time transforming vertices by four matrices regardless of whether a subset is actually influenced by all four of those matrices. This is a worthwhile optimization since all of our vertices will share the same vertex format. If one vertex in the mesh is influenced by four bones, every vertex in the mesh will be transformed by four weights (with space for three in its vertex structure). If a given subset is only influenced by two bones, the remaining two unused weights in the vertex structure will be set to zero, and any matrices that are assigned to slots 3 and 4 on the device will have their contribution zeroed out when the vertex is transformed. The problem with this is that without trimming the number of weights used on a per-subset basis (using the D3DRS_VERTEXBLEND renderstate), the vertices would still be transformed by all four matrices even though the weights of the vertex would zero out the contributions of the final two matrices in this example (making them unnecessary). We never want to be performing unnecessary vertex/matrix multiplications on a per-vertex level since this is very inefficient.

We also want our CActor to support hardware indexed skinning.This same optimization cannot be performed in the indexed skinning case, because the vertex weight containing the indices will always be in the same position in each vertex. Therefore, if we have an indexed skin where one vertex is influenced by four bones, the first three weights (the fourth weight is created on the fly) will always be used to weight the contributions of four matrices. The fourth weight in the vertex structure is used to hold the four matrix indices. In this example, even if a subset is only influenced by two bones (which would only require a single vertex weight in the non-indexed case), the indices will still be stored in the fourth vertex weight and the pipeline will need access to them. So we must set the D3DRS_VERTEXBLEND render state so that all weights (up to the weight that stores the indices) are used. This may cause vertex-matrix multiplications to occur unnecessarily for weights that are set to zero. Of course, this downside is often a worthy tradeoff for the fact that in the indexed skinning case, we have a much bigger matrix palette at our disposal and (potentially) the ability to have a single subset influenced by 256 matrices without having to be subdivided. The result is fewer subsets in the indexed skin and thus greatly enhanced batch rendering performance.

So it seems that our actor will need code to load and render static and skinned meshes simultaneously, and it must also have multiple paths of code for rendering skinned meshes using the three skinning techniques available. The code to load, store and render software skins, non-indexed skins and indexed skins is all slightly different and our actor will need to implement all paths.

Intelligent Auto-Detection

Not only will our actor support the three unique flavors of skinning, it should also provide a means for the application to specify which skinning technique is preferred. Of course, while it is definitely necessary in some circumstances for the application to specifically state which skinning technique should be used, in the general case, most applications would simply prefer the most efficient one to be chosen given the limitations of the hardware it is running on. So we can implement a method that would allow the application to specify the type of skinning it would like the actor to use and we will certainly do that. However, we will not stop there. We do not want to place the burden on the application to determine which skinning techniques are available on the current system before informing the actor of its choice. Therefore, we will also implement a useful auto-detection mode that will allow the application to let the actor determine the best skinning technique to use, based on the installed hardware. The application can simply load the X file and let the actor perform the hardware capability tests before choosing an appropriate skinning method. This maintains the actor's plug and play design goal. We wish to use CActor in any application without excess burden placed on the application. As far as the application is concerned, our actor should just be an object in the world that can be animated and rendered each frame (via its interface). The fact that the actor is internally a complex hierarchy of both regular and skinned meshes should not pollute the application code.

In addition to implementing an auto-detection feature in our actor (as well as a means to allow the application to specifically state which skinning mode the actor should use if it wishes), we will also implement a 'hint' system that the application may use to help bias the auto-detection mechanism of the actor. This will help it make the correct choice on the application's behalf.

Without any hints being passed to the actor by the application, the auto-detection mechanism will make the logical choice under most circumstances. If the hardware can support a mesh using indexed skinning, then this will be chosen and the loaded mesh will be converted into an indexed skin. As we know, this is usually the optimal choice. If hardware support for indexed skinning fails, then the actor will test the hardware for non-indexed skinning support. If this is supported then this will be the next best solution. In other words, if we have hardware support for both indexed and non-indexed skinning solutions for the mesh, the auto-detection mechanism will always choose indexed over non-indexed.

There may be times however when you wish to change this behavior. You may decide that you would like the actor to choose non-indexed hardware skinning over hardware indexed skinning if both are supported. Therefore, we will have several 'hint' flags that the application can pass to the actor to suggest this preference. While it may seem as if you would never want to do such a thing, there are times when non-indexed skinning can actually outperform indexed skinning due to the elimination of the zero contribution weights during rendering. Also, it may be the case that the hardware incurs a slight performance hit when performing indexed skinning due to the additional lookup into the matrix palette. You will usually find however, that the larger matrix palette and subsets resulting from indexed skinning allow it to outperform the non-indexed method.

Finally, what should our auto-detection method do if hardware support for both indexed and non-indexed skinning is absent? You might think that we would fall back to the pure software skinning mode in this case, but that is not what we will do. In fact, the auto-detection mechanism of CActor will never fall back to using the pure software skinning technique by itself. If this mode is required, it must be specifically asked for by the application. What the auto-detection mechanism will do when no hardware support for skinning is available, is use software vertex processing versions of the pipeline's skinning methods. Remember, just because the hardware does not support indexed skinning, does not mean that we cannot use DirectX's skinning pipeline. It simply means we will need to enable software vertex processing when processing this mesh such that the vertices of the mesh are transformed in software (using the host CPU) instead of by the hardware. DirectX's indexed and non-indexed skinning methods will always be available to us even if hardware support for skinning is unavailable. Therefore, what our auto-detection mechanism will do in the absence of any hardware skinning methods, is choose the pipeline's non-indexed skinning method using software vertex processing. We have generally found in our own lab tests that software non-indexed skinning is faster than software indexed skinning in a variety of cases. This is likely due to the fact that the redundant matrix multiplications with zero weight vertices in the indexed case incur a much higher performance hit now that the matrix multiplication is being done on the host CPU. However this is quite dependant on the model and as such, is not always the case. Therefore, the application will also be able to instruct the actor to choose software indexed skinning first (if desired) through the use of 'hint' flags to the auto-detection system.

We now have a path that will always locate an applicable skinning technique even if there is no hardware support. Once again though, even in the software case, hint flags can be used to bias the auto-detection process. We will have a flag that will instruct the actor that if no hardware support is available, we would prefer to use indexed skinning with software vertex processing rather than non-indexed skinning with software vertex processing (the default software technique that is used if no hardware is available).

The CActor class now has a new enumerated type that contains a number of flags. The application can pass one or more of these flags into the CActor::SetSkinningMethod member function prior to loading the actor (via CActor::LoadActorFromX). The SetSkinningMethod function simply stores the passed flags in a new actor member variable so that the LoadActorFromX method will be able to access this information when deciding what type of skin to create.

Below you can see the new SkinMethod enumeration which is now part of the CActor namespace. It contains a number of flags that can be passed into the SetSkinningMethod member function to describe how we would like the meshes to be built during the loading process.

```
enum SKINMETHOD    { SKINMETHOD_INDEXED    = 1,
                     SKINMETHOD_NONINDEXED = 2,
                     SKINMETHOD_SOFTWARE   = 3,
                     SKINMETHOD_AUTODETECT = 4,
                     SKINMETHOD_PREFER_HW_NONINDEXED = 8,
                    SKINMETHOD_PREFER_SW_INDEXED = 16 };
```

Below is a description of the various flags and how they will influence the auto-detection mechanism of the actor during loading.

SKINMETHOD_INDEXED
This flag is tells the actor that we wish to use the pipeline's indexed skinning method. This flag disables the auto-detection process. If hardware support for indexed skinning is not available, then the pipeline's software vertex processing pipeline will be used to perform the indexed skinning. This flag is mutually exclusive to all other flags.

SKINMETHOD_NONINDEXED
This flag is tells the actor that we wish to use the pipeline's non-indexed skinning method. This flag disables the auto-detection process. If hardware support for non-indexed skinning is not available, then the pipeline's software vertex processing pipeline will be used to perform non-indexed skinning. This flag is mutually exclusive to all other flags.

SKINMETHOD_SOFTWARE
Specifying this flag will disable the actor's auto-detection mechanism and tells it *not* to use the DirectX pipeline's skinning methods and to prefer the full software skinning technique instead. Specifying this flag is the only way the actor will ever use a full software skinning implementation. When in pure software mode, the DirectX pipeline will not be used in any way to transform the vertices of the skin into world space. Instead, we will perform the multi-matrix transformation of vertices from model space into world space ourselves. Rendering this mesh will require us setting the world matrix to an identity matrix since we will be passing DirectX a world space transformed skin. This is all done inside the actor's rendering code.

This is the slowest skinning method but is useful if you do not wish to have any limitations placed on the geometry. Even when using software vertex processing with DirectX's skinning methods, we are still limited to a maximum of four influences per vertex. With a pure software implementation this is not the case. We are not limited by either the number of bones that influence a vertex or the number of matrices that can be used in total. This flag is mutually exclusive to all other flags.

SKINMETHOD_AUTODETECT
This is the auto-detection mode flag. It can be combined with the final two modifier flags (shown below). This flag cannot be combined with any of the three flags described previously.

This flag places the actor into auto-detection mode; the default mode of the actor. When a mesh is loaded the actor will query the capabilities of the hardware and choose (what it considers to be) the most appropriate method. It will first try to use hardware indexed skinning. If not available, it will try to use hardware non-indexed skinning as the next best option. Finally, if hardware non-indexed skinning is not available, it means there is no hardware support. It will then fall back to using the pipeline's non-indexed skinning technique with software vertex processing.

This is the default behavior of the auto-detection process. However, you can combine any of the following flags with the SKINMETHOD_AUTODETECT flag to alter the way in which the auto-detection mechanism chooses it skinning technique:

SKINMETHOD_PREFER_HW_NONINDEXED
This is a hint flag that can be combined with SKINMETHOD_AUTODETECT. It can also be combined with SKINMETHOD_PREFER_SW_INDEXED. It changes the default auto-detection process of finding a suitable hardware method such that the actor will first favor non-indexed hardware skinning over indexed hardware skinning if both are supported. You may find with some models that non-indexed skinning may actually be faster than indexed skinning. This hint flag gives the application control in these circumstances. If this hint flag is not used, indexed skinning will always be favored in hardware.

SKINMETHOD_PREFER_SW_INDEXED
This is another hint flag that can be combined with SKINMETHOD_AUTODETECT. It can also be combined with SKINMETHOD_PREFER_HW_NONINDEXED. It changes the default auto-protection process for finding a suitable software skinning method if no hardware support is found. Be default, if no hardware support for skinning is available, it will choose the pipeline's non-indexed skinning method using software vertex processing. This flag instructs the actor, in the absence of hardware support, to favor the pipeline's indexed skinning method with software vertex processing.

These flags cover all options and provide our actor with either explicit instructions about which skinning method to use, or asks for the auto-detection mode to be used along with hint flags that can be used to further control the process. This means our actor will always be able to find a suitable skinning technique without burdening the application with any detection code. For example, in lab project 11.1, the following code is now used to load the actor:

```
CActor * pNewActor = new CActor;

pNewActor->RegisterCallback(  CActor::CALLBACK_ATTRIBUTEID,
                              CollectAttributeID, this );

pNewActor->LoadActorFromX( strFileName, D3DXMESH_MANAGED, m_pD3DDevice );
```

As you can see, nothing has changed at all. We simply allocate a new actor, set the callback method to handle the loading and storing of texture and material resources (optional), and then load the actor just like we always have. We have not even set the skinning method of the actor. So how does the actor know which method to use when loading in skinned data from the X file?

It just so happens that the skinning method of the actor is set to SKINMETHOD_AUTODETECT by default in the constructor. Therefore, since this is the mode you will probably use for your actor object's most of the time, we do not even have to bother setting it. The same code our application used to load a simple mesh hierarchy is now being used to load a hierarchy with (potentially) multiple regular and skinned meshes and animation data. Note how our changes to the actor class have not affected the way the application uses it. Our actor will even been rendered in exactly the same way as previous lab projects since it will be the actor's internal rendering code that will handle the detection and rendering of any skinned meshes contained within.

While the above code is probably how your application will most likely use the actor, it does not demonstrate the various flags we just discussed. If you wish to change the skinning method used by the actor, or bias its auto-detection mechanism from the standard path in some way, you must use these flags and the CActor::SetSkinningMethod function to inform the actor *prior to* loading the X file. Let us have a look at some examples that we might use:

Example 1

```
CActor * pNewActor = new CActor;

pNewActor->RegisterCallback(  CActor::CALLBACK_ATTRIBUTEID,
                              CollectAttributeID, this );

pNewActor->SetSkinningMethod ( CActor::SKINMETHOD_INDEXED );

pNewActor->LoadActorFromX( strFileName, D3DXMESH_MANAGED, m_pD3DDevice );
```

In this example, after creating the actor and registering its attribute callback function, we use the SetSkinningMethod to inform the actor that we definitely wish to use indexed skinning. When the actor is loaded, if hardware support for indexed skinning is available, it will be chosen. However, if no hardware support is available then the pipeline's indexed skinning technique will still be used but with software vertex processing. Even if hardware support for non-indexed skinning is available, it will not be chosen.

Example 2

```
CActor * pNewActor = new CActor;

pNewActor->RegisterCallback(  CActor::CALLBACK_ATTRIBUTEID,
                              CollectAttributeID, this );

pNewActor->SetSkinningMethod ( CActor::SKINMETHOD_SOFTWARE );

pNewActor->LoadActorFromX( strFileName, D3DXMESH_MANAGED, m_pD3DDevice );
```

This example shows the only way the application can instruct the actor to completely bypass the DirectX pipeline's skinning techniques and use a pure software implementation. This can be used for special cases where the DirectX skinning techniques would not suffice (e.g. you wish to use a model that has more than four influences per vertex, and do not want it downgraded to fit the pipeline's techniques).

This is the slowest mode when skinned meshes are contained in the actor hierarchy, because all transformations will happen in software.

Example 3

```
CActor * pNewActor = new CActor;

pNewActor->RegisterCallback(  CActor::CALLBACK_ATTRIBUTEID,
                              CollectAttributeID, this );

pNewActor->SetSkinningMethod ( CActor::SKINMETHOD_AUTODETECT |
                               CActor::SKINMETHOD_PREFER_HW_NONINDEXED |
                               CActor::SKINMETHOD_PREFER_SW_INDEXED );

pNewActor->LoadActorFromX( strFileName, D3DXMESH_MANAGED, m_pD3DDevice );
```

In this example we chose the actor's auto-detection mechanism for finding a suitable skinning method. However, rather than the default mode, we also specify two hint flags. With these two flags the auto-detection mechanism will always try to find a hardware skinning solution first. However, if both indexed and non-indexed skinning techniques are available, it will choose non-indexed hardware skinning. The second hint flag will be ignored if a hardware solution is found and will only influence the auto-detection process when searching for a software solution. The normal strategy of the auto-detection process when no hardware solution is found is to use the pipeline's non-indexed skinning technique with software vertex processing. This flag will instruct the actor to use the pipeline's indexed skinning technique with software vertex processing instead.

We now understand how we wish the auto-detection method of the actor to work. This will go a long way towards helping us understand the code when we examine it. However, before we finally delve into the CActor code, we should discuss how textures, materials, and other attribute based properties will be handled for skinned meshes within the hierarchy.

Skinned Meshes and Subset IDs

In our previous implementations of CActor, each mesh (a CTriMesh) in the hierarchy had the ability to be in either managed or non-managed mode. In managed mode, each mesh contained its own list of texture pointers and materials, and the attribute IDs of each triangle in the attribute buffer indexed into this local list. This meant that attribute IDs were local to the mesh. If the mesh had 5 subsets, the attribute IDs of each triangle have values between 0 and 4. In this mode, the mesh is self-rendering since it has everything it needs stored internally. The mesh renders itself by looping through each of its subsets, setting the texture and material in the matching position in its attribute array before rendering the subset.

This causes a slight problem when dealing with skinned meshes because after we have converted the mesh into a skin (using either ConvertToBlendedMesh or ConvertToIndexBlendedMesh) the resulting mesh will contain completely different subsets from the original mesh that was loaded. The mesh may have been subdivided into additional smaller subsets based on bone influence. The problem is that the
