original per-subset attribute information is loaded by D3DX with a 1:1 mapping with subset IDs. We know that the first texture and material in the mesh's internal attribute array (texture and material table) is the texture and material for the first subset, and so on. After mesh conversion, we would now have an array of attributes stored in the mesh but we can no longer use the new subset IDs of the returned skinned mesh to index into this attribute table. The 1:1 mapping has been lost.

Imagine that subset 0 in the original mesh (which uses texture[0] and material[0]) was influenced by 8 bones and we are using non-indexed skinning and a managed mode mesh. We know that the maximum number of influences per subset in this case can be four. When we use the ID3DXSkinInfo::ConvertToBlendedMesh function to convert the original mesh to a skin, it would have detected this fact and would have split this subset into two in the resulting mesh. Therefore, what was originally a single subset with an ID of 0, has now been split into two subsets with IDs of 0 and 1 respectively. The attribute IDs of all triangles that were in the **original** second subset (assuming one existed) have been incremented so that they now belong to the third subset, and so on. This is done so that the two new subsets that have replaced the initial subset can be rendered one at a time using four matrices each, which the pipeline can handle.

Now we see the problem. Subsets 0 and 1 in the new mesh originally belonged to the same subset (subset 0) so they both must use texture[0] and material[0] in the mesh's attribute array when rendered. The problem is, in managed mode, we always used a 1:1 mapping between subset IDs and attributes in this array in our rendering logic, and this has now been compromised. To render subset 1 in the new mesh, we must still use texture[0] and material[0] and not texture[1] and material[1]. Of course, this is a simple example but in a more complex case, all the original subsets may have been divided into multiple subsets in the resulting mesh. This would mean that all of the attribute IDs of every triangle in the attribute buffer will have been changed. It would seem as if there is no longer a way for us to determine which attribute should be used with which subset.

Of course, this is not the case, because if it were, converting a mesh to a skin would be useless. As an example of how we must overcome this problem, let us imagine that we get passed a mesh in the CreateMeshContainer method that contains skinning information. Let us also imagine that this mesh originally has five subsets. Because this is a skinned mesh we will need to convert the mesh into a skin by using either the ConvertToBlendedMesh function or the ConvertToIndexBlendedMesh function depending on whether we wish to create an indexed or non-indexed skin.

Assuming we are in managed mode for this example, the first thing we might do is load the textures (using the callback) and materials and store them in the mesh's attribute array. At this point all is well because the attribute IDs of each triangle simply index into this texture and material array we have generated inside the mesh. So before we render subset[4], we would need to set texture[4] and material[4]. However, our final task will be to convert this mesh to a skin using ID3DXSkinInfo::ConvertToBlendedMesh. At this point a new mesh will be created and the original one can be released. Let us also assume that the ConvertToBlendedMesh function decided to subdivide every subset in the original mesh into two unique subsets in the resulting mesh for reasons of coping with the maximum bone influences. In the new mesh we now have ten subsets instead of five. The subset IDs of this mesh will now range from 0 – 10 even though our texture and material array still ranges from 0 – 5.

All would be lost for us at this point were it not for the fact that ConvertToBlendedMesh returns an array of D3DXBONECOMBINATION structures. There will be one element in this array for each subset in the **new** skinned mesh. In our example this means there will be 10 elements in this array. Each element in this array contains the rendering information for each subset in the new mesh. It contains an array of bone matrix indices which must be set on the device prior to rendering the subset and also provides useful information such as where the vertices and faces in this subset start and end in the vertex and index buffers respectively. This allows us to efficiently transform and render only the sections of the vertex and index buffer that is necessary when rendering a subset. Finally, and most important to this discussion, is that each D3DXBONECOMBINATION structure also contains the original subset ID that this new subset was created from. As we originally had a 1:1 mapping between the subset IDs and the attributes in the attribute buffer, this original subset ID member tells us exactly where the texture and material we need to use to render this new subset is stored in the mesh attribute array

```
typedef struct _D3DXBONECOMBINATION {
    DWORD AttribId;
    DWORD FaceStart;
    DWORD FaceCount;
    DWORD VertexStart;
    DWORD VertexCount;
    DWORD *BoneId;
} D3DXBONECOMBINATION, *LPD3DXBONECOMBINATION;
```

The AttribId member is the key. It tells us the original index into the attribute array (the array of textures and materials) that should be used to render this subset. If the original first subset (subset 0) was divided into two unique subsets in the skinned mesh, the AttribId member of the first two D3DXBONECOMBINATION structures will be set to 0. This indicates that the first two subsets should use texture[0] and material[0] in the original attribute array.

With this in mind, when rendering a skin in managed mode, our rendering strategy will need to be changed a little. We will still loop through each subset and render it; the only different now is what we consider to be the number of subsets and what we use to index into the attribute array. Previously, we knew that if a managed mesh had five attributes, then it has five subsets, and we could simply render the mesh using the following pseudo-code strategy:

```
for ( i = 0 ; i < NumSubsets ; i++)
{
     pMesh->DrawSubset[i];
}
```

In the above code, we are looking at how the actor might render the various subsets of a CTriMesh stored in a mesh container. If we remind ourselves of the code inside CTriMesh::DrawSubset we can see the rendering logic is simple:

Excerpt from CObject.cpp in previous lab projects

```
void CTriMesh::DrawSubset( ULONG AttributeID )
{
    LPDIRECT3DDEVICE9 pD3DDevice = NULL;
    LPD3DXBASEMESH    pMesh      = m_pMesh;
```

```
    // Retrieve mesh pointer
    if ( !pMesh ) pMesh = m_pPMesh;
    if ( !pMesh ) return;

    // Set the attribute data
    if ( m_pAttribData && AttributeID < m_nAttribCount )
    {
        // Retrieve the Direct3D device
        pD3DDevice = GetDevice( );

        pD3DDevice->SetMaterial( &m_pAttribData[AttributeID].Material );
        pD3DDevice->SetTexture( 0, m_pAttribData[AttributeID].Texture );

        // Release the device
        pD3DDevice->Release();

    } // End if attribute data is managed

    // Otherwise simply render the subset(s)
    pMesh->DrawSubset( AttributeID );

}
```

Take a while to examine the above function and see if you can detect the problem this function will cause going forward. This function implies the 1:1 mapping between the subset ID which is about to be rendered and the texture and material stored in the attribute array. The ‘if’ statement basically determines whether the mesh’s attribute array exists. If it does, this then is a managed mesh and this table contains a texture and material for each subset. As you can see, the subset ID passed into the function is used to fetch the texture and material from the attribute array before making the call to the ID3DXMesh::DrawSubset function to render the triangles. If the attribute array does not exist, then this means this is a non-managed mode mesh and the scene will have already taken care of setting the correct texture and material for this subset. In this case, we simply render the subset.

We have been using this strategy for rendering managed mode meshes all along, and will continue to use the same strategy for managed regular meshes in our actor’s hierarchy. However, if the mesh we intend to render is a skin, then its mesh container will contain an array of D3DXBONECOMBINATION structures, one for each subset in the new mesh. The pseudo-code to render it inside the actor would be as follows (non-indexed example). In this example, pMesh is a pointer to a CTriMesh in our hierarchy.

```
for ( i = 0; i < NumSubsets; i++ )
{
    long AttribID = pBoneCombinationArray[i].AttribId;

    pMesh->DrawSubset[ i , AttribId ];
}
```

Of course, this is a pretty vague example but we will get to the actual code soon enough. The important point here is simply that the before rendering each subset in the skin, we fetch the original ID of the subset we are about to render from the bone combination structure. This is also the index of the texture and material that the original subset used, so we can use it to access the correct texture and material in our array before rendering the subset.

In order to facilitate this change, we will slightly modify our CTriMesh::DrawSubset method. Previously, this method had a single parameter, an attribute/subset ID. As we have seen, this is used to fetch a texture and a material from the mesh's array and set it on the device prior to rendering the requested subset. However, in the above example, we can see that when the actor is rendering a skinned mesh, it needs to pass two parameters into the CTriMesh::DrawSubset. The first parameter should be the attribute/subset ID as always. This is the subset in the underlying ID3DXMesh whose triangles we wish to render. However, now the subset IDs no longer match the position of their respective textures and materials in the managed mesh's attribute array. So, as the second parameter, we pass in an attribute override. In other words, the first parameter describes the physical subset in the mesh we wish to render, while the second parameter contains the index of the texture and material in the managed mesh's attribute array. Therefore, what the above code is doing, is looping though each subset in the new skinned mesh, and using its original subset ID (from the non-skinned mesh) to fetch the texture and material that should be used to render the subset.

Let us have a look at the new version of the CTriMesh::DrawSubset method and how this additional parameter is used. This additional parameter has a default value of –1, meaning no material override will be used and the 1:1 mapping between the subset ID and the attribute table is maintained as before. This means the actor can render managed mode regular meshes in exactly the same way as our prior lab projects simply by not passing in the second parameter.

The new CTriMesh::DrawSubset Method

```
void CTriMesh::DrawSubset( ULONG AttributeID, long MaterialOverride /* = -1 */ )
{
    LPDIRECT3DDEVICE9 pD3DDevice = NULL;
    LPD3DXBASEMESH    pMesh      = m_pMesh;
    ULONG             MaterialID = (MaterialOverride < 0) ?
                                    AttributeID : (ULONG)MaterialOverride;

    // Retrieve mesh pointer
    if ( !pMesh ) pMesh = m_pPMesh;
    if ( !pMesh ) return;

    // Set the attribute data
    if ( m_pAttribData && AttributeID < m_nAttribCount )
    {
        // Retrieve the Direct3D device
        pD3DDevice = GetDevice( );

        pD3DDevice->SetMaterial( &m_pAttribData[MaterialID].Material  );
        pD3DDevice->SetTexture ( 0, m_pAttribData[MaterialID].Texture );

        // Release the device
        pD3DDevice->Release();

    } // End if attribute data is managed

    // Otherwise simply render the subset(s)
    pMesh->DrawSubset( AttributeID );
}
```

As you can see, the new CTriMesh::DrawSubset code is almost identical except for the following line:

```
ULONG MaterialID = (MaterialOverride < 0) ? AttributeID : (ULONG)MaterialOverride;
```

What is happening here is quite simple. We are simply saying that if the material override is –1, then there is no material override and we should assume a 1:1 mapping between the subset ID and the element in the attribute array which contains the subsets texture and material (managed mode only). However, if a material override has been passed in (which will always be the case for a skinned mesh) then we are stating that the material override value should be used to index into the attribute array to fetch the correct texture and material for the subset being rendered.

If we have the actor in non-managed mode, things are quite different for skinned meshes. With regular meshes, we simply passed the loaded texture and material to an attribute callback function. This function (implemented by the CScene class in our code) would store the texture and material in some external array and would return the index of the element in this array back to the mesh. The mesh would then lock the attribute buffer of the mesh and would re-map all faces in the current subset being processed to this new ID value. The non-managed mesh did not store the textures or materials and actually had no idea what the global ID assigned to its triangles even meant. It doesn't matter though because the scene will handle setting the correct textures and materials before rendering those subsets, not the mesh itself. It was possible (as we have previously discussed) that after the global re-mapping of a non-managed mesh, its subset IDs might no longer even be zero based. For example, a mesh which was loaded from an X file with three subsets (0, 1, 2) might be remapped by the scene such that the subset IDs end up being (75, 104, 139). These are just arbitrary numbers as far as the mesh is concerned, but to the scene object, these are global IDs into its own texture and material arrays. In this example, the scene would know that the first subset would need to be rendered using texture[75] in its scene global texture array. There may be other non-managed meshes in the scene which also have subsets with an ID of 75. The scene would know that all of these subsets could be batch rendered because they all share the same texture. In other words, the re-mapping makes the subset IDs of a mesh global instead of local, allowing shared subsets across mesh boundaries.

While none of this is new to us, when an actor is in non-managed mode, we must handle skinned meshes very differently from regular meshes (which will still use this same strategy). We will still have the non-managed mode actor working exactly the same from the applications perspective and this will still allow us to re-map the skinned meshes subsets to use a global pool of textures and materials stored at the scene level. However, unlike the case of a regular mesh, we definitely must *not* lock the skinned mesh's attribute buffer and change the subset IDs of its triangles. Remember, the zero based subset IDs in the skinned mesh have a 1:1 mapping with the D3DXBONECOMBINATION array (calculated when the conversion into a skinned mesh happens), so if we go blindly fiddling with the attribute IDs of triangles in a skinned mesh, we will lose the ability to determine which D3DXBONECOMBINATION structure in its array is applicable to each subset in the skin. As a result, we will no longer know which bone matrices must be bound to the device prior to rendering eaxch subset. No, we must leave the actual subset IDs alone in the skinned mesh case so that we know that BoneCombination[5] for example, describes the bone matrices that must be set before we render subset[5] in the skinned mesh.

Of course, all is not lost. In fact, when you think about what we are trying to achieve you find that in many ways handling global subset IDs in the skinned case is actually easier than in the regular case. The whole point of this mode is really just to allow the mesh to use textures and materials stored in the

scene's database. We can do that simply by re-mapping the AttribId member of each bone combination structure instead of having to re-map the attribute IDs of the triangles themselves.

As a quick example, let us assume that our actor is in non-managed mode. We know that this will mean that that an application defined attribute callback function will have been registered with the actor and used to re-map all the attribute IDs into global IDs. The following snippet of code shows how after a mesh is loaded, if it is in non-managed mode, we loop through each subset in the mesh and call the attribute callback function. This function is called for each subset and passed the texture and material which the scene can store somewhere. The function will return a new global ID for that subset. This is a snippet from the CreateMeshContainer method we have been using in previous projects. In this code, you are reminded that we collect all the new global subset IDs in the local pAttributeRemap array. At the end of this code, each element in this array will describe the new global ID's of each subset.

```
for ( i = 0; i < NumMaterials; ++i )
{
   if ( Callback.pFunction )
   {
      COLLECTATTRIBUTEID CollectAttributeID = (COLLECTATTRIBUTEID)Callback.pFunction;
      AttribID = CollectAttributeID( Callback.pContext, pMaterials[i].pTextureFilename,
                                     &pMaterials[i].MatD3D, &pEffectInstances[i] );

       // Store this in our attribute remap table
       pAttribRemap[i] = AttribID;

       // Determine if any changes are required so far
       if ( AttribID != i ) RemapAttribs = true;

    } // End if callback available

} // Next Material
```

In our previous projects, once this re-map array has been compiled, our next task is to lock the attribute buffer of the mesh and re-map the IDs of each triangle in the mesh so that they now use the global IDs.

Re-mapping the attributes of a regular mesh

```
ULONG * pAttributes = NULL;

// Lock the attribute buffer
pMesh->LockAttributeBuffer( 0, &pAttributes );

// Loop through all faces
for ( i = 0; i < pMesh->GetNumFaces(); ++i )
{
     // Retrieve the current attribute ID for this face
      AttribID = pAttributes[i];

      // Replace it with the remap value
      pAttributes[i] = pAttribRemap[AttribID];
} // Next Face

// Finish up
pMesh->UnlockAttributeBuffer( );
```

The above code is not new to us and shows what we have always done and will continue to do when working with regular meshes in non-managed mode. It locks the attribute buffer, steps through each face and changes its attribute from a local subset ID to a global subset ID using the re-mapping information stored in the pAttribRemap array compiled in the previous section of code. This code will still be employed for regular meshes, but as discussed previously, if we start fiddling about with the attribute IDs of a skinned mesh, we will loose the 1:1 mapping between subset IDs and elements in the bone combination table. What we do in the non-managed skinned case is the following:

```
LPD3DXBONECOMBINATION pBoneComb =
  (LPD3DXBONECOMBINATION)MeshContainer->pBoneCombination->GetBufferPointer();

for ( i = 0; i < pMeshContainer->AttribGroupCount; ++i )
{
   // Retrieve the current attribute / material ID for this bone combination
   AttribID = pBoneComb[i].AttribId;

   // Replace it with the remap value
   pBoneComb[i].AttribId = pAttribRemap[AttribID];
}
```

In the non-managed skinned case we first fetch a pointer to its bone combination array. Remember, this array will be generated when we use the ID3DXSkinInfo::ConvertToBlendedMesh function. In this example it is assumed that this bone combination table was stored in the mesh container.

We next loop through each subset in the mesh, which is equal to the number of D3DXBONECOMBINATION structures. Instead of re-mapping the actual triangle attribute, we simply re-map the original attribute ID stored in each D3DXBONECOMBINATION structure.

So, where does this leave us? If we have an actor in non-managed mode that contains a single skinned mesh, we will end up with a mesh that has no internally stored attribute information (just as in the regular non-managed mode case). Unlike the non-managed mode regular mesh case, its subset IDs will still be local and zero based. However, what the mesh container will contain is a bone combination structure for each subset in the new mesh. Each bone combination structure will contain (inside the AttribId member) the new global ID that the scene can use to identify the texture and material that should be used to render each subset.

This might sound like a huge shift in our scene's rendering strategy if it wishes to render an actor in managed mode. However, no changes need to be implemented by the scene. Below, you can see a slightly compacted version of the scene's rendering code. For simplicity, each object in the scene is assumed to be a CActor:

```
void CScene::Render( CCamera & Camera )
{
    ULONG i, j;
    long  MaterialIndex, TextureIndex;

    …

    // Process each object
```

```
    for ( i = 0; i < m_nObjectCount; ++i )
    {
        CActor    * pActor = m_pObject[i]->m_pActor;

        // Set up actor / object details
        pActor->SetWorldMatrix( &m_pObject[i]->m_mtxWorld, true );

        // Loop through each scene owned attribute
        for ( j = 0; j < m_nAttribCount; j++ )
        {
           // Retrieve indices
           MaterialIndex = m_pAttribCombo[j].MaterialIndex;
           TextureIndex  = m_pAttribCombo[j].TextureIndex;

           // Set the states

           m_pD3DDevice->SetMaterial( &m_pMaterialList[ MaterialIndex ] );
           m_pD3DDevice->SetTexture( 0, m_pTextureList[ TextureIndex ]->Texture );

           // Render all faces with this attribute ID
          pActor->DrawActorSubset( j );

        } // Next Attribute

    } // Next Object

}
```

This rendering code assumes that all the actors in the scene have been created as non-managed actors. As such, the scene contains global arrays of textures and materials used by all meshes in all actors in the scene. As you can see, our rendering strategy has not changed. We simply loop through each actor and set its world matrix to position it correctly in the scene. For each actor, we loop through every global attribute combination managed by the scene and set the corresponding texture and material for that global attribute combination. Finally, we pass the index of that global attribute ID into CActor::DrawActorSubset where we expect the matching triangles to be rendered with this single call.

When we had only regular meshes in the actor's hierarchy, the CActor::DrawActorSubset method was quite straightforward. It would simply traverse the hierarchy looking for mesh containers. Once a mesh container had been located the global ID passed into the DrawActorSubset method could be directly passed to the ID3DXMesh::DrawSubset method to render the corresponding triangles. This is because triangle attributes IDs would have been mapped to these global IDs. However, with non-managed skins a slightly different rendering approach will be needed since the link between the subset we wish to render and the global attribute ID is in the AttribId member of each element in the D3DXBONECOMBINATION array.

When we wish to draw the subset of a non-managed skin, we will loop through each of its bone combination structures and find the subset that uses this global ID (if it exists). Below we see a very simplified rendering example which will be fleshed out later when we cover the actual source code. It demonstrates how the actor would render the requested subset for a skinned mesh. AttributeID is assumed to contain the subset ID passed in by the scene describing the global subset it wishes to render.

```
LPD3DXBONECOMBINATION pBoneComb =
      (LPD3DXBONECOMBINATION)MeshContainer->pBoneCombination->GetBufferPointer();

for ( i = 0; i < pMeshContainer->AttribGroupCount; ++i )
{
     if (pBoneComb[i].AttribId != (ULONG)AttributeID )
          continue;

     // Set up the bone stuff here ( shown later )

     // Draw CTriMesh
     pMesh->DrawSubset( i , pBoneComb[i].AttribId );
}
```

In this example we are showing special case code to render the subset of a skinned mesh. What is important about this code is that it works for both managed and non-managed modes. To understand why, let us step through what is happening.

We first fetch the bone combination array and loop through each element (subset) stored there. For example, let us imagine that we wish to render global attribute ID 57. We loop through each bone combination structure and test to see if the current subset being processed has 57 in the AttribId member of its bone combination structure. If not, then we skip the current subset and continue the search. Once we do find a subset that has a 57 match, we call the CTriMesh::DrawSubset method which we looked at earlier in this lesson. This function is the means by which this all works out nicely. As the first parameter we pass in the subset we wish to render and as the second parameter we pass in the AttribId member as the material override. If this is a managed mode mesh, then the material override is used to select the correct texture and material in its internal attribute array and send it to the device prior to rendering the subset. If this is a non-managed mode mesh then the material override will be ignored. For example, if we find that subset 4 in this mesh has 57 in the AttribId member of its bone combination structure, this simply means that we need to render subset 4 of the mesh (the material and texture have already been set by the scene). This will all come together very quickly when we look at the new rendering and loading code for CActor later in the workbook.

Summing up, the application's interaction with the actor will not change from earlier projects, even when skinned meshes exist in the hierarchy. The actor loading and rendering code will take care of rendering the special cases. It will use different rendering and loading code if a mesh is a regular mesh or a skinned mesh as well as special case code for managed and non-managed flavors.

Non-Indexed Skinned Mesh Rendering Optimization

As discussed in the textbook, we will sometimes be confronted with a mesh that has some subsets that can be rendered in hardware and others that can only be rendered in software. In our rendering code, we will have to render these meshes using a two pass approach. In the first pass we could disable software vertex processing and loop through each subset in the mesh. For each subset, we would test how many bones influence it, and if it is smaller or equal to the number supported by the hardware, we would render the subset. After we have looped through every subset, we will have rendered all subsets in the mesh that were hardware compliant using hardware acceleration. In the second pass, we would enable

software vertex processing and do a search for subsets that need to be rendered in software, Once again, we would loop through every subset in the mesh, but this time we would count the bone influences of each subset and only render subsets where the number of bone influences is larger than the number supported by the hardware. By the end of this second pass, all subsets will have been rendered.

While this approach is certainly more efficient then just rendering all subsets with software vertex processing, it does require doing two conditional passes through each subset of the mesh. Furthermore, in each pass, for each subset, we need to count the number of bones that influence that subset. This involves counting the number of Bone IDs in the subset's corresponding bone combination structure. All of this looping, counting, and testing is less than ideal for a time critical function, so we will implement a separate re-map buffer in the non-indexed case that contains the subset IDs batched by hardware compliance. For example, imagine that we have a non-indexed skin with ten subsets. Also imagine that instead of performing the tests mentioned above, we perform them at startup when the mesh is first created. Let us assume that in this example, we learn that subsets 2, 4, 5 and 8 have more bone influences than the hardware can handle.

Without optimization, our render logic would look something like this:

```
// First Pass ( Hardware Subset Pass )
pDevice->SetSoftwareVertexProcessing( false );

For ( i = 0; i < NumAttributes; i++)
{
    If ( Subset[i] == Hardware Compliant ) Render Subset[i];
}

// Second Pass ( Software Subset Pass )
pDevice->SetSoftwareVertexProcessing ( true );

For ( i = 0; i < NumAttributes; i++)
{
    If ( Subset[i] != Hardware Compliant ) Render Subset[i];
}
```

This approach is less than optimal. We can perform these tests when the mesh is first created so we should be able to store the subset IDs in an additional array grouped by hardware/software compliance. In fact, that is exactly what we will do. When the mesh is first created, we will loop through the subsets in two passes. In the first pass we will search for all subsets that are supported in hardware and add them to this additional re-map array. In the second pass we will search for all subsets that are not supported by hardware and add them to the array as well.

Using our current example, if a mesh has ten subsets, we will need a re-map array that contains ten subset IDs. As mentioned, subsets 2, 4, 5 and 8 cannot be rendered using hardware. Therefore, in the first pass, we would add subsets IDs 0, 1, 3, 6, 7, and 9 to the re-map array, and in the second pass subset IDs 2, 4, 5 and 8 would be added. The sorted array of subset IDs would now look like this:

[0, 1, 3, 6, 7, 9, 2, 4, 5, 8]

All we are doing is using this array to store the subset IDs in an optimal rendering order. Additionally, our mesh container can store the index into this array where the software subsets start. In that case, our rendering logic for a non-indexed mesh would now look like the following.

```
// First Pass ( Hardware Subset Pass )
pDevice->SetSoftwareVertexProcessing( false );

For ( i = 0; i < SoftwareStartIndex; i++)
{
    Render Subset[ Remap[I] ];
}

// Second Pass ( Software Subset Pass )
pDevice->SetSoftwareVertexProcessing ( true );

For ( i = SoftwareStartIndex; i < NumAttributes; i++)
{
    Render Subset[ Remap[i] ];
}
```

Although it looks like we do two passes here, we only ever have to loop through the entire subset array once. In the above code, it is assumed that SoftwareStartIndex was calculated at mesh creation time and contains the index into the re-map array where the software subsets begin. Remap is assumed to be the array that contains the ordered subset IDs. We thus loop through each subset but use the re-map array to fetch the ID of the subset that must be rendered next.

We have now discussed many of the hurdles we must overcome to implement skinned mesh support in CActor. While some of this information may be a bit vague or seem very complicated at the moment, our detailed walkthrough of the source code should give you all the insight you need.

Lab Project 11.1 - Implementation Goals

1) Extend CActor to provide the loading and managing of hierarchies that contain skinned meshes.

2) Allow CActor to handle the loading and managing of hierarchies that contain mixed geometry types. The actor should be able to render itself even if the hierarchy contains multiple static and skinned meshes.

3) Encapsulate skinned mesh support inside CActor such that providing skinned support does not place any additional burden on the application. The application should be able to simply load the X file using CActor::LoadActorFromX like it always has and have the details of loading and rendering the different geometry types handled behind the scenes.

4) Implement our skinned support such that managed and non-managed actor modes are still available to the application.

Lab Project 11.1 - The Source Code

Most of the changes to the CActor class will be added to existing functions. The primary changes will show up in functions which load and render the actor. These changes are focused around the CAllocateHierarchy::CreateMeshContainer method which is where the code that takes the loaded mesh and coverts it into a skin is located. CActor::DrawSubset and CActor::DrawMeshContainer are also going to be enhanced to facilitate multiple rendering techniques for regular meshes and skinned meshes of various flavors (software, indexed, and non-indexed). A few new helper methods will also be added to CActor to assist in the building process.

Our New Mesh Container

Before we look at the CActor class declaration, we first need to extend our derived D3DXMESHCONTAINER structure. As you will recall, each frame that has a mesh attached will have that mesh stored in a mesh container. Previously this mesh container has had to hold nothing more than a pointer to a CTriMesh, but now we have much more per-mesh information to worry about. For example, a skinned mesh will need to have access to the bone combination table so that it knows which matrices to use when transforming each of its subsets. It will also need to store two arrays of matrix information. As discussed in the textbook, in order to render a skinned mesh, we will need access to each of its bone matrices. The bone matrices are the absolute frame matrices in the hierarchy which will be updated every time an animation is applied to the bones. We do not want to have to traverse the hierarchy each time we need to collect the bones before we set them on the device, so we will traverse the hierarchy at load time and store matrix pointers to each bone in the mesh container. We will also store (in a separate array) the bone offset matrices for each bone used by the mesh. There will be a 1:1 mapping between the bone matrix pointer array and the bone offset matrix array such that, if a subset we are about to render uses bone [5], we will multiply bone[5] with bone offset[5] and set the resulting matrix on the device. There are many more members we will need to add, so let us have a look at our new D3DXMESHCONTAINER derived structure.

```
struct D3DXMESHCONTAINER_DERIVED : public D3DXMESHCONTAINER
{
    CTriMesh   * pMesh;
    bool         Invalidated;
    ULONG        SkinMethod;
    D3DXMATRIX * pBoneOffset;
    D3DXMATRIX** ppBoneMatrices;
    DWORD        AttribGroupCount;
    DWORD        InfluenceCount;
    LPD3DXBUFFER pBoneCombination;
    ULONG        PaletteEntryCount;
    bool         SoftwareVP;
    ULONG      * pVPRemap;
    ULONG        SWRemapBegin;
    LPD3DXMESH   pSWMesh;
};
```

Let us discuss the members of this now quite large structure. Remember, the members you see above are in addition to the members inherited from D3DXMESHCONTAINER. Every mesh in our hierarchy will be contained in one of these structures and attached to a parent frame. If the mesh container contains a regular mesh, most of these members will be unused.

CTriMesh *pMesh (All Meshes)
We have had this member in all previous versions of CActor. It stores the CTriMesh pointer which points to the mesh that will be rendered when this mesh container is encountered during the rendering pass of the hierarchy. This mesh may be in managed or non-managed mode and may contain a regular mesh or a skin. The only difference between a regular mesh and a skin is that the skin will contain vertex weights and the rest of the members in this structure will be used to determine which matrices should be set on the device prior to rendering it. However, what this mesh represents in the various different skinning modes needs some explanation.

Regular Mesh
If the mesh container stores a regular mesh then this is where that regular mesh is stored. It is this mesh that is rendered when the mesh container is encountered during the rendering pass of the hierarchy. It represents the model space mesh data that was loaded from the X file.

Non-Indexed & Indexed Skinning Mesh
If the mesh container stores a mesh that will be used as a skin by the pipeline, this CTriMesh will contain the skin in its reference pose. This is the mesh that was generated with a call to either the ConvertToBlendedMesh or ConvertToIndexedBlendedMesh functions. This mesh will be multi-matrix transformed by the pipeline during the rendering pass of the hierarchy. It does not contain the exact data loaded from the X file; instead it contains the original mesh converted into a skinned mesh. The vertices will contain weights, but the geometry will still represent the reference pose originally loaded from the X file.

Software Skinned Mesh
The use of the CTriMesh in the software skinned case may be slightly confusing at first. You will recall from the textbook that when performing software skinning we actually require two ID3DXMesh's (or at least two vertex buffers). We have a source mesh which contains the original model space mesh geometry loaded from the X file (the reference pose) and we also need a destination mesh to store the transformed vertices generated by the ID3DXSkinInfo::UpdateSkinnedMesh method. This needs to be done whenever bones in the hierarchy have been animated that would cause the shape or position of the skin to change.

Therefore, the source mesh will always contain the untransformed skin that was loaded, and the destination mesh is continually updated when transformations are applied. The destination mesh is always the mesh that gets rendered since it contains the world space version of the skin. When this mesh is rendered, the device world matrix should be set to identity.

You will see in a moment that our new extended mesh container structure stores an additional pointer to an ID3DXMesh interface called pSWMesh. This means the mesh container has the ability to store two ID3DXMesh interfaces (the other is inside the CTriMesh). We can use one mesh to store the original reference pose vertex data and another to transform into and render

from. So, in the software skinning case does the CTriMesh member contain the source mesh or the destination mesh?

The obvious choice would be to use the CTriMesh as the destination mesh since this is the mesh that we render each time we traverse the hierarchy. We could store the model space reference pose geometry in the other ID3DXMesh (pSWMesh) and transform it into the CTriMesh's vertex buffer whenever the hierarchy frames are updated. After all, in managed mode the CTriMesh object contains all the attributes it needs to render itself, so the CTriMesh should contain the transformed data and be used as the desination mesh. However, this is not really consistent with how all other mesh types that we can store in the hierarchy store their data. This makes such a design choice awkward for a number of reasons.

For starters, in both the regular and pipeline skinned mesh cases, the CTriMesh always stores the untransformed mesh (it is transformed in the pipeline). Thus, if the application wanted to explore the hierarchy and access the data of any mesh contained therein, it would expect the mesh data of the CTriMesh to be defined in model space. We would break with this approach if we stored the transformed vertex data in this object in the software skinned case only. But again, this mesh is also where the attribute data is stored and it is the mesh that we would want to use for rendering purposes. This seems to create a small dilemma.

As it happens, we will perform a little trick when rendering a software skin which will allow us to have the best of both worlds. You will recall that the CTriMesh class has an Attach method which allows us to attach and detach any ID3DXMesh as its underlying mesh data. With this in mind we will do the following:

The CTriMesh object will always house the ID3DXMesh object that contains the model space geometry in its reference pose and the additional ID3DXMesh (pSWMesh) will be the mesh that we transform the mesh data into each time the actor's hierarchy is updated. This allows us to stay consistent with how the actor works in all other modes. That is, if an application wished to retrieve the vertex buffer of any mesh in the hierarchy, it will always gain access to the model space vertex data. In the software case, the transformed mesh data will be stored in the additional ID3DXMesh pointed to by the pSWMesh variable. All is well so far, except for the fact that the standalone ID3DXMesh (pSWMesh) that contains the transformed vertices does not have any information about which subsets use which textures and materials. It also does not have the useful rendering methods that automate the setting of textures and materials in managed mode since it is not encapsulated in a CTriMesh. It is CTriMesh that provides us with these tools.

Every time the hierarchy is updated we will need to rebuild any software skins. We will use the ID3DXSkinInfo::UpdateSkinnedMesh method to transform the model space vertices from the CTriMesh vertex buffer into our destination ID3DXMesh (pSWMesh) vertex buffer. However, when it comes time to render this mesh, we will temporarily detach the CTriMesh's underlying ID3DXMesh and in its place we will attach our transformed mesh (pSWMesh). We can then use the CTriMesh methods to render the mesh with full access to all texture and materials. Once we have rendered it, we will detach the transformed mesh and restore the CTriMesh's original ID3DXMesh that contains the untransformed reference pose data. This approach addresses all or our concerns.

bool Invalidated (Software Skinning Only)
This boolean member variable is applicable only to software skinning. In the textbook we learned that when performing software skinning, we use the ID3DXSkinInfo::UpdateSkinnedMesh method to multi-matrix transform vertices from a source mesh into a destination mesh. The pipeline plays no part in the world space transformation process since we essentially hand a world space destination mesh to the pipeline for rendering. However, the problem is that if the bones in the hierarchy are updated by an animation for example, the destination mesh will need to be rebuilt. That is, we will have to transform the vertices from the source mesh into the destination mesh all over again so that the bone position changes are reflected in the new destination mesh. Of course, we do not wish to do this every time we render the mesh since this would hurt performance if we did so needlessly. We only want to do it if the hierarchy has been updated. Therefore, when an animation is applied to the hierarchy, the mesh container will become invalid. During our UpdateFrames method, for each frame we visit during the update, we will set the Invalidated member of any attached mesh container to true.

Before we render a mesh container, we will first test to see if it contains a software skin, and if so, check its validity status. If it invalid, we rebuild the destination mesh (using UpdateSkinnedMesh), set the Invalidated boolean back to false, and then render the mesh. Moving forward, when we render the actor, the destination mesh containing the world space skin will simply be rendered without being rebuilt. It will only have to be rebuilt from the source mesh data when another animation is applied to the hierarchy which invalidates the mesh container all over again. This is a handy flag since it removes any management burden from the application. The application can simply apply animations and render the actor and the actor will automatically rebuild invalidated software skins before they are rendered.

ULONG SkinMethod (All Skinned Meshes)
This member contains the skinning method being used by the mesh stored in this container. This is set using the CActor::SetSkinningMethod function prior to the hierarchy being constructed. The default mode for the actor is SKINMETHOD_AUTODETECT. However, depending on the hardware support available, the actor may create a hierarchy that contains skins created for different skinning techniques. For example, it may find that some can be created as hardware skins and others will have to be created as software skins. So this member may not be the same across all mesh containers in the hierarchy.

```
enum SKINMETHOD    { SKINMETHOD_INDEXED = 1,
                     SKINMETHOD_NONINDEXED = 2,
                     SKINMETHOD_SOFTWARE = 3,
                     SKINMETHOD_AUTODETECT = 4,
                     SKINMETHOD_PREFER_HW_NONINDEXED = 8,
                     SKINMETHOD_PREFER_SW_INDEXED = 16 };
```

This member is not used for regular meshes.

D3DXMATRIX * pBoneOffset (All Skinned Meshes)
This array is allocated to contain the bone offset matrices for each bone matrix in the hierarchy. It is used by all skinned meshes and will be populated at mesh creation time. When D3DX is loading the hierarchy and a skin is encountered in the X file, it will call our ID3DXAllocateHierarchy::CreateMeshContainer callback function passing an ID3DXSkinInfo interface pointer. The ID3DXSkinInfo object contains all the skinning information, such as which weights apply to which vertices for each matrix in the hierarchy. For each bone, it will also store a bone offset matrix.

We will extract those bone offset matrices and store them in this array so that we can access them during the rendering pass. When a subset uses bone[5] for example, it means we need to combine bone offset matrix[5] with bone matrix[5] (stored in the array below) and set this combined matrix in the appropriate matrix slot on the device prior to rendering that subset.

D3DXMATRIX ppBoneMatrices (All Skinned Meshes)**
Every frame in the hierarchy that is attached to vertices in a skin is referred to as a bone. In fact, it will ultimately be the absolute frame matrix (not relative matrix) which is the final bone matrix. Before we set a bone matrix on the device, we must first combine it with its bone offset matrix. The problem is that our bone matrices are stored in the hierarchy and would require a hierarchy traversal every time we need them to render a subset. Instead, at mesh creation time, we will fetch all the bone offset matrices from the ID3DXSkinInfo object and store them in the array described above. For each bone offset matrix, the ID3DXSkinInfo object will also contain the name of the bone (the frame name) in the hierarchy to which it corresponds. Therefore, in a one time pass, we will traverse the hierarchy and store pointers to all the bone matrices (absolute frame matrices) in this matrix pointer array so we will have direct access to them during rendering. By storing matrix pointers it also means this array will not have to be rebuilt when the matrices have animations applied to them. What we will have is a 1:1 mapping between the bone offset array and this bone matrix pointer array. This will allow us to efficiently fetch a bone matrix and its corresponding bone offset matrix before combining them and sending the result to the device.

DWORD AttribGroupCount (Pipeline Skinned Meshes Only)
This member will contain the number of subsets in the skinned mesh. This may be quite different from the number of subsets that were described in the original mesh that was passed into the CreateMeshContainer callback. Remember, the ID3DXSkinInfo::ConvertToBlendedMesh function will convert the original mesh into a skinned mesh and, when doing so, it may need to break the mesh into new subsets based on bone contribution. This member contains the final number of subsets in the mesh, which corresponds to the number of D3DXBONECOMBINATION structures in the bone combination array (described next).

LPD3DXBUFFER pBoneCombination (Pipeline Skinned Meshes Only)
When one of the pipeline skinning methods is being used by our actor, we will need to convert the original ID3DXMesh into a skinned mesh using the ID3DXSkinInfo::ConvertToBlendedMesh or ID3DXSkinInfo::ConvertToIndexedBlendedMesh functions. As we have discussed in the accompanying textbook, this function will create a new mesh with the correct number of weights allocated in the vertices. The resulting mesh will also include the weights and matrices used by each vertex, subdividing subsets where necessary.

These skinned mesh conversion functions will return an ID3DXBUFFER which contains an array of D3DXBONECOMBINATION structures. There will be one element in this array for each subset in the newly created skinned mesh. We will store the buffer in this member variable of the mesh container. We will need access to the bone combination buffer when rendering pipeline skinned meshes because each structure in the array tells us the original subset ID for each subset. We use this to index into a managed mode mesh's attribute table to fetch the texture and material for that subset. Each bone combination structure in this array also informs us of the bone matrices that need to be sent to the device for each subset. These bone indexes are stored in the BoneId array inside the D3DXBONECOMBINATION structure. For example, BoneId[2]=57 informs our rendering code that before rendering this subset, we

must fetch bone matrix[57] from the bone matrix array, bone offset matrix[57] from the bone offset array and combine them together before assigning them to matrix slot[2] on the device. For non-indexed skinned meshes, the BoneId array of each subset will, at most, contain four valid elements, as only a maximum of four matrices can ever be set on the device. For indexed skinning, the BoneId array could contain up to 256 valid elements since we have the ability (hardware permitting) to set 256 bone matrices on the device simultaneously. This member is not used for software skinning or for regular meshes.

DWORD InfluenceCount (Pipeline Skinned Meshes Only)

This member is only used by pipeline skinned meshes. It helps us set the correct D3DRS_VERTEXBLEND render state prior to rendering a given subset. The value of this member will be returned to us by the ConvertToBlendedMesh and ConvertToIndexedBlended mesh functions and has a slightly different meaning in each case:

Non-Indexed Skinning

In the non-indexed case, it informs us of the size of the BoneId array in each D3DXBONECOMBINATION structure. For example, if this value was 4, we would know that the BoneId array for every subset will have 4 elements. Not all elements will necessarily be used, as a given subset may only use 1 or 2 bones for example. In such cases, the unsused elements will be set to UINT_MAX. We need to know how large the BoneID arrays are because our code will need to search through a subset's BoneId array prior to rendering the subset to collect valid bone indices. If we did not know the size, we would not know how many elements in the BoneId array to test. The value returned from ID3DXSkinInfo::ConvertToBlendedMesh will be the maximum number of bones/matrices that influence a single subset in the mesh. This will assure us that the BoneId array will contain this many elements even though all subsets may not use them all. When rendering a non-indexed skinned mesh, we can use this value to test the BoneId array for valid bone indices and also count how many bones that actual subset is using. This allows us to set the D3DRS_VERTEXBLEND render state to the correct number of weights for each subset prior to rendering it. This allows us to rid ourselves of redundant zero weight contribution matrix multiplications.

Indexed Skinning

In the indexed case this value has a slightly different meaning although it is still used to set the D3DRS_VERTEXBLEND render state as in the non-indexed case. In order to render a subset using indexed skinning, we must correctly configure the D3DRS_VERTEXBLEND render state to correctly inform the pipeline of the number of weights in each vertex. Unlike the non-indexed case where we can adjust this render state on a per-subset basis to select only the weights actually used, in the indexed case it must be set such that it informs the pipeline of the number of total weight components our vertex has. This is because the pipeline will need to know where the Matrix Indices Component (the last weight) is stored in the vertex.

Therefore, unlike the non-indexed case, we cannot make the optimization of setting this render state on a per subset basis so that only non-zero weight matrices are multiplied. We must inform the pipeline of the exact layout of weights in the vertex structure. Since the ConvertToIndexedBlendedMesh function will create a vertex structure with enough weights to cater for the vertex with the most bone influences, every vertex will have the same number of weights and have their indices in the same position. Therefore, if this value tells us how we

should set the D3DRS_VERTEXBLEND render state, it also tells us the maximum number of bones that influence a single vertex in the mesh.

Unlike the non-indexed case, this value does not tell us of the size of the BoneId array contained in each subset's D3DXBONECOMBINATION structure. In indexed mode, the two concepts are decoupled. The number of weights in a vertex can still be 4 at most, but a single subset of triangles could index into a palette of, for example, 100 matrices. In this case then, the BoneId array for each subset would have to be large enough to hold 100 elements. So, when setting the bone matrices for an indexed subset, we would need to loop through 100 BoneId elements checking for valid bone matrix IDs. Obviously, not all subsets would use 100 matrices in this mesh, but if one subset did, the BoneId array for every subset would be large enough to hold this many elements, even if many elements were unused.

In the indexed skinning case, the size of the BoneId array is actually equal to the size of the device matrix palette that we wish to use. This is calculated in a separate step and stored in the PaletteEntryCount member of the mesh container (described next).

ULONG PaletteEntryCount (Pipeline Indexed Skinning Only)
This member will be used for indexed skinned meshes and contains the current size of the matrix palette being used on the device. This number also describes the number of elements in each subset's BoneId array (for indexed skins only) since the BoneId array must have one element for each matrix slot on the device that a vertex may index.

bool SoftwareVP (Pipeline Indexed Skinning Only)
This Boolean member is used for pipeline indexed skinning only. It is set during the mesh creation phase to inform our renderer that the device will not be able to transform this mesh in hardware and that we must enable software vertex processing before making the draw call. We will typically set this to true if we discover, during mesh creation, that there exists a face (or many faces) that have more bone influences than there are slots in the matrix palette. Unlike the non-indexed case where we may have some subsets that can be hardware transformed and some that cannot, in the indexed case, if there is a single triangle in that mesh that has more bone influences than the device has to offer, the entire mesh must be transformed using software vertex processing.

We determine whether an indexed skin can be hardware transformed and rendered by testing the maximum number of influences per face against the number of slots available in the matrix palette. For example, if there is a triangle that has 12 bone influences, but the device only support 8 matrix slots, this device cannot transform this mesh in hardware and software vertex processing must be used instead. As long as the device supports at least 12 matrices we will always be able to render the indexed skin in hardware. This is because a triangle has three vertices and each vertex can be influenced by four bones at most. As a result, we will never encounter a situation where a single triangle is influenced by more than twelve bones. As long as at least twelve matrices are available, the ConvertToIndexedBlendedMesh function will be able to divide the mesh into hardware compliant subsets (even if a given subset only has one triangle in it).

ULONG * pVPRemap (Pipeline Non-Indexed Skinning Only)
Earlier we learned that in the non-indexed case, we may have some subsets that can be rendered using hardware vertex processing and others that require software vertex processing. We found out that instead of having to perform two complete passes (hardware and software) through the all the subsets at render time, we could determine (at mesh creation time) which subsets belong to which pool and group the subset IDs in a new array. We could loop through all the subsets, find the hardware capable ones and add them to the array first, then loop through the subsets again, find all the non-hardware capable subsets and add them to this same array. At the end of this process, we would have all the hardware capable subsets stored at the beginning of the array followed by the software ones. When rendering the non-indexed skin, we can simply render all the hardware capable subsets stored at the beginning of the array first, then enable software vertex processing and render the rest of the subsets in the array. This provides a nice optimization in our rendering code beyond what we discussed in the textbook.

This member will point to an array of subset IDs in the mesh, ordered into two groups (hardware and software subsets). The following member of the mesh container will store the index into this array where the software subsets begin so that during rendering we know exactly when to enable software vertex processing. This will eliminate all hardware compliance tests that were originally performed per-subset in the rendering code examples we discussed in the textbook.

This member is used only by non-indexed skins, since we can never render an indexed skin using a mixture of hardware and software subsets.

ULONG SWRemapBegin (Pipeline Non-Indexed Skinning Only)
This member is used alongside the array described previously. It stores the index into the pVPRemap array where the software subset IDs begin. We know that all subsets in the array preceding this index can be rendered with software vertex processing disabled, while all subsets starting from this index (to the end of the array) must be rendered with software vertex processing enabled.

This member is used only by non-indexed skins, since we can never render an indexed skin using a mixture of hardware and software subsets.

LPD3DXMESH pSWMesh (Software Skinning Only)
When performing pure software skinning we will need to transform the model space mesh data into world space ourselves prior to sending the vertex data to the pipeline for rendering. We perfom this task using the ID3DXSkinInfo::UpdateSkinned mesh. This method takes an array of bone and bone offset matrices, a source mesh, and a destination mesh. The function uses the passed matrix information to multi-matrix transform the model space vertices in the source mesh into world space vertices in the destination mesh. The destination mesh then contains the geometry that we pass to the pipeline. Therefore, unlike other skinning techniques, where transformation is performed in the pipeline, when performing software skinning we need an additional mesh (or at least an additional vertex buffer) to receive the results of the world space transformation.

This member (pSWMesh) is the destination mesh when software skinning is being used. Everytime the hierarchy is updated and the bones of the mesh have changed, we rebuild the world space version of the mesh using the ID3DXSkinInfo::UpdateSkinnedMesh method. The model space geometry is stored in our CTriMesh's underlying ID3DXMesh. It is this destination mesh that we render.

You will note that this is a regular ID3DXMesh and not a CTriMesh, so it would seem that we lose access to the handy rendering functions and texture and material information for each subset normally stored in the CTriMesh class. However, as discussed earlier, during rendering we will temporarily detach the CTriMesh's current ID3DXMesh and attach this destination mesh containing the world space version of the geometry. We will then render the CTriMesh normally which will use the world space geometry. After the mesh has been rendered, we will detach the destination mesh and re-attach the CTriMesh's original model space ID3DXMesh.

We have now covered the new additions to our mesh container structure. As you can see, it has now become a lot more complex with many more members. Also remember that the base class from which our mesh container is derived also has an ID3DXSkinInfo pointer member which we have not used in previous lab projects. This will now be used to store the ID3DXSkinInfo interface pointer for a mesh that is passed to the CreateMeshContainer method during the X file loading process. We will need this interface in many places, especially in the software skinning case where this interface actually contains the UpdateSkinnedMesh method that performs the software transformation of vertices from the model space source mesh into the world space destination mesh.

Source Code Walkthrough - CAllocateHierarchy

In previous lab projects, we have used CAllocateHierarchy (derived from ID3DXAllocateHierarchy) as our callback class. An instance of this class was passed to D3DXLoadMeshHierarchyFromX by our actor and its methods were used for frame and mesh container creation during hierarchy construction. You will hopefully remember that this class should implement the four functions of the base class: CreateFrame, CreateMeshContainer, DestroyFrame and DestroyMeshContainer.

You will also recall that every time a frame is encountered in the X file during the loading process, D3DX will call our CAllocateHierarchy::CreateFrame method. This will allow us to allocate the frame memory in whatever way best suits our application. We can then hand it back to D3DX for hierarchy attachment. This allows us to allocate frame structures derived from D3DXFRAME where we can add additional member variables and tailor it to our applications needs. For example, right from the beginning of our hierarchy usage, we used a derived frame structure that had an additional matrix that would be used to store the world space transform of the frame/bone. Likewise, whenever a mesh is encountered by D3DX during the rendering process, the CAllocateHierarchy::CreateMeshContainer function would be called and passed all the mesh information from the X file (e.g., the mesh geometry, the textures and materials, and any skinning information).

Our CAllocateHierarchy::CreateFrame function is unchanged in this lab project since we have no need for new members in our frame structure. However, the CAllocateHierarchy::CreateMeshContainer function will change significantly since we have to add code that creates managed and non-managed flavors of indexed skinned meshes, non-indexed skinned, meshes and software skinned meshes (in addition to the managed/non-managed standard meshes from before).

CAllocateHierarchy::CreateMeshContainer

We will cover the CreateMeshContainer function before we cover the code to CActor::LoadActorFromX. Our reason for doing this is because one of the first things the LoadActorFromX function does is called D3DXLoadMeshHierarchyFromX which then calls the CAllocateHierarchy::CreateMeshContainer method for every mesh contained in the X file. Therefore, with respect to program flow, it makes more sense to cover this function first since it is where all the mesh data is actually created, where all the bones are assigned to the skin, and where the mesh container's members are assigned their values. By the time the D3DXLoadMeshHierarchyFromX function returns program flow back to CActor::LoadActorFromX, any meshes (skins or regular) will have been created and attached to the frame hierarchy. There will be a tiny bit of additional work the actor will need to do after the hierarchy has been loaded to complete the setup process for skinned meshes, but we will get to that in a moment.

This function was already getting pretty large even before skinned support was added. Fortunately however, we have covered all of this code in detail previously and the first ¾ of the function code is unchanged from the prevous lab project. The new skinning support has been conveniently bolted onto the end of the function, for the most part. We will show the entire function in this section and discuss it. The first few parts of the function will only be briefly reviewed since we have already covered this code in previous lab projects. This function also makes calls into a few new CAllocateHierarchy helper functions, so we will cover the code to these functions immediately after.

D3DX passes this function the name of the mesh in the X file that is currently being loaded and the D3DXMESHDATA structure that contains the ID3DXMesh (which contains the geometry loaded from the file). It is also passed an array of D3DXMATERIAL structures describing the texture and material used by each subset in that mesh and an array of effect instances (one for each subset). We will ignore the effects array until Module III when we learn about rendering with effect files. The number of materials (subsets) used by the mesh and the mesh face adjacency information is also passed in. The penultimate parameter is one we have ignored in previous projects -- it is a pointer to an ID3DXSkinInfo interface which will be non-NULL when the mesh has skinning information defined in X file. Finally, we are passed the address of a D3DXMESHCONTAINER structure which, on function return, we will assign to point at the new mesh container that we are about to allocate and populate with the passed information.

```
HRESULT CAllocateHierarchy::CreateMeshContainer
                            ( LPCTSTR Name,
                              CONST D3DXMESHDATA * pMeshData,
                              CONSTD3DXMATERIAL*pMaterials,
                              CONST D3DXEFFECTINSTANCE *pEffectInstances,
                              DWORD NumMaterials,
                              CONST DWORD *pAdjacency,
                              LPD3DXSKININFO pSkinInfo,
                              LPD3DXMESHCONTAINER *ppNewMeshContainer)
{
    ULONG                      AttribID, i;
    HRESULT                    hRet;
    LPD3DXMESH                 pMesh          = NULL, pOrigMesh = NULL;
    D3DXMESHCONTAINER_DERIVED *pMeshContainer = NULL;
    LPDIRECT3DDEVICE9          pDevice        = NULL;
```

```
    CTriMesh                   *pNewMesh       = NULL;
    MESH_ATTRIB_DATA           *pAttribData    = NULL;
    ULONG                      *pAttribRemap   = NULL;
    bool                        ManageAttribs  = false;
    bool                        RemapAttribs   = false;
    CALLBACK_FUNC               Callback;

    // We only support standard meshes ( no progressive )
    if ( pMeshData->Type != D3DXMESHTYPE_MESH ) return E_FAIL;

    // Extract the standard mesh from the structure
    pMesh = pMeshData->pMesh;

    // Store the original mesh pointer for later use (in the skinning case)
    pOrigMesh = pMesh;

    // We require FVF compatible meshes only
    if ( pMesh->GetFVF() == 0 ) return E_FAIL;

    // Allocate a mesh container structure
    pMeshContainer = new D3DXMESHCONTAINER_DERIVED;
    if ( !pMeshContainer ) return E_OUTOFMEMORY;

    // Clear out the structure to begin with
    ZeroMemory( pMeshContainer, sizeof(D3DXMESHCONTAINER_DERIVED) );

    // Copy over the name
    // for the string belongs to the caller (D3DX)
    if ( Name ) pMeshContainer->Name = _tcsdup( Name );

    // Allocate a new CTriMesh
    pNewMesh = new CTriMesh;
    if ( !pNewMesh ) { hRet = E_OUTOFMEMORY; goto ErrorOut; }
```

The above section of code is essentially unchanged from previous lab projects. It first tests to see that it is not a progressive mesh that we have been passed (which we will not support in this lab project). If it is, we return immediately. We fetch the passed ID3DXMesh interface into a local pointer for ease of access and then test that this mesh has a valid FVF vertex format (once again, we exit if this is not the case). We will discuss non-FVF meshes in Module III. One minor change is the additional line that stores the original mesh pointer. We will use this pointer only when we are working with skins because the skinning process will change the mesh subsets and various D3DX utility functions will require that we have the original (pre-skinned) data available (for saving to file for example). Once these tests are out of the way, we allocate a new derived mesh container and initialize all its members to zero for safety. Then we copy the name of the mesh that was passed into the function into the ‘Name’ member of the mesh container. Finally, we allocate a new CTriMesh which will eventually be used to store our mesh data and attached to the mesh container.

Before attaching the passed ID3DXMesh to our new CTriMesh object, we test the FVF flags to see if the mesh contains normals. We require normals in our demo so that we can use the lighting pipeline. If no normals exist then we will clone the passed mesh into a new mesh that contains vertex normals and attach this cloned mesh to our CTriMesh object. If the passed mesh already contains normals then (as you can see in the ‘else’ code block), we simply attach it to our new CTriMesh.

```
    // If there are no normals add them to the mesh's FVF
    if ( !(pMesh->GetFVF() & D3DFVF_NORMAL) ||
          (pMesh->GetOptions() != m_pActor->GetOptions()) )
    {
        LPD3DXMESH pCloneMesh = NULL;

        // Retrieve the mesh's device (this adds a reference)
        pMesh->GetDevice( &pDevice );

        // Clone the mesh
        hRet = pMesh->CloneMeshFVF( m_pActor->GetOptions(),
                                    pMesh->GetFVF() | D3DFVF_NORMAL,
                                    pDevice, &pCloneMesh );
        if ( FAILED( hRet ) ) goto ErrorOut;

        //we don't release the old mesh here, because we don't own it
        pMesh = pCloneMesh;

        // Compute the normals for the new mesh
        if ( !(pMesh->GetFVF() & D3DFVF_NORMAL) )
            D3DXComputeNormals(pMesh, pAdjacency );

        // Release the device, we're done with it
        pDevice->Release();
        pDevice = NULL;

        // Attach our specified mesh to the new mesh
        pNewMesh->Attach( pCloneMesh );

        // We can release the cloned mesh interface here,
        // CTriMesh still has a reference to it so it wont be deleted
        pCloneMesh->Release();

    } // End if no vertex normal, or options are hosed.
    else
    {
        // Simply attach our specified mesh to the CTriMesh
        pNewMesh->Attach( pMesh );

    } // End if vertex normals
```

At this point we have a new CTriMesh object whose underlying ID3DXMesh contains the geometry initially loaded from the X file. The next section of code we will look at is also unchanged from the previous lab project.

We start by testing whether this actor (technically, its meshes) is in managed mode or non-managed mode. You will recall from previous lessons that a CTriMesh (or CActor) is automatically placed into non-managed mode by the registration of the CALLBACK_ATTRIBUTEID callback function. If this function is not registered (pointer is NULL), then the mesh should be created in managed mode and we set the local Boolean variable ‘ManageAttribs’ to true. If the callback has been registered, then the callback function pointer will not be NULL and the Boolean variable will be set to false.

After determining a mesh is in managed mode, the following instructs the CTriMesh object to allocate an internal attribute data array to store the textures and materials for each subset. After the CTriMesh::AddAttributeData method is called to allocate the array, we call the CTriMesh::GetAttributeData method to get a pointer to the start of this array. We store this pointer in the local variable pAttribData which will be used later to step through the mesh's attribute array and copy textures and materials. Remember, at this point, the attribute array for the managed mesh is empty.

```
    // Are we managing our own attributes ?
    ManageAttribs =
    (m_pActor->GetCallback( CActor::CALLBACK_ATTRIBUTEID).pFunction == NULL);

    // Allocate the attribute data if this is a manager mesh
    if ( ManageAttribs == true && NumMaterials > 0 )
    {
        if ( pNewMesh->AddAttributeData( NumMaterials ) < -1 )
            { hRet = E_OUTOFMEMORY; goto ErrorOut; }

        pAttribData = pNewMesh->GetAttributeData();

    } // End if managing attributes
```

The next section of code is the 'else' block of the conditional code shown above. It is executed if the mesh is in non-managed mode (i.e., the CALLBACK_ATTRIBUTEID function has been registered with the actor). This code is also unchanged from the previous lab projects. It basically allocates an array that is large enough to hold a global subset ID for each subset in the mesh (pAttribRemap). These global IDs are returned to us by the scene object's attribute callback function. This array is used to re-map the subsets of the mesh to use global IDs instead of local ones. In this section of code however, once the re-map array is allocated, we initialize it with the current subset IDs of the mesh. These may be overwritten with global IDs later, but this is done just so we safely initialize the array.

```
    else
    {
        // Allocate attribute remap array
        pAttribRemap = new ULONG[ NumMaterials ];
        if ( !pAttribRemap ) { hRet = E_OUTOFMEMORY; goto ErrorOut; }

        // Default remap to their initial values.
        for ( i = 0; i < NumMaterials; ++i ) pAttribRemap[ i ] = i;
    } // End if not managing attributes
```

So, if our mesh is in managed mode, we now have a pointer to an empty attribute table that will need to be filled with texture and material information. If the mesh is a non-managed mode mesh, we have a temporary re-map array which we will use to collect global IDs for each of its current subsets.

In the next section of code (also unchanged) we process the materials for each mesh subset. In the managed case, this means extracting the material information (diffuse, specular etc) from the passed material buffer and storing it in the corresponding entry in the managed mesh's internal attribute array. If a CALLBACK_TEXTURE callback function has also been registered by the application, then it will be called to process the texture for each material/subset. Below we see the first section of the material processing loop (handling the managed case):

```
    // Loop through and process the attribute data
    for ( i = 0; i < NumMaterials; ++i )
    {
        if ( ManageAttribs == true )
        {
            // Store material
            pAttribData[i].Material = pMaterials[i].MatD3D;
            pAttribData[i].Material.Ambient = D3DXCOLOR( 1.0f, 1.0f,
                                                         1.0f, 1.0f );

            // Request texture pointer via callback
            Callback = m_pActor->GetCallback( CActor::CALLBACK_TEXTURE);

            if ( Callback.pFunction )
            {
              COLLECTTEXTURE CollectTexture =(COLLECTTEXTURE)Callback.pFunction;

              pAttribData[i].Texture =
              CollectTexture( Callback.pContext, pMaterials[i].pTextureFilename );

                // Add reference. We are now using this
                if ( pAttribData[i].Texture ) pAttribData[i].Texture->AddRef();
            } // End if callback available

        } // End if attributes are managed
```

The above code takes care of populating the managed mesh's attribute array with the texture pointers and material information.

The second part of the loop is the 'else' code block of the conditional which processes each material for non-managed meshes. This code is also unchanged from previous projects.

```
        else
        {
            // Request attribute ID via callback
            Callback = m_pActor->GetCallback( CActor::CALLBACK_ATTRIBUTEID );
            if ( Callback.pFunction )
            {
                COLLECTATTRIBUTEID CollectAttributeID =
                                  (COLLECTATTRIBUTEID)Callback.pFunction;

                AttribID =
                CollectAttributeID( Callback.pContext,
                                    pMaterials[i].pTextureFilename,
                                    &pMaterials[i].MatD3D,
                                    &pEffectInstances[i] );

                // Store this in our attribute remap table
                pAttribRemap[i] = AttribID;

                // Determine if any changes are required so far
                if ( AttribID != i ) RemapAttribs = true;
            } // End if callback available
        } // End if we don't manage attributes
```

```
    } // Next Material
```

We have now processed all the materials. In the case of a managed mesh, the internal attribute table of the mesh now contains all the textures and materials the mesh needs to draw itself. In the non-managed case, we have a temporary array describing the new global ID of each subset. We have not yet applied these global IDs to the mesh data.

In the next section of code we test to see if we were passed any face adjacency information for the mesh by D3DX (which we should have). If so, then we have to copy this face adjacency information into our mesh container's face adjacency array. We never know when we might need the face adjacency information for a mesh, so it is a wise thing to store it in the mesh container just in case. However, we must make a copy of the data and not simply assign the mesh container's member pointer to point straight at it because the adjacency information we have been passed is in memory owned by D3DX and will be destroyed when the function returns. This would leave our mesh container with a dangling pointer. So we allocate a new face adjacency array and copy over the data. Notice how this new array is pointed to by the mesh container's pAdjacency member discussed earlier.

```
    // Copy over adjacency information if any
    if ( pAdjacency )
    {
        pMeshContainer->pAdjacency=new DWORD[ pMesh->GetNumFaces()*3];

        if ( !pMeshContainer->pAdjacency )
        { hRet = E_OUTOFMEMORY; goto ErrorOut; }

        memcpy( pMeshContainer->pAdjacency,
                pAdjacency,
                sizeof(DWORD) * pMesh->GetNumFaces() * 3 );

    } // End if adjacency provided
```

From this point forward, we will start to see the new code that has been added to deal with skinned meshes. Skinned meshes have to be handled very different from regular meshes in a number of different ways, as we will now see.

The next section of code is executed if the mesh we have been passed is a skinned mesh. If we were passed a regular mesh, our job is almost done since the mesh stored in the CTriMesh is pretty much exactly what we want it to be (with the exception of some attribute buffer re-mapping in the non-managed case, which happens towards the end of the function). However, if it is supposed to be a skinned mesh, then the CTriMesh's underlying ID3DXMesh will have to be converted.

The following code tests the ID3DXSkinInfo interface pointer we have been passed by D3DX. If it is not NULL, then it means this ID3DXSkinInfo object contains skinning information for this mesh and that we have encountered a skin in the X file. The first thing we will do in this case is store the ID3DXSkinInfo interface pointer in the mesh container since we will need access to the bone and vertex weight information in many places in our code. We are also careful to increment the reference count when we copy the interface pointer into the mesh container.

```
    // Is this a 'skinned' mesh ?
    if (pSkinInfo != NULL)
    {
        LPD3DXMESH pSkinMesh;

        // first save off the SkinInfo and original mesh data
        pMeshContainer->pSkinInfo = pSkinInfo;
        pSkinInfo->AddRef();
```

We also know from the textbook that the ID3DXSkinInfo object contains the bone offset matrix for every bone used by the skin. We already discussed why we need efficient access to these matrices during rendering which is why we added a bone offset matrix pointer to our mesh container. What we will do is use this pointer to allocate an array of bone offset matrices in the mesh container and copy the bone offset matrices from the ID3DXSkinInfo object into this new array.

```
        // Allocate a set of bone offset matrices, we need to store
        // these to transform any vertices from 'character space' into 'bone space'
        ULONG BoneCount = pSkinInfo->GetNumBones();

        pMeshContainer->pBoneOffset = new D3DXMATRIX[BoneCount];

        if ( !pMeshContainer->pBoneOffset )
            { hRet = E_OUTOFMEMORY; goto ErrorOut; }

        // Retrieve the bone offset matrices here.
        for ( i = 0; i < BoneCount; ++i )
        {
            // Store the bone
            pMeshContainer->pBoneOffset[i] =*pSkinInfo->GetBoneOffsetMatrix(i);

        } // Next Bone
```

The above code first determines how many bones influence this skin, using the ID3DXSkinInfo::GetNumBones method. Since there is a matching bone offset matrix defined for every bone used by the mesh, the number of bones value also tells us how many bone offset matrices there are in the ID3DXSkinInfo object. Once this array is allocated, the code loops through each bone and uses the ID3DXSkinInfo::GetBoneOffsetMatrix method to fetch the bone offset matrix for the corresponding bone offset index. This bone offset matrix is then copied into the mesh container's bone offset matrix array at the same index position. It is very important that we keep a 1:1 mapping between the indices of bone offset matrices stored in our mesh container and their indices in the ID3DXSkinInfo object since this mapping will be essential later when fetching the actual bone matrix pointers from the hierarchy.

In the next section of code we finish off the bulk of the skinned mesh processing through the use of the CAllocateHierarchy::BuildSkinnedMesh helper function. This function (which we will examine next) generates the skinned mesh from the original ID3DXMesh that we currently have. We pass this function the mesh container, the original ID3DXMesh that we have been currently working with, and also the address of an ID3DXMesh interface pointer which on function return will point to a new ID3DXMesh in skinned format. The new mesh (pSkinMesh) will contain vertex weights and possibly vertex matrix indices (in the indexed skinned mesh case). The function will also populate the new members of the mesh container that are necessary during rendering.

Upon return from the BuildSkinnedMesh function, we will have a skinned ID3DXMesh, but it will not be attached to our CTriMesh object. The CTriMesh's underlying ID3DXMesh pointer is still pointing to the original source mesh, so we will replace it so that the CTriMesh now points to the newly generated skin. Notice in the following code that the Attach method of our CTriMesh has an additional Boolean parameter that we set to true. This is because we have added a new behavior to this method. Originally, when we attached a new ID3DXMesh to our CTriMesh object, the attribute table would also be released (for managed meshes). That is, all data that currently existed in the CTriMesh was flushed. However, in this new case, we simply want to replace the geometry (the ID3DXMesh) and leave all the texture and material data intact. Therefore, if true is passed as this parameter, we simply replace the ID3DXMesh pointer and leave the attribute data of the managed mode alone. After all, the skinned mesh will still be using this texture and material data.

```
        // Build the skinned mesh
        hRet = BuildSkinnedMesh( pMeshContainer, pMesh, &pSkinMesh );
        if ( FAILED(hRet) ) goto ErrorOut;

        // pass True to the bReplaceMeshOnly parameter.
        pNewMesh->Attach( pSkinMesh, NULL, true );
        pMesh = pSkinMesh;

    } // End if skin info provided
```

At this point in the code our CTriMesh has all the correct geometry contained and will contain either a skinned or regular ID3DXMesh. The next section of code that we will execute was also found in previous lab projects, but has some additional code to examine.

As in our previous lab projects, one of the last tasks this function has to perform is the re-mapping of the mesh attribute buffer using the global IDs for each subset we compiled earlier. This is only done when the actor/mesh is in non-managed mode. You will recall that we used the attribute callback function to fetch the global IDs for each subset and stored them in the local pAttribRemap array. This array contains an entry for every subset in the original mesh. When we were dealing only with regular meshes, we would simply lock the mesh attribute buffer, loop through each face, and set it to its new global ID. For regular meshes we will still perform this same task. In fact, if we are using software skinning, we will also do the same thing because we are really just using the original source mesh and transforming into a destination mesh ourselves prior to rendering. So in the case of software skinning, the triangles will still be grouped into the same subsets as the original mesh. In the next section of code we test to see if the mesh is a regular or a software skinned mesh and also whether the mesh is in non-managed mode. If so, we adopt the strategy we have all in previous CActor versions and remap the attribute buffer.

```
    // Remap attributes if required
    if ( pAttribRemap != NULL && RemapAttribs == true )
    {
        // Is a skinned mesh ?
        if ( !pSkinInfo ||
             pMeshContainer->SkinMethod == CActor::SKINMETHOD_SOFTWARE )
        {
            ULONG * pAttributes = NULL;

            // Lock the attribute buffer
```

```
            hRet = pMesh->LockAttributeBuffer( 0, &pAttributes );
            if ( FAILED(hRet) ) goto ErrorOut;
            // Loop through all faces
            for ( i = 0; i < pMesh->GetNumFaces(); ++i )
            {
                // Retrieve the current attribute ID for this face
                AttribID = pAttributes[i];

                // Replace it with the remap value
                pAttributes[i] = pAttribRemap[AttribID];

            } // Next Face
```

If the mesh is a software skinned mesh then we must remember that we also have an additional destination mesh stored in the mesh container. This is the mesh that we will be transforming into when we transform the mesh into world space. Therefore, this mesh will also have to have its attribute buffer updated in the same way. After all, we want the subsets in both the source and destination meshes to be the same (the only difference between the two is that one is in model space and the other is in world space). They both use the same textures and materials for each subset, so let us reflect the global subset changes in the destination mesh as well.

The next section of code locks the attribute buffer of the destination mesh and performs a memory copy from the CTriMesh's attribute buffer (which is still locked) into the destination mesh attribute buffer. Remember, at this point we have already updated the source mesh's attribute buffer so we can just copy the attribute buffer directly into the destination mesh such that they are now identical.

```
            // In the software skinning case, we need to reflect any
            // changes made into our SW Mesh
            if ( pSkinInfo &&
                 pMeshContainer->SkinMethod == CActor::SKINMETHOD_SOFTWARE )
            {
                ULONG * pSWAttributes = NULL;

                // Lock the attribute buffer and copy the contents over
                hRet = pMeshContainer->pSWMesh->LockAttributeBuffer(0,
                                                                    &pSWAttributes
                                                                    );
                if ( SUCCEEDED(hRet) )
                {
                    memcpy( pSWAttributes,
                            pAttributes,
                            pMesh->GetNumFaces() * sizeof(ULONG) );
                    pMeshContainer->pSWMesh->UnlockAttributeBuffer( );

                } // End if succeeded
            } // End if software skinning

            // Finish up
            pMesh->UnlockAttributeBuffer( );

        } // End if not skinned
```

Finally, we unlock both the attribute buffers and our mesh is ready to go. However, all we have seen above is the section of the conditional that handles the attribute re-map for non-managed meshes that are either standard meshes or software skins.

In the next section of code we will see the 'else' code block of the conditional which is executed when we are in non-managed mode (as above), but we are using one of the pipeline skinning techniques (Indexed or Non-Indexed Skinning). Why do we need special case code for pipeline skins? Why can't we just alter the attribute buffers for these meshes to contain the new global subset IDs as we did in the regular and software skinning cases?

When we call CAllocateHierarchy::BuildSkinnedMesh, if we have chosen one of the pipeline skinning techniques, the appropriate ID3DXSkinInfo function (ConvertToBlendedMesh or ConvertToIndexedBlendedMesh) will be called to create a new ID3DXMesh which has vertex weights in the vertices. Of course, these functions do much more than just add weights to vertices; they also calculate which bone matrices each subset must use. This information is returned in the bone combination array. These functions may decide that a given subset cannot be rendered because the faces in that subset collectively use more matrix slots than the device has to offer and in this case, the function will often break the subset into multiple subsets, where each uses a smaller set of matrices that the device can handle in hardware. This is where we find our problem…

The returned mesh may have more subsets than the original mesh. In fact, this is usually the case. This is not really a major problem of course, because we are provided with a D3DXBONECOMBINATION structure for each subset in the new mesh. Each structure will contain the original subset ID that this new subset was generated from. This means when we render a managed mode skin, we still have access to the index of the original texture and material in the mesh's internal attribute array that was used by the subset that this new subset was spawned from. However, it is the non-managed mode mesh we are processing now, and we want the scene to be able to batch render this mesh using global subset IDs across mesh boundaries. But what we cannot do is physically change the attribute buffer of the skinned mesh because the local subset IDs are mapped directly to the bone combination table that was returned from the skinned mesh conversion functions.

Of course, all we are really interested in doing is providing a way for the application to call CActor::DrawSubset with the global ID that it generated when the re-map buffer was being compiled and have it all work properly. Since the scene is responsible for setting the texture and material that corresponds to this global ID, all it is really asking is that the actor draw any faces that are connected to this global ID. It is not as if this global ID is used internally by the mesh to set textures and materials as in the managed mesh case, so this is actually very easy to achieve. In fact, it takes less work than in the regular mesh case.

We will not bother altering the values of the mesh attribute buffer at all; internally, all subset IDs will remain zero-based local IDs which map 1:1 with the bone combination table. In the managed mode case, we can use the AttribId member of each bone combination table to index into the texture and materials in the attribute table of the mesh. In the non-managed mode case, we can just store the new global ID here instead:

```
        else
        {
             LPD3DXBONECOMBINATION pBoneComb =(LPD3DXBONECOMBINATION)
                        pMeshContainer->pBoneCombination->GetBufferPointer();

            for ( i = 0; i < pMeshContainer->AttribGroupCount; ++i )
            {
                // Retrieve the current attribute ID for this bone combination
                AttribID = pBoneComb[i].AttribId;

                // Replace it with the remap value
                pBoneComb[i].AttribId = pAttribRemap[AttribID];

            } // Next Attribute Group

        } // End if Skinned mesh

    } // End if remap attributes
```

Basically, we fetch the bone combination table and loop through each of its elements. There will be one element in this array for every subset in the skin. Also remember that this bone combination table will have been created in the CAllocateHierarchy::BuildSkinnedMesh function (which we will cover shortly). Each bone combination structure contains the original subset ID that this new subset was created from. However, in a non-managed mode mesh we no longer need this information since we have no intention of letting the mesh set its own textures and materials. So we will replace the current subset ID with the new global ID compiled for the original subset during the re-mapping process. Our bone combination structures now contain the global ID that was generated for the original (material-based) subset ID which the new (bone-based) subset was generated from. This connection between global IDs and local subsets in a non-managed pipeline skinned mesh and is simple, but may be a little hard to understand at first. Things will fall into place a little more when we actually see this being used in the rendering code later on.

At this point in the code, our CTriMesh is complete. It either holds a regular mesh, a software skin, or one of the pipeline skin types. We no longer need the temporary array we used to store subset re-map information for the non-managed case so we delete it. Also, if we have created a skinned mesh, then the pMesh local interface pointer (that points to our CTriMesh's underlying ID3DXMesh) can also be released as we no longer need it. We release it in the skinned case, because we incremented the skin's reference count earlier in the function when we assigned this local pointer to point at the new skin. Finally, if the CTriMesh is anything other than a software skinned mesh, we perform the usual optimizations (vertex welding and optimize in place). Do you know why we do not perform these optimizations when we have a software skin?

```
    // Release remap data
    if ( pAttribRemap ) delete []pAttribRemap;

    // If this is a skinned mesh, we must release our overriden copy
    // only the CTriMesh will now reference a copy.
    if ( pSkinInfo ) pMesh->Release();

    // Attempt to optimize the new mesh ( unless software skin ).
    if ( !(pSkinInfo && pMeshContainer->SkinMethod==CActor::SKINMETHOD_SOFTWARE) )
```

```
    {
        // Optimize
        pNewMesh->WeldVertices( 0 );
        pNewMesh->OptimizeInPlace( D3DXMESHOPT_VERTEXCACHE );

        // Release the adjacency information, it is no longer valid
        if ( pMeshContainer->pAdjacency ) delete []pMeshContainer->pAdjacency;
        pMeshContainer->pAdjacency = NULL;

    } // End if not software skinned mesh
```

We do not optimize a software skin because, as we know, this will sometimes remove or move vertices and indices inside the vertex and index buffers for better cache coherency and to clean the mesh of any un-used vertices. The problem we have if we do this with a software skinned mesh, is that we need to use the ID3DXSkinInfo object to transform the mesh. This object stores all the vertex index and bone index information which is used by the ID3DXSkinInfo::UpdateSkinnedMesh method. If we start removing vertices from this mesh, all the per-vertex information stored in the ID3DXSkinInfo object will be invalidated and will no longer correctly index the actual vertices inside the mesh. We could implement some re-mapping logic here if we wanted to, but we have decided to live with the limitation in this demo. It is very rare that you will be using the actor for software skinning, so we will just put up with the fact that a software skin will not have its geometry optimized.

The next section of code is virtually unchanged from previous lab projects, although there is one small modification. Like before, it stores our new CTriMesh in the mesh container, but this time what it stores in the mesh container's MESHDATA member varies depending on whether this is a skin. If it is not, then we store a copy of the CTriMesh's underlying ID3DXMesh just as before. However, if it is a skin, then we need to store the original mesh data instead since our CTriMesh subsets have been modified during the skin creation process. This is why we made a copy of the original mesh data pointer at the start of the function. This allows D3DX functions (e.g., D3DXSaveMeshHierarchyToFile) to find the correct mesh data exactly where they expect to find it. In the managed case, we also copy over the texture names and material information into the mesh container's pMaterials array. Once again, this is where D3DX will expect the per-subset material information to be if the actor is saved out to disk. Remember, saving the actor only works with managed mode actors since this is the only mode in which the actor is even aware of the textures and materials that are being used to render it.

```
    // Store our mesh in the container
    pMeshContainer->pMesh = pNewMesh;

    // Store the details so that the save functions have access to them.
    if ( pSkinInfo )
    {
        // Here we store the original mesh, because the actual mesh stored
        // in our CTriMesh has been split up into multiple subsets and prepared
        // for skinning. We need the original data so that we can save the correct
        // data back out.
        pMeshContainer->MeshData.pMesh = pOrigMesh;
        pOrigMesh->AddRef();

    } // End if skinning
    else
    {
```

```
        // When not skinning, we are save to save out our optimized mesh data.
        pMeshContainer->MeshData.pMesh = pNewMesh->GetMesh();

    } // End if not skinning

    // Save the remaining details.
    pMeshContainer->MeshData.Type  = D3DXMESHTYPE_MESH;
    pMeshContainer->NumMaterials   = NumMaterials;

    // Copy over material data only if in managed mode so we can save X file)
    if ( NumMaterials > 0 && ManageAttribs == true )
    {
        // Allocate material array
        pMeshContainer->pMaterials = new D3DXMATERIAL[ NumMaterials ];

        // Loop through and copy
        for ( i = 0; i < NumMaterials; ++i )
        {
            pMeshContainer->pMaterials[i].MatD3D = pMaterials[i].MatD3D;
            pMeshContainer->pMaterials[i].pTextureFilename
                           = _tcsdup( pMaterials[i].pTextureFilename );

        } // Next Material

    } // End if any materials to copy
```

Finally, we assign the passed mesh container pointer to point at our new mesh container structure so that it will be accessible to D3DX on function return.

```
    // Store this new mesh container pointer
    *ppNewMeshContainer = (D3DXMESHCONTAINER*)pMeshContainer;

    // Success!!
    return D3D_OK;

ErrorOut:

    // If we drop here, something failed
    DestroyMeshContainer( pMeshContainer );

    if ( pDevice      ) pDevice->Release();
    if ( pAttribRemap ) delete []pAttribRemap;
    if ( pNewMesh     ) delete pNewMesh;

    // Failed....
    return hRet;
}
```

At the bottom of the function you see the section of code that is jumped to when an error occurs. It simply cleans up any memory being used when the error occurred before returning failure.

CAllocateHierarchy::BuildSkinnedMesh

A new function that has been added to our CAllocateHierarchy class is the BuildSkinnedMesh method. We learned while covering the previous function that this function is called to convert the regular ID3DXMesh into a new skinned mesh. The function accepts three parameters. The first parameter is a pointer to the mesh container in which the skin information will be stored. Remember, there are many other new members in our mesh container now that hold information about the skin; this function will assign these members the correct values for the type of skin created. The second parameter is a pointer to an ID3DXMesh containing the regular mesh which needs to be converted into a skin. We saw in the last function, that for this parameter we pass in the ID3DXMesh that was loaded from the X file and assigned to the CTriMesh. As the final parameter, we pass the address of an ID3DXMesh interface pointer which will be assigned the address of the new skinned mesh we create. When this function returns the skinned mesh to the calling function, the original mesh is removed from the CTriMesh and the new skinned mesh (pMeshOut) will be attached in its place. The original mesh can then be deleted.

Let us now have a look at this method a section at a time. The function first retrieves the device being used by the actor so that we can retrieve the capabilities of the device to test it for the varying levels of skinning support. Once we have retrieved the capabilities, we release the device interface since we no longer need it.

```
HRESULT CAllocateHierarchy::BuildSkinnedMesh
                                    ( D3DXMESHCONTAINER_DERIVED * pMeshContainer,
                                      LPD3DXMESH pMesh,
                                      LPD3DXMESH * pMeshOut )
{
    D3DCAPS9            Caps;
    HRESULT             hRet;
    ULONG               i, j, k;
    LPD3DXSKININFO      pSkinInfo  = pMeshContainer->pSkinInfo;
    LPDIRECT3DDEVICE9   pDevice    = NULL;

    // Retrieve the Direct3D Device and poll the capabilities
    pDevice = m_pActor->GetDevice();
    pDevice->GetDeviceCaps( &Caps );
    pDevice->Release();
```

In the next line of code we call the other new member function of our CAllocateHierarchy class, called DetectSkinningMethod. This function is a very simple utility that returns one of the following:

SKINMETHOD_INDEXED
SKINMETHOD_NONINDEXED
SKINMETHOD_SOFTWARE

If the current skinning method for the actor has been set to anything other than SKINMETHOD_AUTODETECT, this detection function will simply return the mode that was specified. In other words, the function returns the skin method chosen by the application for the actor. However, if the actor's skinning method has been set to SKINMETHOD_AUTODETECT, this function will query the hardware to find the best skinning method available. This will be either SKINMETHOD_INDEXED or SKINMETHOD_NONINDEXED.

```
    // Calculate the best skinning method and store
    pMeshContainer->SkinMethod = DetectSkinningMethod( pSkinInfo, pMesh );
```

At this point, we now have the skinning method that will be used for this mesh (stored in our mesh container's SkinMethod member). The remainder of the BuildSkinnedMesh function is divided into three sections that create the mesh as either an indexed skin, a non-indexed skin, or a software skin. The first section creates an indexed skinned mesh if that is what has been requested.

The first thing we do in the indexed case is fetch the index buffer of the source mesh so that we can pass it into the ID3DXSkinInfo::GetMaxFaceInfluences function. This function will use the index buffer to determine the maximum number of bones that influence a given triangle in the mesh. We need to know this because the device must have at least this many matrix slots, otherwise the indexed skin will not be able to be transformed with hardware vertex processing. Remember, the ConvertToIndexedBlendedMesh function will subdivide the mesh into smaller subsets if necessary so that each subset can be transformed with the number of matrix slots available, even if it has to break the mesh down into lots of one triangle subsets. However, if there are one or more triangles in this mesh that have more influences than the device has matrix slots, then this mesh can not be transformed by the hardware (not even if it is broken down into one triangle subsets). In such a case, we will have to revert to software vertex processing when rendering this mesh.

```
    // Built differently based on the type of skinning required
    if ( pMeshContainer->SkinMethod == CActor::SKINMETHOD_INDEXED )
    {
        ULONG MaxFaceInfluences;
        ULONG Flags = D3DXMESHOPT_VERTEXCACHE;

        LPDIRECT3DINDEXBUFFER9 pIB;
        hRet = pMesh->GetIndexBuffer(&pIB);
        if (FAILED(hRet)) return hRet;

        // Retrieve the maximum number of influences for the mesh index buffer
        hRet = pSkinInfo->GetMaxFaceInfluences( pIB,
                                                pMesh->GetNumFaces(),
                                                &MaxFaceInfluences);
        pIB->Release();
        if (FAILED(hRet)) return hRet;
```

In the above code, we fetch the maximum number of influences for a given face in the mesh and store that in the MaxFaceInfluences local variable. We then release the index buffer interface we fetched earlier since we no longer need it.

We now know the maximum number of influences a single face uses in the mesh and we know that if this is larger than the number of matrices supported by the device in hardware then this mesh must be rendered using indexed skinning. Actually, that is not quite true! It is possible in some cases that the number of influences for a given face could actually be larger than 12. However, as the pipeline only supports four influences per vertex (i.e., 12 per face), we know that if this is the case, the ConvertToIndexedBlendedMesh function will simply ignore any per-vertex influences over the maximum of four. Even if we have skinning information that tells us a face is influenced by more than 12 matrices, the ConvertToIndexedBlendedMesh function would downgrade the resulting mesh so that

at most there would only ever be 12 influences per face. We are going to compare the MaxFaceInfluences member we just calculated against the number of matrices available on the device to see if the resulting indexed mesh can be rendered in hardware. The problem is, if MaxFaceInfluences is higher than 12, we will fail the hardware case and drop into software mode, even though the resulting mesh will have at most 12 influences per face.

For example, imagine that we have a device that supports 12 matrices and that we have determined that the maximum number of influences per face is 20. We would compare 12 against 20 and find that the maximum face influences is larger than the number of matrices available. In this case we would fail and fall back to software vertex processing. However, this would technically be unnecessary because we know that ConvertToIndexedBlendedMesh will drop those surplus influences as no face can ever have more than 12 influences. Thus, the generated skinned mesh would have a maximum face influence count of 12. We have 12 matrices on our example device matrix palette so this mesh could have been rendered in hardware. Therefore, we must take this into account when performing the comparison against the number of matrices available on the device.

In order to do this we modify the MaxFaceInfluences value so that it can never be larger than 12. We do this by assigning MaxFaceInfluences the minimum between its current value and 12. If maximum face influences is less than 12, its value will be unchanged; if the maximum face influence is greater than 12, it will be assigned 12. As long as the device supports 12 matrices, we will always be able to render the indexed skin in hardware, even if it is broken into one triangle subsets.

```
        MaxFaceInfluences = min( MaxFaceInfluences, 12 );
```

Next we fetch the number of matrices the device supports in hardware. The device capability member that tells us this is the MaxVertexBlendMatrixIndex cap. This is the highest matrix index that the device supports in hardware. Since this is a zero-based number, we know that if this value is 31 for example, the device supports 32 matrices (matrices 0 – 31). To calculate the number of matrices supported by the device, we simply add one to this value.

```
        ULONG MaxSupportedIndices = Caps.MaxVertexBlendMatrixIndex + 1;
```

Next we test to see if the mesh has normals. If it does then it means lighting is being used and the normals must also be transformed. When this is the case, half of the matrix slots will be taken up with matrices to transform the normals. Thus, we actually lose half the number of bones we can transform simultaneously. For example, if the device supports 256 matrices but the vertices have normals, the driver will need to keep reserve half that amount (128) for storing additional copies of the matrix (the inverse transpose of each bone matrix) to transform the normals. While we do not have to set these normal matrices ourselves, we have to be aware that the hardware will need space for them and take this into account. In the next line of code we divide the number of available hardware matrix slots the device can use if normals are present.

```
        if ( pMesh->GetFVF() & D3DFVF_NORMAL) MaxSupportedIndices /= 2;
```

Finally, we test to see if the number of matrices supported by the device (MaxSupportedIndices) is smaller than the maximum number of influences a single face uses. If it is, then the mesh has one or

more triangles that cannot be transformed using hardware vertex processing. In the following code snippet, you can see that when this is the case, we set the mesh container's SoftwareVP member to true so that we know during rendering we must enable software vertex processing before rendering this mesh. We also combine the local Flags member with the D3DXMESH_SYSTEMMEM flag. These flags will be used in a moment to describe the resource pool we would like the skinned mesh to be created in. Since this is going to be a software vertex processing mesh, we want the mesh to be created in system memory so that the CPU can efficiently access the data.

```
        if ( MaxSupportedIndices < MaxFaceInfluences )
        {
            // HW does not support indexed vertex blending. Use SW instead
            pMeshContainer->PaletteEntryCount = min(256,
                                                    pSkinInfo->GetNumBones());
            pMeshContainer->SoftwareVP = true;
            Flags |= D3DXMESH_SYSTEMMEM;
        }
```

In the above code you can also see that we store the number of matrices that will be used for rendering in the mesh container's PaletteEntryCount. Because this is the software vertex processing case, we always have 256 matrix slots on the device to call upon. However, this value will be passed into the ConvertToIndexedBlendedMesh function and will ultimately decide the size of each subset's BoneId array in the returned bone combination table. Certainly we do not want every subset to have a 256 entry BoneId array if we never use more than 20 matrices for a given subset. This is very important, since we will have to loop through and test for valid bone IDs during the rendering of a subset. There is no point in testing every element of a 256 element bone ID array when we only use a handful of bones per subset. So, although we can technically use up to 256 bone matrices, we will never need more matrix slots than the number of bones in the skin. Therefore, the palette size is calculated to be only as large as we need it to be (i.e., either 256 or the number of bones in the skinned mesh, whichever is smaller). When this value is passed to the CovertToIndexedBlendedMesh function, the BoneID array of each subset will contain this many elements. (Of course, each subset may not use all those elements.)

In the following code, we see the 'else' block to the above conditional. It gets executed if the hardware matrix palette is large enough to cater for the the maximum number of matrices that influence a given face.

```
        else
        {
            pMeshContainer->PaletteEntryCount = min( MaxSupportedIndices,
                                                     pSkinInfo->GetNumBones() );
            pMeshContainer->SoftwareVP = false;
            Flags |= D3DXMESH_MANAGED;
        }
```

Do not forget that MaxSupportedIndices is the number of matrix slots available on the device, which may have already been divided in half if normals are being used. We then set the mesh container's SoftwareVP member to false so that we know we can render this mesh in hardware. As this is a hardware vertex processing mesh, we add the D3DXMESH_MANAGED flag to the flags member so that the mesh we create will be allocated in the managed resource pool (video memory).

We have now done all the preparation work for creating the indexed skinned mesh. All that is left to do is create the mesh itself using the ID3DXSkinInfo::ConvertToIndexedBlendedMesh function:

```
        // Convert the mesh
        pSkinInfo->ConvertToIndexedBlendedMesh( pMesh,
                                                Flags,
                                                pMeshContainer->PaletteEntryCount,
                                                pMeshContainer->pAdjacency,
                                                NULL, NULL, NULL,
                                               &pMeshContainer->InfluenceCount,
                                               &pMeshContainer->AttribGroupCount,
                                               &pMeshContainer->pBoneCombination,
                                                pMeshOut );

    } // End if Indexed Skinning
```

The first parameter is the source ID3DXMesh that was passed into the function. This will contain the original geometry that was loaded from the X file and is the mesh we wish to clone into a skinned mesh.

The second parameter contains the mesh creation flags which we have seen many times before. As we just discussed, if we have determined we need to software vertex process this mesh, these flags will specify that the new mesh should be created in the system memory resource pool. If the hardware can transform and render this mesh, the flags will instruct the function to create the new mesh in the managed resource pool.

The third parameter is the palette size we calculated earlier. This tells the function how many matrix slots it can utilize and influences how the function breaks the mesh up into subsets. The larger the palette size, the better chance we have of subsets not being split into smaller subsets based on bone combination. However, as discussed above, this should not be larger than is needed.

The fourth parameter is the adjacency information for the source mesh which was calculated and stored in the mesh container prior to this function being called (we were passed this array by D3DX in the CreateMeshContainer method).

We pass NULL as the next three parameters since we are not interested in receiving the face adjacency information or the face and vertex re-map information of the output mesh (the skin).

As the eighth parameter, we pass the address of our mesh container's InfluenceCount member, which the function will fill with the maximum number of bones that influence a given **vertex**. This tells us how many weights will be in the vertex format of the output mesh and is used during rendering to set the vertex blending render state to allow the pipeline to account for the correct number of weights in each vertex it transforms.

The ninth parameter is the address of the mesh container's AttributeGroupCount member. On function return, it will contain the number of subsets in the new output mesh. This will also describe the number of D3DXBONECOMBINATION structures in the bone combination table.

The tenth parameter is the address of our mesh container's ID3DXBuffer interface pointer (pBoneCombination). On function return, it will contain an array of D3DXBONECOMBINATION structures; one for each subset in the new mesh. Each element in this array will describe the bone and bone offset matrices used by the subset. We must set these bone matrices on the device prior to rendering the subset.

As the final parameter, we pass in the address of an ID3DXMesh interface pointer which, on successful function return, will point to our new skinned mesh.

At this point our indexed skinned mesh has been successfully created and there is nothing else to do in the indexed skinned case.

We will now discuss the section of code that is executed if a non-indexed skinned mesh is to be created. This will be the case if the appliction specifically set the actor to use SKINMETHOD_NONINDEXED or if the auto detection function returned SKINMETHOD_NONINDEXED as the most efficient skinning method supported by the hardware.

In the non-indexed case, creating the mesh is a lot easier. In the following code you can see that we immediately call ID3DXSkinInfo::ConvertToBlendedMesh to create the mesh and we do not have to worry about calculating palette sizes or anything like that. The function is passed exactly the same parameters as in the non-indexed case.

```
    else if ( pMeshContainer->SkinMethod == CActor::SKINMETHOD_NONINDEXED )
    {
       ULONG CurrentIndex = 0;
       // Convert the mesh
       pSkinInfo->ConvertToBlendedMesh(pMesh,
                                       D3DXMESH_MANAGED | D3DXMESHOPT_VERTEXCACHE,
                                       pMeshContainer->pAdjacency,
                                       NULL, NULL, NULL,
                                       &pMeshContainer->InfluenceCount,
                                       &pMeshContainer->AttribGroupCount,
                                       &pMeshContainer->pBoneCombination,
                                        pMeshOut );
```

Once thing to watch out for in the above code is the value returned in the mesh container's InfluenceCount member since it has a slightly different meaning than in the indexed case. In the indexed case, this is the maximum number of bones that influence a given vertex in the mesh. It can be used during rendering to set the D3DRS_VERTEXBLEND render state correctly. In the non-indexed case, this value will be set to contain the maximum number of bones that influence a given **subset**. It is implicitly also the palette size (which is 4 at most). In the non-indexed case, InfluenceCount describes the size of each subset's BoneId array, while in the indexed case, the palette size member contained this value.

At this point we have created our new non-indexed mesh. However, unlike the indexed case, where the mesh is either in hardware or software vertex processing mode, in the non-indexed case it is possible to have a mixture of subsets -- some of which can be rendered in hardware and some which cannot. So our next task will be to find which subsets use more bone influences than the device can handle (4 at most)

and store them as subsets that need to be rendered with software vertex processing enabled. You will recall from our earlier discussions that this will involve stepping though the bone combination structure in two passes. In the first pass we will find all hardware capable subsets and store them in our mesh container's pVPRemap array. We will then take another pass though the subsets searching for any software-only subsets and add them to the pVPRemap array as well.

At the end of this process, the pVPRemap array will contain the indices of all hardware capable subset IDs followed by all the software-only subset IDs. We will have them stored in two batches that can be efficiently rendered without having to perform these tests each time we render. Before we render the batch of software-only subsets, we will have to enable software vertex processing.

So how do we determine which subsets in our new skinned mesh are hardware supported? Well, first we fetch a pointer to the bone combination array that was returned from the ConvertToBlendedMesh function call. We then allocate the subset re-map array to store a number of elements equal to the number of subsets in the new mesh:

```
        LPD3DXBONECOMBINATION pBoneComb = (LPD3DXBONECOMBINATION)
                              pMeshContainer->pBoneCombination->GetBufferPointer();

         // Allocate space for the vertex processing remap table
         pMeshContainer->pVPRemap = new ULONG[ pMeshContainer->AttribGroupCount ];
         if ( !pMeshContainer->pVPRemap )
             { (*pMeshOut)->Release(); return E_OUTOFMEMORY; }
```

Now we have a pointer to the bone combination table (one element for each subset) and an empty array of ULONG's which we are about to populate with the mesh's subset IDs in hardware/software order.

We will need to loop through each subset twice. In the first pass through the outer loop we will be searching for hardware subsets and adding their IDs to our re-map array. In the second iteration of the loop we will be adding software subsets.

```
        // Loop through each of the attributes and determine how many bones
        // influence the vertices in this set, and determine whether it is
        // software or hardware.
         for ( i = 0; i < 2; ++i )
         {
             // First pass is for hardware, second for software
             for ( j = 0; j < pMeshContainer->AttribGroupCount; ++j )
             {
```

Our next task will be to fetch the bone combination structure for the current subset being processed and check each element in its BoneId array to see if it holds a valid index (UNT_MAX == invalid). As discussed earlier, the mesh container's InfluenceCount member now holds the number of elements in each BoneId array, so we will use this to loop through each element. For every valid bone ID we find, we will increment the local loop variable InfluenceCount to keep a running tally for the current subset of how many bones it is influenced by.

```
                ULONG InfluenceCount = 0;
```

```
                // Loop through for each of our maximum 'influence' items
                for ( k = 0; k < pMeshContainer->InfluenceCount; ++k )
                {
                   // If there is a bone used here, increase our max influence
                    if ( pBoneComb[ j ].BoneId[ k ] != UINT_MAX) InfluenceCount++;

                } // Next influence entry
```

At the end of the inner loop shown above, we have calculated the number of bones needed to render the current subset being processed and stored the result in the local InfluenceCount variable. We now test this value against the device capability MaxVertexBlendMatrices, which tells us how many of the possible 1-4 matrices used by the non-indexed skinning technique are supported by the device. If this subset has more influences than the hardware can support then we have found a subset that must be rendered with software vertex processing. Therefore, if we are on the second pass (i == 1) of the outer loop (the pass that searches for software subsets) we add this subset's index to the re-map array. Alternatively, if we have found a subset that can be rendered in hardware and we are on the hardware search pass (i == 0) we add the subset ID to the re-map array.

However, notice that in the first pass (the hardware pass), whenever we add a subset to the re-map array, we also increment the mesh container's SWRemapBegin variable. The idea is that at the end of the first pass, this value will contain the index into the re-map array where the block of software subsets begin. This allows us to easily render the hardware and software subsets in two blocks during the rendering traversal of the hierarchy.

```
                if ( InfluenceCount > Caps.MaxVertexBlendMatrices )
                {
                    // If it exceeds, we only store on the software pass
                    if ( i == 1 ) pMeshContainer->pVPRemap[ CurrentIndex++ ] = j;

                } // End if exceeds HW capabilities
                else
                {
                    // If it is within HW caps, we only store on the first pass
                    if ( i == 0 )
                    {
                        pMeshContainer->pVPRemap[ CurrentIndex++ ] = j;
                        pMeshContainer->SWRemapBegin++;

                    } // End if HW pass

                } // End if within HW capabilities

            } // Next attribute group

            // If all were found to be supported by hardware, no need to test for SW
            if ( pMeshContainer->SWRemapBegin >= pMeshContainer->AttribGroupCount )
                break;

        } // Next Pass
```

Note at the bottom of the outer loop (the pass loop) that we test to see if the SWRemapBegin member of the mesh container is equal to the number of subsets in the mesh. If this test is performed at the end of

the first pass (the hardware pass) and is found to be true, it means that all subsets can be hardware rendered so there is no need to execute the second pass because no software subsets exist. When this is the case, we simply break from the loop instead of continuing on to the second iteration of the loop.

At this point, we have created our non-indexed mesh and determined which subsets need to be hardware or software rendered. Our job is almost done except for one small matter. If we found that some of the subsets needed to be rendered in software, then it means that we need to enable software vertex processing before we render those subsets. But in order for us to render a mesh in the managed resource pool using software vertex processing, the mesh must have been created with the D3DXMESH_SOFTWAREPROCESSING flag. You can be sure that the ConvertToBlendedMesh function did not create our mesh with this flag, so if software subsets are needed, we must clone our skinned mesh so that we can add this new flag. This is what the next section of code does. It clones our skinned mesh into a new skin capable of software vertex processing. We then release the original skin and use the clone instead. After that, our job is done; we have successfully created our non-indexed skinned mesh.

```
        // If there are entries which require software processing, we must clone
        //  our mesh to ensure that software processing is enabled.
        if ( pMeshContainer->SWRemapBegin < pMeshContainer->AttribGroupCount )
        {
            LPD3DXMESH pCloneMesh;

            // Clone the mesh including our flag
            pDevice = m_pActor->GetDevice();
           (*pMeshOut)->CloneMeshFVF( D3DXMESH_SOFTWAREPROCESSING |
                                      (*pMeshOut)->GetOptions(),
                                      (*pMeshOut)->GetFVF(),
                                      pDevice,
                                      &pCloneMesh );
            pDevice->Release();

            // Validate result
            if ( FAILED( hRet ) ) return hRet;

            // Release the old output mesh and store again
            (*pMeshOut)->Release();
            *pMeshOut = pCloneMesh;

        } // End if software elements required

    } // End if non indexed skinning
```

The next and final section of code is executed if a pure software skinned mesh is to be used. The only way this case can ever be executed is if the application specifically set the actor's skinning method to SKINMETHOD_SOFTWARE since the auto detection code will never fall back to this mode. This is because the auto-detection method favors the pipeline skinning techniques using software vertex processing over pure software skinning.

If we are using software skinning, then we already have the mesh created. The source mesh passed into the function (which is currently attached to our CTriMesh) already contains the model space vertices of the skin in its reference pose, and there is nothing else we have to do to it. However, we will need an

additional mesh (a destination mesh) that we can use to transform our geometry into prior to rendering. Therefore, we simply clone the current mesh to create a copy and assign it to the mesh container's pSWMesh member. While this mesh currently contains a copy of the vertex data in the source mesh, the vertex data itself will be overwritten as soon as we call ID3DXSkinInfo::UpdateSkinnedMesh in response to a hierarchy update. However, by cloning it in this way, our destination mesh will have the same index and attribute buffer as the source mesh, which is exactly what we want. After all, it is only the vertex buffer of the destination mesh that will be overwritten each time the mesh is updated; the index and attribute information should be identical for both meshes.

```
    else if ( pMeshContainer->SkinMethod == CActor::SKINMETHOD_SOFTWARE )
    {
        // Clone the mesh that we'll be using for rendering software skinned
        pDevice = m_pActor->GetDevice();

        hRet = pMesh->CloneMeshFVF( D3DXMESH_MANAGED,
                                    pMesh->GetFVF(),
                                    pDevice,
                                    &pMeshContainer->pSWMesh );
        pDevice->Release();

        // Validate result
        if ( FAILED( hRet ) ) return hRet;

        // Add ref the mesh, we're going to pass it straight back out
        pMesh->AddRef();
        *pMeshOut = pMesh;

    } // End if Software Skinning

    // Success!!
    return D3D_OK;
}
```

Finally, we now have covered the two largest and arguably most intimidating functions in this lab project. These are the functions that load the mesh, populate the mesh container, and generate a skinned mesh in any of our supported flavors. But we do still have one gap in the coverage thus far -- at the very top of the BuildSkinnedMesh function, a call was made to CAllocateHierarchy::DetectSkinningMethod. This function determines which skinning method the actor should used based on the current skinning method of the actor set by the application and the capabilities of the hardware (if the actor is in the default auto detect mode).

CAllocateHierarchy::DetectSkinningMethod

This method is called at the top of the BuildSkinnedMesh function to determine the skinned mesh creation strategy that should be employed. The first part of the function simply tests to see whether auto-detection of a skinning method is even required. The default skinning method of the actor is SKINMETHOD_AUTODETECT (set in the constructor), which means the function should try to determine the most efficient skinning method for the current hardware. However, the application can change the skinning mode of the actor prior to the load call to specifically state that that it would like to

use indexed, non-indexed, or software skinning. In such cases, this function has no work to do since auto-detection is not required. The function will simply return the current skin mode of the actor as set by the application.

In the first section of this function we retrieve the skinning mode of the actor. If it set to anything other than SKINMETHOD_AUTODETECT, then auto detection is not required and this function can simply return the actor's skinning method back to BuildSkinnedMesh:

```
ULONG CAllocateHierarchy::DetectSkinningMethod( ID3DXSkinInfo * pSkinInfo,
                                                LPD3DXMESH pMesh ) const
{
    HRESULT hRet;
    ULONG   SkinMethod = m_pActor->GetSkinningMethod();

    // Autodetecting?
    if ( !(SkinMethod & CActor::SKINMETHOD_AUTODETECT) )
    {
        // We are not to autodetect, so just return it
        return SkinMethod;

    } // End if no auto-detect
```

If the SKINMETHOD_AUTODETECT method is chosen, then the 'else' block of this conditional will be executed (shown below). The rest of this function simplifies the auto-detection process by first finding out if both indexed skinning and non-indexed skinning are supported in hardware for this mesh. Once we have compiled this information, we can decide which one to use based on any modifier flags that may have been passed to influence the process.

We initially create two local boolean variables called bHWIndexed and bHWNonIndexed which will be initially set to false (meaning none are supported). We will then perform the appropriate tests for each skinning technique and set these variables to true if we find the mesh is supported in hardware by these skinning techniques.

In the first section of the 'else' block we get the capabilities of the current device being used by the actor. Our first test will be to see if hardware indexed skinning is supported for our mesh.

```
    else
    {
        LPDIRECT3DINDEXBUFFER9  pIB;
        D3DCAPS9                Caps;
        LPDIRECT3DDEVICE9       pDevice;
        ULONG                   MaxInfluences;
        bool                    bHWIndexed = false, bHWNonIndexed = false;

        // Retrieve the Direct3D Device and poll the capabilities
        pDevice = m_pActor->GetDevice();
        pDevice->GetDeviceCaps( &Caps );
        pDevice->Release();

        // First of all we will test for HW indexed support
        bHWIndexed = false;
```

We will get the index buffer of the mesh and pass it into the ID3DXSkinInfo::GetMaxFaceInfluences function. This will return (in the MaxInfluences local variable) the maximum number bones influencing a single triangle in the mesh. If this number is greater than the number of hardware matrix slots on the device, hardware indexed skinning is not supported for this mesh. If the maximum face influences is less than or equal to the number of matrix device slots, then we can perform hardware indexed skinning, so we set the bHWIndexed boolean to true.

```
        // Retrieve the mesh index buffer
        hRet = pMesh->GetIndexBuffer(&pIB);
        if ( !FAILED(hRet) && Caps.MaxVertexBlendMatrixIndex > 0  )
        {
            // Retrieve the maximum number of influences for the mesh index buffer
                    pSkinInfo->GetMaxFaceInfluences( pIB,
                                                     pMesh->GetNumFaces(),
                                                     &MaxInfluences );

            pIB->Release();

             if (Caps.MaxVertexBlendMatrixIndex + 1 >= MaxInfluences )
                 bHWIndexed = true;

        } // End if no failure
```

Now we will test to see if this mesh can be rendered in hardware using non-indexed skinning. We use the ID3XSkinInfo::GetVertexInfluences method to retrieve the maximum number of bones that influence a single vertex in the mesh. This will be a maximum of 4 in the non-indexed case. If we have fewer matrices to use than this, then it means there are vertices in this mesh that require more matrices/weights than are supported by the hardware. For example, if the maximum vertex influence is 4, then we need all four matrix slots to be used to transform this mesh in hardware. If we only have two matrix slots on the device, then hardware non-indexed support for this mesh is not available. If this is not the case and we do have enough matrices, we set the Boolean variable bHWNonIndexed to true.

```
        // Now we will test for HW non-indexed support
        bHWNonIndexed = false;

        // It should be safe to assume that if the maximum number of vertex
        // influences is larger than the card capabilities, then at least one
        // of the resulting attribute groups generated by ConvertToBlendedMesh
        // will require SoftwareVP
        hRet = pSkinInfo->GetMaxVertexInfluences( &MaxInfluences );

        // Validate
        if ( !FAILED(hRet) && Caps.MaxVertexBlendMatrices >= MaxInfluences )
              bHWNonIndexed = true;
```

At this point, we now know which skinning techniques are supported in hardware (none, one, or both). All we have to do now is choose the best one. In the next section of code you can see that if hardware indexed support is available and non-indexed hardware support is not available, then our job is easy -- we want to use the indexed skinning method. Even if both were supported in hardware this would be preferable.

```
        // Return the detected mode
        if ( bHWIndexed == true && bHWNonIndexed == false )
        {
            // Hardware indexed is supported in full
            return CActor::SKINMETHOD_INDEXED;

        } // End if only indexed is supported in full in hardware
```

If this is not the case, then we try the opposite test to see if non-indexed is supported in hardware but indexed is not. Once again, this is an easy choice for us since we are always going to favor the hardware option.

```
        else if ( bHWNonIndexed == true && bHWIndexed == false )
        {
            // Hardware non-indexed is supported in full
            return CActor::SKINMETHOD_NONINDEXED;

        } // End if only non-indexed is supported in full in hardware
```

If we get this far, then it might mean that both skinning types are supported in hardware and we have to make a choice. Usually, we will always choose indexed over non-indexed skinning. However we discussed earlier that when we set the actor's skinning method, we can also specify the SKINMETHOD_PREFER_HW_NONINDEXED modifier flag. If this flag is set, it means that the application would like to favor hardware non-indexed skinning over hardware indexed skinning when both are available. So in the next section of code, you can see that if both hardware skinning methods are available, we return SKINMETHOD_INDEXED unless this modifier flag has been set. If it is, we return SKINMETHOD_NONINDEXED instead.

```
        else if ( bHWNonIndexed == true && bHWIndexed == true )
        {
            // What hardware method do we prefer since they are both supported?
            if ( SkinMethod & CActor::SKINMETHOD_PREFER_HW_NONINDEXED )
                return CActor::SKINMETHOD_NONINDEXED;
            else
                return CActor::SKINMETHOD_INDEXED;
        }
```

Finally, if we get this far without returning a skinning method, it means none of the pipeline skinning methods are supported in hardware. Now we will need to choose which one to use with software vertex processing. Again, remember that auto-detection always returns a pipeline skinning technique and never returns pure software skinning mode.

It is difficult to make a blanket statement about which skinning technique will be more efficient when using software vertex processing. Indexed skinning allows much better batch rendering potential, but then again, the multiplication of redundant matrices with zero weights could really hurt performance now that those matrix multiplications are being done on the CPU. Non-indexed skinning can often result in smaller subsets, but it also benefits from being able to set the D3DRS_VERTEXBLEND render state on a per-subset basis during rendering.

For our purposes, we make a design decision that says that the default auto-protection process would choose software non-indexed skinning over software indexed skinning. However, the application can specify the SKINMETHOD_PREFER_SW_INDEXED modifier flag if desired. If this flag is not set, we will return SKINMETHOD_NONINDEXED; otherwise we will return SKINMETHOD_INDEXED instead. Below we see the remainder of the function:

```
        else
        {
            // What software method do we prefer since neither are supported?
            if ( SkinMethod & CActor::SKINMETHOD_PREFER_SW_INDEXED )
                return CActor::SKINMETHOD_INDEXED;
            else
                return CActor::SKINMETHOD_NONINDEXED;

        } // End if both provide only software methods

    } // End if auto detect
}
```

We have now covered the complete hierarchy and mesh creation process for a CActor class which supports skinned meshes. All of the functions we covered in this section are executed when the actor calls the D3DXLoadMeshHierarchyFromX function. So let us now have a look at the CActor::LoadActorFromX function to see if anything has changed. This is the function that is called from the application to load an X file into an actor.

CActor::LoadActorFromX

We know that CActor::LoadActorFromX calls the D3DXLoadMeshHierarchyFromX function to load X files. We also know that the D3DX function will call CAllocateHierarchy::CreateMeshContainer for every mesh found in the file. Therefore, all of the functions we have discussed earlier (CreateMeshContainer, BuildSkinnedMesh, and DetectSkinningMethod) are executed at this time; once for each mesh in the file. When D3DXLoadMeshHierarchyFromX returns program flow back to CActor::LoadActorFromX we might assume then that our work is done and no changes to this function would need to be made. While this is mostly true, some small modifications will be required.

After the hierarchy and its meshes have been loaded, any skinned mesh containers that exist in the hierarchy will not yet have all the information they need. You will recall that our mesh container structure stores an array of bone matrix pointers and an array of corresponding bone offset matrices. We saw in the CreateMeshContainer method how we populated the mesh container's bone offset array without any difficulty -- we extracted the bone offset matrices that were stored in the ID3DXSkinInfo object and copied them into the mesh container. We can do this for bone offset matrices because they are stored inside the file and never change. However, we have not yet copied all the bone matrix pointers from the hierarchy into the mesh container's bone matrix pointer array. Why did we not do this at the same time as we copied over the bone offset matrices? The reason is quite simple…

During hierarchy construction, the frame hierarchy has not been fully loaded yet, so we might not have access to all of the frames used as bones by the skin. For example, imagine a skinned mesh uses five bones and its mesh container is attached to the first (parent) bone. When D3DX is loading the hierarchy, it will do so one frame at a time. It will call CAllocateHierarchy::CreateFrame first to allow our callback to allocate the frame structure. Next it will test to see if a mesh is present, and if so, will call CAllocateHierarchy::CreateMeshContainer. Herein we find our problem; the mesh we are creating uses five frames as bones and yet four of those bones have not even been loaded or processed yet. So how can we possibly copy all the bones into the mesh's bone matrix array when the skeleton has not yet been fully loaded? Of course, we cannot. That is why we must collect the bone matrices for each mesh as a final step *after* the entire hierarchy has loaded and D3DXLoadMeshHierarchyFromX has returned program flow back to us.

The CActor::LoadActorFromX function has had a single function call added to handle this task. It is called CActor::BuildBoneMatrixPointers and it will be invoked right after the loading function returns. We will look at this function in a moment, but its job is very simple. For each mesh container in the hierarchy, it finds the matching bone matrix in the hierarchy for each bone offset matrix (these are linked by bone name) stored in the mesh container. It then copies that bone matrix pointer into the array in the mesh container. Remember, the bone matrices are the absolute matrices of the frames in the hierarchy being used as bones by the skin. At the end of the BuildBoneMatrixPointers function, every mesh container in the hierarchy will contain an array of bone offset matrices and a matching array of bone matrix pointers with a 1:1 correspondence between the two arrays.

Before we cover the CActor::BuildBoneMatrixPointers function, let us have a quick look at modifications to CActor::LoadActorFromX so that you can see where we have added this new function call. The code to this function will not be explained since we have now it many times before. We have highlighted in bold the new code that has been added.

```
HRESULT CActor::LoadActorFromX( LPCTSTR FileName, ULONG Options,
                                LPDIRECT3DDEVICE9 pD3DDevice,
                                bool bApplyCustomSets /* = true */ )
{
    HRESULT hRet;
    CAllocateHierarchy Allocator( this );

    // Release previous data!
    Release();

    // Store the D3D Device here
    m_pD3DDevice = pD3DDevice;
    m_pD3DDevice->AddRef();
    m_nOptions = Options;

    // Load the mesh heirarchy and the animation data etc.
           D3DXLoadMeshHierarchyFromX( FileName,
                                       Options,
                                       pD3DDevice,
                                       &Allocator,
                                       NULL,
                                       &m_pFrameRoot,
```

```
                                        &m_pAnimController );

    // Build the bone matrix tables for all skinned meshes stored here
    if ( m_pFrameRoot )
    {
        BuildBoneMatrixPointers( m_pFrameRoot );
    }

    // Copy the filename over
    _tcscpy( m_strActorName, FileName );

    // Apply our derived animation sets
    if ( m_pAnimController )
    {
        // Apply our default limits if they were set before we loaded
        SetActorLimits( );

        // If there is a callback key function registered, collect the callbacks
        if ( m_CallBack[CALLBACK_CALLBACKKEYS].pFunction != NULL )
            ApplyCallbacks();

        // Apply the custom animation set classes if we are requested to do so.
        if ( bApplyCustomSets == true )
        {
            ApplyCustomSets();
        }
    } // End if any animation data

    // Success!!
    return D3D_OK;
}
```

CActor::BuildBoneMatrixPointers

This is a recursive function that is called once by the CActor::LoadActorFromX function, where it is passed a pointer to the root frame. The function will then recurse until it has visited every frame in the hiearchy. It is only interested in finding frames that have mesh containers that store skinned meshes. Once a skin is found, it will collect the bone matrices that it uses and store them in the mesh container's bone pointer array.

The first section of the function tests to see if the frame we are currently processing contains a mesh container that stores a skinned mesh (i.e., the pSkinInfo member will is non-NULL).

```
HRESULT CActor::BuildBoneMatrixPointers( LPD3DXFRAME pFrame )
{
    HRESULT hRet;

    // Has a mesh container?
    if ( pFrame->pMeshContainer )
    {
        D3DXMESHCONTAINER_DERIVED * pContainer =
                            (D3DXMESHCONTAINER_DERIVED*)pFrame->pMeshContainer;
```

```
        LPD3DXSKININFO pSkinInfo  = pContainer->pSkinInfo;

        // if there is a skinmesh, then setup the bone matrices
        if ( pSkinInfo != NULL )
        {
```

At this point we know there is a skin stored at this frame so we need to get the addresses of all bone matrices it needs to use so we can store them in the mesh container's array. This will provide us easy access to them during rendering.

The first thing we must do is allocate the mesh container's bone matrix pointer array so that there are enough elements to hold a matrix pointer for every bone it uses. The ID3DXSkinInfo for this mesh will tell us that information via its GetNumBones member.

```
        ULONG BoneCount = pSkinInfo->GetNumBones(), i;

        // Allocate space for the bone matrix pointers
        pContainer->ppBoneMatrices = new D3DXMATRIX*[BoneCount];
        if ( pContainer->ppBoneMatrices == NULL ) return E_OUTOFMEMORY;
```

We are now ready to start searching for bone matrices. The important point however is that we wish to find and add them to the array in the right order so that we have a perfect pairing between the bone offset matrix array and the bone matrix pointer array. This is not a problem because the ID3DXSkinInfo object contains every bone offset matrix and the name of the bone/frame it belongs to. Since we simply copied over the bone offset matrices into the mesh container (in CreateMeshContainer) in the same order, we can take advantage of this fact. We just have to loop through each bone in the ID3DXSkinInfo object and retrieve its name. We then search for a frame in the hierarchy with the same name and store the address of its absolute matrix in the array.

```
        // Store the bone pointers
        for ( i = 0; i < BoneCount; ++i )
        {
               // Find the matching frame for this bone
               D3DXFRAME_MATRIX * pMtxFrame =
                 (D3DXFRAME_MATRIX*)D3DXFrameFind( m_pFrameRoot,
                                                   pSkinInfo->GetBoneName(i) );
               if ( pFrame == NULL ) return E_FAIL;

               // Store the matrix pointer
               pContainer->ppBoneMatrices[ i ] = &pMtxFrame->mtxCombined;

        } // Next Bone
```

The above code does all the work. We set up a loop to iterate through each bone in the ID3DXSkinInfo and use the D3DXFrameFind function to perform a search (starting from the root) for a frame with the same name as the bone name. This function will return a pointer of that frame and we can copy its absolute matrix address into the bone pointer array. When this loop ends, all bone matrices for this mesh will have their pointers stored in the mesh container.

Usually this would be the end of the road, but we do need to perform one additional test to cater for the pure software skinning case. You will recall that when performing software skinning, we have to manually combine the bone matrices and the bone offset matrices into a temporary array before handing this combined array off to the ID3DXSkinInfo::UpdateSkinnedMesh function. Since all software skins only need to use this buffer temporarily during the update of their skin, we can create one matrix buffer that can be used by all software skinned meshes. Therefore, we have added a new matrix pointer m_pSWMatrices to our CActor class that can be used as a temporary matrix mixing buffer. We have also added a member called m_nMaxSWMatrices which will store the current size of this array. Since this array will only be used for software skins, it will be initially set to NULL and the m_nMaxSWMatrices variable set to zero.

This buffer must be large enough to cater for all the matrices used by the software skin with the maximum number of bones. We can use this same buffer for skins that have fewer bone combinations as this simply means that some of the elements in this array will not be used.

In the next section of code we test to see if the current skin being processed is a software skin. If it is, then we test to see if the current size of this temporary matrix array is large enough to facilitate this mesh. If not, then the temporary matrix array is resized to the number of bones used by the mesh. Obviously, the first time a software skin in encountered, this will always be the case because the array size will be set to zero. However, when processing other mesh containers later, we mind find other software skinned meshes that use even more bones and the array will be resized again. By the time the BuildBoneMatrixPointers function returns back to LoadActorFromX, this temporary matrix buffer will be large enough to handle any software skin in the hierarchy.

```
            // If we are in software skinning mode, we need to allocate our
            // temporary storage. If there is not enough room, grow our temporary
            // array.
            if ( pContainer->SkinMethod == SKINMETHOD_SOFTWARE
                 && m_nMaxSWMatrices < BoneCount )
            {
                // Release previous memory.
                if ( m_pSWMatrices ) delete []m_pSWMatrices;
                m_pSWMatrices = NULL;

                // Allocate new memory
                m_pSWMatrices = new D3DXMATRIX[ BoneCount ];
                m_nMaxSWMatrices = BoneCount;

                // Success ?
                if ( !m_pSWMatrices ) return E_OUTOFMEMORY;

            } // End if grow SW storage

        } // End if skinned mesh

    } // End if has mesh container
```

At this point we have fully populated the mesh container and there is nothing left to do at this frame. So, using the recursive behavior we have seen so many times before, we continue to walk the hierarchy, first visiting the sibling list and finally visiting the child list.

```
    // Has a sibling frame?
    if (pFrame->pFrameSibling != NULL)
    {
        hRet = BuildBoneMatrixPointers( pFrame->pFrameSibling );
        if ( FAILED(hRet) ) return hRet;

    } // End if has sibling

    // Has a child frame?
    if (pFrame->pFrameFirstChild != NULL)
    {
        hRet = BuildBoneMatrixPointers( pFrame->pFrameFirstChild );
        if ( FAILED(hRet) ) return hRet;

    } // End if has child

    // Success!!
    return D3D_OK;
}
```

At the end of this function, the entire hierarchy is complete. Our actor's mesh containers will have all the information they need in order to be transformed and rendered. The only new part of CActor that is left for us to look at is the rendering code.

CActor::DrawMeshContainer

Although our actor is now much more complex than it used to be, nothing has changed from the perspective of the application regarding how the actor is rendered. As in all of our previous lab projects that have used CActor, the scene is managing the textures and materials, so rendering each actor consists solely of looping through each subset and calling the DrawSubset method with the global ID for the subset we wish to draw.

You will hopefully recall that CActor::DrawSubset is a simple wrapper function around the first call to the recursive function CActor::DrawFrame. It passes in the root frame and the subset ID that was requested to be drawn by the application. The CActor::DrawFrame function then recursively walks the hierarchy looking for mesh containers. Once a mesh container is found, the CActor::DrawFrame function calls the CActor::DrawMeshContainer function, passing in the mesh container and the subset ID that needs to be rendered. It is in the CActor::DrawMeshContainer function that all the rendering work is done. This function has changed significantly from previous lab projects since it has been expanded to render both regular meshes and skins (indexed, non-indexed skins, and pure software). This function now also manages the setting of the bone matrices on the device (pipeline skinning) before the requested subset is rendered. In the software skinning case, the function updates the destination mesh in software if the hierarchy has been updated since the last frame.

DrawMeshContainer is divided up into four sections. Each section takes case of rendering a different mesh type. The first section handles the rendering of the mesh subset if it is an indexed skin. The second section contains the rendering logic for a non-indexed skin. The third section is renders a pure software skin, and the final section handles regular meshes. This is now a pretty large function (although not too complex), so we will cover it a piece at a time.

We will begin with the indexed skinning case. You can see below that we first test to see if the mesh container we are about to render contains a skinned mesh or not. If the mesh container's pSkinInfo member is set to NULL then we will skip the entire skinned code block and proceed to the bottom of the function where the regular mesh will be rendered normally. If a skin does exist, we first test to see if the skinning method is indexed.

```
void CActor::DrawMeshContainer(LPD3DXMESHCONTAINER pMeshContainer,
                               LPD3DXFRAME pFrame,
                               long AttributeID /* = -1 */ )
{
    ULONG                        i, j, MatrixIndex;
    D3DXFRAME_MATRIX           * pMtxFrame  = (D3DXFRAME_MATRIX*)pFrame;
    D3DXMESHCONTAINER_DERIVED * pContainer(D3DXMESHCONTAINER_DERIVED*)pMeshContainer;
    CTriMesh                   * pMesh      = pContainer->pMesh;
    LPD3DXSKININFO               pSkinInfo  = pContainer->pSkinInfo;
    D3DXMATRIX                   mtxEntry;

    // Is this a skinned mesh ?
    if ( pSkinInfo != NULL)
    {
        if ( pContainer->SkinMethod  == SKINMETHOD_INDEXED )
        {
            // We have to render in sofware
            if ( pContainer->SoftwareVP )m_pD3DDevice->SetSoftwareVertexProcessing( TRUE );

            // Set the number of blending indices to be used
            if ( pContainer->InfluenceCount == 1 )
             m_pD3DDevice->SetRenderState( D3DRS_VERTEXBLEND,D3DVBF_0WEIGHTS );
            else
             m_pD3DDevice->SetRenderState(D3DRS_VERTEXBLEND,pContainer->InfluenceCount-1);

            // Enable indexed blending
           if( pContainer->InfluenceCount )
              m_pD3DDevice->SetRenderState( D3DRS_INDEXEDVERTEXBLENDENABLE, TRUE );
```

The first thing we do in the indexed skinning case is test to see if the mesh container's SoftwareVP boolean is set to true. If it is, then it means we determined during the loading phase that this mesh has one or more triangles that are influenced by more bones than the device has matrix slots in its palette. If so, this mesh must be rendered using software vertex processing and we call the appropriate API call to make that so.

Our next task in the above code is to correctly switch on vertex blending in the pipeline using the D3DRS_VERTEXBLEND render state. We must set it for the value that describes the vertex format of the mesh. This assures that the pipeline knows the location of the indices within each vertex structure. The mesh container also stores the influence count which tells us the maximum number of bone influences per-vertex. This also tells us (if you subtract 1) the number of weights contained in the vertex structure. Remember that the last weight is calculated on the fly by the pipeline, so a three weight vertex structure would actually use four matrices. So, you can see that we first test to see if the influence count is equal to 1. If so, then every vertex in this mesh is influenced by only one bone. When this is the case, no actual vertex blending occurs since vertex blending assumes the influence of multiple matrices on a single vertex. Thus, the vertex structure will have no weights defined at all because the pipeline will assume a weight of 1.0 for the only matrix used for transformation.

However, if the influence count is not 1, then we know that by subtracting one from this amount, we have the actual number of weights stored in the vertices. This is exactly the value we should set the vertex blend render state to. It is very important that we do this correctly in the indexed skinning case because if we pass in a vertex blend renderstate of *n*, the pipeline will expect the indices to be stored in weight *n* + 1. If we set this value incorrectly, we are giving bad information to the pipeline about the format of our vertices, and it may try to fetch the matrix palette indices from the wrong weight causing all manner of incorrect transformations.

Finally, the last thing we do in the above code is test to see if the maximum vertex influence count is greater than 1. If so, we enable indexed vertex blending. This is another important point to remember. It is possible to render an indexed skinned mesh without using any form of vertex blending. This is typically the case if every vertex in the mesh is only influenced by a single bone. For example, we could have a skin that collectively uses a palette of 200 bones but no one vertex ever uses any more than one of those bones for its transformation process. In this case, while we are still rendering a skin using indices into the matrix palette for the mesh as a whole, no vertex blending needs to be performed for its vertex transformations. After all, if a vertex is only to be transformed by a single matrix there is nothing to blend. In such a case we simply transform the vertex by the single bone matrix. This is exactly why such a mesh would also have no need for weights in its vertices. So, we only enable indexed vertex blending when necessary.

Now that we have prepared the device to render our skin, our next task is to loop through each subset and render it. The information for each subset is stored in the mesh container's bone combination table, so we fetch a pointer to that first. We then loop through each subset/bone combination structure and process it. Take a look at the following code that renders each subset and we will talk about it afterwards:

```
            // Get a usable pointer to the combination table
            LPD3DXBONECOMBINATION pBoneComb = (LPD3DXBONECOMBINATION)
                                   pContainer->pBoneCombination->GetBufferPointer();

            // Loop through each of the attribute groups and calculate the
            // matrices we need.
            for ( i = 0; i < pContainer->AttribGroupCount; ++i )
            {
             if ( AttributeID >= 0 && pBoneComb[i].AttribId !=(ULONG)AttributeID )
                    continue;

                // First calculate the world matrices
                for ( j = 0; j < pContainer->PaletteEntryCount; ++j )
                {
                  // Get the index
                  MatrixIndex = pBoneComb[i].BoneId[j];

                  // If it's valid, set this index entry
                  if ( MatrixIndex != UINT_MAX )
                  {
                      // Generate the final matrix
                      D3DXMatrixMultiply( &mtxEntry,
                                          &pContainer->pBoneOffset[ MatrixIndex ],
                                           pContainer->ppBoneMatrices[ MatrixIndex ] );

                        // Set it to the device
                        m_pD3DDevice->SetTransform( D3DTS_WORLDMATRIX( j ), &mtxEntry );
```

```
                } // End if valid matrix entry

            } // Next Palette Entry

            // Draw the mesh subset
            pMesh->DrawSubset( i, pBoneComb[i].AttribId );

        } // Next attribute group
```

The first thing we do when we enter the subset loop is test to see if this subset is the subset that we actually want to render. Although we are looping through each subset, if the caller has requested that only subset *n* is to be rendered, we will skip any others. If no subset ID has been passed then this usually means that we are using managed meshes. When this is the case we wish to render every subset in the mesh since the CTriMesh will take care of setting the texture and material on the device before it renders the triangles. You can see in the above code that if the passed attribute ID is less than zero, no subsets wil be skipped and all will be rendered. This is the value that gets passed to the DrawMeshContainer function when managed meshes are being rendered.

Once we have decided that we wish to process a subset, our next task is to loop through each element in the BoneID array of the subset (which will have PaletteEntryCount elements). We do this to fetch the indices of the bones that influence the subset which need to be sent to the device prior to rendering. If any of the BoneId elements for a given subset are set to UINT_MAX then this subset does not use that matrix slot and the element can be ignored. The index of the BoneId element in the array describes the matrix slot that the bone index it contains should be set to. For example, if BoneId[5]=10, it means bone 10 in the mesh container's bone matrix array should be assigned to matrix slot 5 on the device. You can see that we use the bone index stored in each BoneId element to fetch the correct bone matrix and its corresponding bone offset matrix from the mesh container's array. We then multiply them together to create a single combined matrix which is set in its appropriate position in the matrix palette.

After we have looped though every element in the BoneId array for the current subset we are processing, we will have assigned all the bone matrices to their correct places in the device's matric palette and we are ready to render the mesh subset. We do this with a call to CTriMesh::DrawSubset. Notice that we pass in two parameters. The first parameter is the local subset of the mesh we wish to render. (Remember, we never re-map subset IDs when using skins.) The second parameter, which is used only in managed mode, describes the index for the texture and material used by this subset in the mesh's internal attribute table. Thus, the mesh can correctly set the texture and material on the device before rendering the subset. Obviously, if the mesh is in non-managed mode, this second parameter is unnecessary since the mesh assumes that the application has set the texture and material before making the draw call. If this is confusing, just remember that earlier in the lesson, we discussed how the AttribId member of a bone combination structure contains the original subset ID that this new subset was created from when the mesh was converted to a skin. This describes the index into the mesh's attribute data array for the texture and material used by that subset.

At this point, we have rendered our indexed skinned mesh (or a requested subset) and our job is done. Before we exit however, we should reset those device states we changed and set them back to their defaults. As you can see, in the closing statements of the indexed skinning case, we disable indexed vertex blending, set the vertex blending render state back to zero and return software vertex processing back to its default state.

```
            // Reset the blending states
            m_pD3DDevice->SetRenderState( D3DRS_INDEXEDVERTEXBLENDENABLE, FALSE );
            m_pD3DDevice->SetRenderState( D3DRS_VERTEXBLEND, 0 );

            // Reset back to hardware vertex processing if required
            if ( pContainer->SoftwareVP )
                 m_pD3DDevice->SetSoftwareVertexProcessing( FALSE );

        } // End if indexed skinning
```

In the next section we will look at the code that handles the non-indexed case. This code is very similar except for a few minor changes here and there. As before, the code starts by getting the mesh's bone combination table so that it has access to the bone and attribute information for each subset. We then loop through each subset to process and eventually render it as we did before. Once again, in the following code you can see that if a specific subset ID was passed in and the current subset we are processing does not match, we skip it. This ensures only the requested subset is rendered for non-managed mode meshes.

```
        else if ( pContainer->SkinMethod == SKINMETHOD_NONINDEXED )
        {
            // Get a usable pointer to the combination table
            LPD3DXBONECOMBINATION pBoneComb =
              (LPD3DXBONECOMBINATION)pContainer->pBoneCombination->GetBufferPointer();
            // process each subset
            for ( i = 0; i < pContainer->AttribGroupCount; ++i )
            {
                // Retrieve the remapped index
                ULONG iAttribID = pContainer->pVPRemap[ i ];

                // Enable software processing if we reached our SW begin index
                if ( i == pContainer->SWRemapBegin )
                    m_pD3DDevice->SetSoftwareVertexProcessing( TRUE );

                if ( AttributeID >= 0 &&
                     pBoneComb[ iAttribID ].AttribId != (ULONG)AttributeID ) continue;
```

At the center of the subset loop there is a fundamental change. With indexed skinning, the mesh is either in software or hardware mode, but with non-indexed skinning there may be a mixture of both types. You will recall that to speed up the switching process, we created a subset re-map array so that the subsets are stored and processed in order of hardware capability (hardware capable subset IDs followed by software subset IDs). So we will process the subsets not in the usual 0 to *n* order, but in the order they are stored in this re-map array. The code above does just that.

We fetch the bone combination table and then set up a loop to iterate through the number of subsets. At the start of each iteration we fetch the next subset we wish to process from the re-map array. We then test the current loop variable 'i' to see if it is equal to our mesh container's SWRemapBegin. We calculated this value earlier as the position in the re-map array where hardware subsets end and software subsets begin. If we hit that index, then it is time to enable software vertex processing for the rest of the subsets we process. Finally, we test the subset ID against the subset ID passed into the function (AttribID). If this is not the subset our application specifically wished to render then we skip to the next iteration of the loop.

Now we know which subset we are processing and we also know which bone combination structure to use, so we can fetch the bone matrix indices it uses. We set up a loop to loop through each element in the BoneID array. This will be a maximum of four in the non-indexed case, but may be less if the hardware does not support all four matrix slots. This value will be stored in our mesh container's InfluenceCount member as in the indexed case. In the non-indexed case, this value actually contains the total number of bones that influence a given subset, but is pretty much the same thing as far as determining the size of the palette being used is concerned.

As discussed earlier, in the non-indexed case we do not have matrix indices in the vertices to worry about, so we can set the D3DRS_VERTEXBLEND render state on a per-subset level so that we do not unnecessarily blend using matrices that have zero weights defined in the vertex. However, in order to perform this optimization, we must know how many matrices this subset uses (among all its vertices). In the following loop, we simply test each BoneId element for this subset to see if a valid BoneId is stored there. Each time we find one, we set the local variable MaxBoneIndex equal to loop variable 'j'. At the end of this loop, MaxBoneIndex will contain a value between 0 and 3 describing the highest matrix index that influences this subset. If this was 2 for example, then we know that we can set the D3DRS_VERTEXBLEND render state to process only 1 weight (the second weight is calculated by the pipeline). This would save us having to incorporate matrices 2 and 3 into the calculation unnecessarily as their contribution would have zero weight anyway. Remember, without doing this step, if one vertex in the mesh was influenced by four bones, but all the rest were influenced by only one, we would multi-matrix transform every vertex in the mesh using four matrices, even if those matrices contribute nothing.

```
                ULONG MaxBoneIndex = UINT_MAX;

                // Count the number of bones required for this attribute group
                for ( j = 0; j < pContainer->InfluenceCount; ++j )
                {
                    // If this is not an 'empty' bone, increase our max bone index
                    if ( pBoneComb[ iAttribID ].BoneId[ j ] != UINT_MAX ) MaxBoneIndex = j;

                } // Next Influence Item
```

We now know how many matrix slots this subset uses. So let us take another pass through the BoneId array and actually build the matrices this time. For each BoneId element in the array, we fetch the Bone index it describes. We then use this index to fetch the bone matrix and the bone offset matrix for the mesh container's arrays and bind them to the device in the correct matrix slot.

```
                // First calculate the world matrices
                for ( j = 0; j <= MaxBoneIndex; ++j )
                {
                    // Get the index
                    MatrixIndex = pBoneComb[ iAttribID ].BoneId[j];

                    // If it's valid, set this index entry
                    if ( MatrixIndex != UINT_MAX )
                    {
                        // Generate the final matrix
                        D3DXMatrixMultiply( &mtxEntry,
                                            &pContainer->pBoneOffset[ MatrixIndex ],
                                            pContainer->ppBoneMatrices[ MatrixIndex ] );

                        // Set it to the device
```

```
                        m_pD3DDevice->SetTransform( D3DTS_WORLDMATRIX( j ), &mtxEntry );

                    } // End if valid matrix entry

                } // Next Palette Entry
```

At this point the device has been assigned all the matrices needed to transform and render this subset. We will now set the vertex blend render state to process MaxBoneIndex weights and finally draw the actual subset using CTriMesh::DrawSubset.

```
                // Set the blending count to however many are required / in use
                m_pD3DDevice->SetRenderState( D3DRS_VERTEXBLEND, MaxBoneIndex );

                // Draw the mesh subset
                pMesh->DrawSubset( iAttribID, pBoneComb[ iAttribID ].AttribId );

            } // Next attribute group
```

With every subset of the mesh now processed and rendered, all that is left to do before exiting the non-indexed skinning case is reset the render states we may have changed to their default settings.

```
            // Reset the blending states
            m_pD3DDevice->SetRenderState( D3DRS_VERTEXBLEND, 0 );

            // Disable software processing if it was enabled
            if ( pContainer->SWRemapBegin < pContainer->AttribGroupCount )
                 m_pD3DDevice->SetSoftwareVertexProcessing( FALSE );

        } // End if Non-Indexed
```

We have now covered the rendering section that deals with both pipeline skinning methods. The final skinning method we have to deal with is pure software skinning. In many ways, software skinning is much simpler since we do not have the bone combination relationship to deal with and we do not have to worry about tweaking the vertex blend and software vertex processing render states.

In software skinning the basic process is:

1) Combine every bone matrix with every bone offset matrix used by the mesh and store in our temporary array.

2) Lock the vertex buffer's of the model space source mesh and the destination mesh.

3) Pass the combined matrices and both vertex buffers into the ID3DXSkinInfo::UpdateSkinnedMesh function. On function return, the destination mesh will contain world space geometry that has been calculated using multi-matrix transformations.

4) Set the device world matrix to an identity matrix (destination mesh already in world space)

5) Render the mesh

The basic process is not new to us but is listed above for your review. There are one or two things in the code that we have added for efficiency and convenience which will be discussed before we look at the code.

First, we really do not want to regenerate the skinned mesh (as described above) every time we wish to render it. If none of its bones have changed position since the last build then this is unnecessary since the world space geometry in the destination mesh will still be current. As mentioned earlier, we have added a boolean variable called Invalidated to our mesh container structure. The mesh only gets rebuilt if this value is set to true; otherwise we simply render the current destination mesh. The Invalidated boolean is set to true (for every mesh container) when the hierarchy is updated (e.g., after animation has been applied) inside the CActor::UpdateFrameMatrices function. If it is set to true when it comes time to render this mesh, we will rebuild the world space destination mesh (prior to rendering it) and then reset this Boolean back to false after this has been done. This way, we only rebuild the destination mesh when a change occurs to the hierarchy.

Below you will see the code to all the steps outlined above. It fetches every bone matrix and bone offset matrix stored inside the mesh container and combines each pair into a resulting temporary matrix buffer (m_bSoftwareMatrices). It then locks the vertex buffers of the source and destination mesh prior to passing them into the ID3DXSkinInfo::UpdateSkinnedMesh method along with the combined matrix buffer. This is the code for the software skinning case:

```
        else if ( pContainer->SkinMethod == SKINMETHOD_SOFTWARE )
        {
            D3DXMATRIX  Identity;
            ULONG       BoneCount = pSkinInfo->GetNumBones();
            PBYTE       pbVerticesSrc;
            PBYTE       pbVerticesDest;

            // Get the actual mesh
            LPD3DXBASEMESH pSrcMesh = pMesh->GetMesh();
            if ( !pSrcMesh ) pMesh->GetPMesh();

            // If the data has been invalidated since last rendering, update our SW mesh
            if ( pContainer->Invalidated )
            {
                // Loop through and setup the bone matrices
                for ( i = 0; i < BoneCount; ++i )
                {
                    // Concatenate matrices into our temporary storage
                    D3DXMatrixMultiply( &m_pSWMatrices[i],
                                        &pContainer->pBoneOffset[i],
                                        pContainer->ppBoneMatrices[i] );

                } // Next Bone

                // Lock the input and output vertex buffers
                pSrcMesh->LockVertexBuffer(D3DLOCK_READONLY, (LPVOID*)&pbVerticesSrc);
                pContainer->pSWMesh->LockVertexBuffer( 0, (LPVOID*)&pbVerticesDest);

                // Generate the newly skinned mesh data
                pSkinInfo->UpdateSkinnedMesh( m_pSWMatrices,
                                              NULL,
                                               pbVerticesSrc,
                                               pbVerticesDest );
```

```
                // Unlock the buffers
                pSrcMesh->UnlockVertexBuffer();
                pContainer->pSWMesh->UnlockVertexBuffer();

            } // End if update required
```

At this point, our destination ID3DXMesh (pSWMesh) contains the new position of our software skin's vertices in world space. Therefore, we must make sure when we render it that the world matrix is set to an identity matrix since we do not wish an additional world transform to be applied.

```
            // Already in world space so set world to identity
            D3DXMatrixIdentity( &Identity );
            m_pD3DDevice->SetTransform( D3DTS_WORLD, &Identity );
```

The next section of code requires some explanation. The world space vertices are currently stored in pSWMesh. This is just an ID3DXMesh and, as such, has no attribute data linked to it. We cannot use the CTriMesh interface to render this mesh because it is not attached to a CTriMesh. The CTriMesh stored in our mesh container is currently attached to the source mesh (pSrcMesh) which contains the model space skin data. Therefore, we will temporarily attach the destination mesh to the CTriMesh instead, so that we can use its draw functions and borrow is texture and material data (for managed mode meshes).

```
            // Attach the SW mesh to our CTriMesh (attach only) for rendering
            pMesh->Attach( pContainer->pSWMesh, NULL, true );
```

We are now ready to render the CTriMesh since it currently contains the world space mesh geometry. If the application specified a subset to be rendered, then we call CTriMesh::DrawSubset. If not, we assume this is a managed mode skin and call CTriMesh::Draw. We know from previous lab projects that this function simply calls DrawSubset for each subset in the mesh.

```
            // Render the mesh or subset
            if ( AttributeID >= 0 )
            {
                // Draw the subset
                pMesh->DrawSubset( (ULONG)AttributeID );

            } // End if attribute specified
            else
            {
                // Draw the mesh as a whole
                pMesh->Draw( );

            } // End if no attribute specified
```

With the mesh now rendered, we re-attach the CTriMesh's original ID3DXMesh which contains the geometry in its model space reference pose. We do this to be consistent for the application. In all other skinning techniques and in the case of regular meshes, the application could access the CTriMesh stored at each mesh container and would expect it to be in model space. By switching it back again, we make sure that this assumption is correct when software skinning is being used. After all, we never know what somebody will want to do with our actor. For example, they may be traversing our hierarchy in order to build model space bounding volumes for each of the meshes.

```
            // Re-attach our source mesh
            pMesh->Attach( pSrcMesh, NULL, true );

            // Now we can release our source mesh
            pSrcMesh->Release();

        } // End if software skinned
    } // End if skinned
```

That ends the software skinning conditional code block, and consequently, the entire skinned mesh rendering code block. The only conditional code block left to cover is executed if the mesh stored here is not a skin, but a standard mesh. When this is the case, we render the mesh as we always have.

```
    else
    {
        // Render the mesh
        if ( AttributeID >= 0 )
        {
            // Draw the subset
            pMesh->DrawSubset( (ULONG)AttributeID );

        } // End if attribute specified
        else
        {
            pMesh->Draw( );
        } // End if no attribute specified
    } // End if not skinned
}
```

While that was quite a big rendering, each rendering method taken individually is fairly small.

Conclusion

We have now covered all of the modifications to CActor that provide automatic support for the loading, transformation, and rendering of skinned meshes. There is no need to look at modified code in the CScene or CGameApp class because, there is none. We have managed to expand our actor functionality without the application needing to know about the changes. Thus, we have accomplished all of our design goals that we stated early in the lesson.

In the next lesson we will continue to explore what can be achieved with both animation and skinned meshes. In the workbook, we will add a data-driven animation layer to CActor, allowing us to select which combinations of animation sets we wish to play on the fly in response to use input or other game events. In our textbook, we will also gain a much deeper understanding of how the data for a skinned mesh is laid out when we create a new class derived from CActor that will be used to procedurally generate skinned tree meshes. The examination of the CTreeActor code will demonstrate how we can build skinned meshes and skeletal hierarchies procedurally as well as how to generate procedural animation for the skeletal structure. This should be a nice way to round off our current studies of skinned meshes and skeletal hierarchies. The combination of all of these concepts in our workbook will make for a good way to mark the halfway point in this course.

Chapter Twelve

Skinning II

Introduction

At this point in the course we have learned how to load X file frame hierarchies and traverse and render them. We have also learned how to load skinned mesh data from an X file and render those skinned meshes such that the hierarchy acts as a system of bones that influence the world space positions of the skin's vertices. Of course, loading data from an X file is only half the story. We can also procedurally generate meshes, hierarchies, bones, and skins. This can prove to be handy for lots of things, like random generation of terrain or even for vegetation on that terrain to cite just two obvious examples. Typically such code uses algorithms that generate geometry based on both fixed rules and some degree of randomness. How the two concepts work together is generally based on some set of input parameters and controls to the procedure. For example, if we were randomly generating a terrain mesh, we might specify some rules to the procedure stating that water can only exist below a certain altitude, or that snow can only be placed on mountaintops above a certain altitude. In both cases, those altitudes are likely to be input to the terrain generator via a configuration file or through a GUI tool.

Figure 12.1

Regardless of the example we choose, the important point is that you will undoubtedly reach a point at some time in your programming career where you will have to generate meshes and/or texturing information from within your code. For some game assets it is just easier to do it this way (versus getting your artists to create everything by hand). Trees are a good example. Every tree is different in reality, so if you wanted to represent even a small forest of say, 40 unique trees, it would require the artist to generate 40 different tree meshes, where each branch and maybe even each leaf would have to be carefully hand-crafted and textured. The time involved would be considerable, and most serious game development projects would simply not have the resources to spare for such an undertaking. So not surprisingly, representing realistic trees within a game world has typically been an area that has fallen to tools developers to aid the creative process. There are currently some commercial products (e.g., SpeedTree™) available that are designed to do nothing more than generate realistic trees that look organic while remaining within a specified polygon budget (the polygon count of a single tree is very important as we rarely have just one tree in a given scene – especially an outdoor scene). These products produce some incredibly realistic results, but they can also be very expensive. Since commercial tools are generally not in the budget for most students, we decided to introduce code for generating our own trees. This will be a great way to conclude our studies of skins and skeletons and it has the added benefit of providing you with a useful tool in the short term at no extra cost (other than the time you will have to spend writing the code). To be clear, we are not going to claim that our trees are going to exhibit the same level of quality or performance as those produced in the commercial tools, but we are sure that you will find them to be an adequate substitute in the short term while you are still in training.

In Figure 12.1 we see a tree that has been generated procedurally using a new class that we will create in this chapter (called CTreeActor). What cannot be seen in the image is that this tree is really a combination of skinned meshes and bones. The bones are animated to simulate how a tree might move in blowing wind. Our tree class will be derived from CActor and as such we can reuse much of its functionality. CActor already has code to represent, animate, and render skinned meshes, so this is code we will not have to rewrite in our tree class (thankfully). In fact, CTreeActor will simply add some hierarchy and skinned mesh creation functions to the base class that allow us to populate the actor's hierarchy using a different means. As we have seen, currently CActor can be populated only by loading an X file. With CTreeActor we will add functions that generate the bone and mesh data for tree meshes and add them to the hierarchy manually.

> **Note**: While it is perfectly legitimate to use CTreeActor to generate trees in your code at level load time (for example), it is really supposed to be used as tool. That is, usually you will use CTreeActor to generate some number of random trees and when it creates a tree you like, you will save that actor to an X file for use in your game. This way, your actual game code need only load the trees using a normal CActor just like any other X file. You may also wish to save the trees out to X files and then import them into a level editor for placement. GILES™ now ships with a tree plug-in to allow you to create trees from within its GUI. The GILES™ tree plug-in uses CTreeActor for its tree generation.

A CTreeActor object will represent a single tree in the scene. Its frame hierarchy will describe the bones of the entire tree representation (the skeleton of the trunk and all its branches). CTreeActor's creation functions will also generate animation data for this hierarchy programmatically that will animate the tree such that its branches and leaves blow from side to side in simulated wind. Sharing this same bone hierarchy will be multiple meshes, one skinned mesh for each branch. What we will have at the end of this chapter (and associated lab project) is a class that we can use to generate tree meshes with random configurations with a single function call. For the most part, using the tree class will be no more complicated than calling the CTreeActor::GenerateTree function where we would usually call the CActor::LoadActorFromX function. Therefore, the code that we have added to CTreeActor is strictly confined to the creation process as a replacement for loading of X file data. Once the CTreeActor::GenerateTree function has built the frame hierarchy and its various branch meshes, we can position, animate, and render the tree using the same CActor methods we have always used.

Since this is going to be a fairly complex task, we will break the coverage of CTreeActor into two separate lab projects (12.1 and 12.2) which will be covered in two different sections in this textbook. In the first section of this book we will write the code that generates the main branch structure of the tree (Lab Project 12.1). This will involve procedurally creating multiple skinned meshes (one per branch). Once we have our CTreeActor fully capable of creating such a network of animating skinned branch meshes, we will add simple leaves to our trees (Lab Project 12.2). Doing it in two steps like this will make the code easier to understand and the entire process a little less overwhelming.

> **Note:** This chapter obviously represents a departure from the way we have done things thus far in the training series. Generally, source code discussions were limited to our workbooks while the textbooks concentrated more on higher level theoretical ideas. So it is worth noting that the line between textbooks and workbooks is likely to blur quite a bit as we move forward in this course (and indeed in the remainder of the series). As we start to get into more implementation specific topics (such as we will here), it will become difficult and impractical to split things up as cleanly as we have done in the past. Instead what we will find is that the work will be shared between the two books. For example, there will be times when the textbook will cover the implementation details in addition to the design ideas and

theory, while the workbook focuses on how to integrate and use the systems developed in the textbook. To be sure, this will not happen all the time, and again, the line will be somewhat blurred. Certainly there will be times in the future when the old model shows itself again and the code will be confined almost exclusively to the workbooks. But when it is not practical to do so, we will approach the topics like you will see here in this chapter. Indeed, throughout the rest of this course, you should expect to see this approach being used in nearly every chapter.

Also note that since this chapter is essentially just an extension of the ideas introduced in the last chapter, there will be no new accompanying presentation. We are going to focus exclusively on writing code this time around. Of course, the material in Lecture 11 is completely applicable to what we will do here, so please refer to the presentation as the need arises.

Figure 12.2

The tree in Figure 12.1 essentially consists of two geometry building techniques. Skinned meshes are used to represent the trunk and branches of the tree, while the leaves are represented using a series of criss-crossed quads. As we will be discussing the technique used for leaf generation in a later section, in this first section we will focus on creating only the trunk and branches of the tree. In essence, our first version of CTreeActor will only generate "winter" trees. Figure 12.2 shows what the tree shown in Figure 12.1 will look like without the leaves. This is what the trees we generate in the first section of this chapter will look like.

Of course, while it is essential to have trees at your disposal if you ever intend to represent an outdoor environment other than the Sahara Desert or the Atlantic Ocean, providing you with organic looking trees was not the motivation behind this lesson. The real goal behind this project was to come up with a task that would put to the test everything you have learned about since the beginning of the course, but with some new twists. For example, you learned how keyframe data is generated back in Chapter Ten, but so far we have only demonstrated how to load and playback that data. Similarly, in Chapter Eleven, we discussed the relationship between vertices in a skin, the bones that influence them, and the individual animations that animate those bones in the hierarchy. But even that material was focused on working with pre-generated data. In short, to really understand a skeletal animation system (or arguably, any system for that matter), it will be helpful to work on a project where every bit of data is generated from scratch right in your own code. This is exactly the educational experience that CTreeActor will provide, as you can see just by glancing at our to-do list:

- We will need to generate the meshes for each branch and of course, the bones which those meshes attach to.

- We will have to calculate the bone offset matrix for each bone in our hierarchy such that it is relative to the bone at which the branch mesh begins and not the root of the entire tree.

- We will have to manually connect the vertices to the bones that animate them.

- We will have to create an animation controller for the actor, which we will then populate with keyframe data that we will generate.

It seems that we have quite a bit of work to do, and indeed we do. But believe it or not, the actual code we will write to extend CActor into our derived tree class will be fairly small. It is still quite a complex process that we will be undertaking however, which is why we will first discuss the system design and try to nail down how it will all work. Then we can start dealing with source code and implementation details.

12.1 An Overview of the Tree Generation System

Our tree will be made up of a number of branches that will be randomly generated using a recursive process. Even the trunk of the tree will just be a branch (considered the "root branch" of the tree). Each branch will be "grown" using a recursive and random process that may, at any given segment within the branch, cause another child branch (or multiple child branches) to be generated. Each child branch generated from the root branch (the trunk) will also be built in exactly the same way. As each child branch is grown, there is a chance that any given segment within that branch may spawn multiple child branches of its own, and so on. Do not worry too much about what a branch segment is at the moment, we will get to that in a moment.

We will feed the generator procedure a number of input parameters that will be used to influence the growth of the tree and its individual branches. For example, one parameter we will feed in will be a growth direction vector that will describe the world space direction in which we wish the tree (the trunk branch) to initially start growing. We will also feed in probability variables that describe the odds that a branch segment might split into one, two, three or four more child branches at any given segment along its length. In addition we will feed in variables that influence the amount that a child branch's direction vector can be randomly deviated from its parent branch (while still maintaining the general overall growth direction of the tree as a whole). Further, we provide variables that allow us to specify the size of the tree and the resolution at which we place bones within that tree. Other variables will specify the resolution of the mesh branches, allowing us to control exactly how many vertices are used to create a given branch segment. This will allow us to directly influence the face count of the tree and tailor the tree to our specific polygon budget. So before we discuss any code, let us first examine the system that we will use at a high level. This way when we discuss the code later on, we will understand the input variables and how we are using them.

Figure 12.3 : A branch made out of a single cylinder

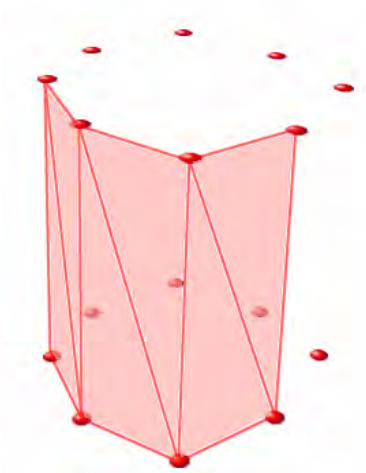

Figure 12.4: The two rows of vertices created triangles that wrap around a cylinder

As mentioned, our tree will essentially just be a hierarchy of branches. If we think in terms of primitive objects, a branch could be represented at a very coarse level by a cylinder mesh (see Figure 12.3). Already, this image looks like a very rough approximation of the trunk of a tree, especially when it is mapped using a tree bark texture. What we are looking at in Figure 12.3 is a single cylinder mesh. It has eight vertices arranged in a circle around the top and eight vertices arranged in a circle around the bottom of the cylinder. In this image we can only see four of the eight vertices used at the top and the bottom of the cylinder as we are only looking at one of its sides. As Figure 12.4 clearly demonstrates, we can use these two rows of vertices to create triangles that form the cylinder primitive. Each pair of vertices from the top and bottom rows can be indexed to form a quad (two triangles). When we do this for every matching pair of vertices in the top and bottom rows, we have an un-capped cylinder, which when textured, would look like the branch shown in Figure 12.3.

Having vertices only at the top and the bottom of each branch (one cylinder), does not afford us much flexibility when it comes to shaping the branch into something more interesting. While we could decrease the radius of the circle formed by the top row of vertices to make the cylinder get thinner as it nears its end, this would still be a perfectly uniform thinning out of the branch from bottom to top. We might imagine for example, that we would want the branch to end in a tip, possibly by moving all vertices in the top row into a single center point. However, the branch would then become a perfect cone and we really cannot have a tree where all the branches are perfectly coned shaped. So instead of making each branch using a single cylinder, a branch will be comprised of multiple cylinders stacked on top of each other.

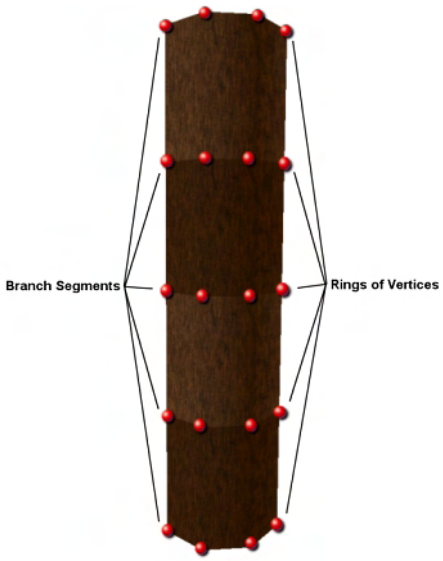

Figure 12.5 : A branch mesh constructed from multiple branch segments

We will refer to each cylinder as a **branch segment** as shown in Figure 12.5. Our branch will now consist of not just two rows of vertices arranged in a circular pattern, but *N* rows of vertices which form multiple branch segments. With the exception of the first row of vertices (at the bottom of the branch) and the last row of vertices (at the top of the branch), all other rows will consist of shared vertices that form the top of one branch segment and the bottom of another. In Figure 12.5, we show how our branch mesh might look consisting of multiple branch segments. All segments still belong to the same mesh, after all, they are all part of the same branch and we have already mentioned the fact that each branch will be its own skinned mesh.

Now that we have vertices at regular intervals along the branch, we can adjust the radius of the circles formed by each row of vertices such that the faces that form the branch get thinner and thicker as we desire. In our code, we will use the index of the branch segment within the branch we are currently building to determine the radius of its vertices (with some degree of randomness thrown in) such that all branches generally get thinner until they end in a point at their tip. It would be a waste representing the tip of any branch using a row of eight vertices that essentially exist in the same position, so when adding the final row of vertices to a branch (to complete the final segment of a branch), we will insert just a single vertex that exists at the center of the circle. Every vertex in the penultimate row of vertices will be indexed along with this final vertex to turn the final branch segment into a cone.

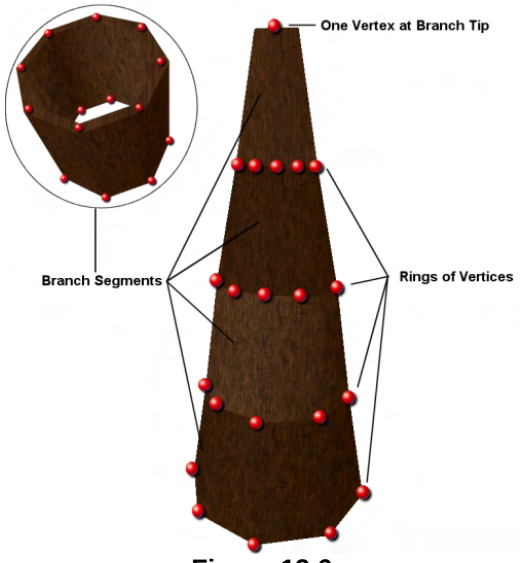

Figure 12.6

Figure 12.6 shows how a branch might look with uniform scaling applied to the vertices at each segment boundary. It also demonstrates how the final branch segment of any branch is terminated using a single vertex at its tip. While this shows a uniform scaling making the branch appear cone shaped, this is not something we are limited to doing. By changing the radius of the circle formed by each ring of vertices we can make the branch mesh swell or contract at the segment boundaries. The circular inset in figure

12.6 also reminds us that all branch segments (except the top segment) are essentially uncapped cylinders that slot together as a natural product of the fact that they share the same vertices at the segment boundaries. The top segment is obviously an exception to this rule where the faces of this segment will each be generated using the final 'tip' vertex and each pair of vertices from its base row of vertices.

So, each branch will be a mesh made up from a number of branch segments. Furthermore, each tree will be made from a number of branch meshes. In Figure 12.7 we see a tree that is made up of 7 branches. Admittedly it is a poor looking tree and there is much left to be done, but the relationship shown here is the important concept to understand.

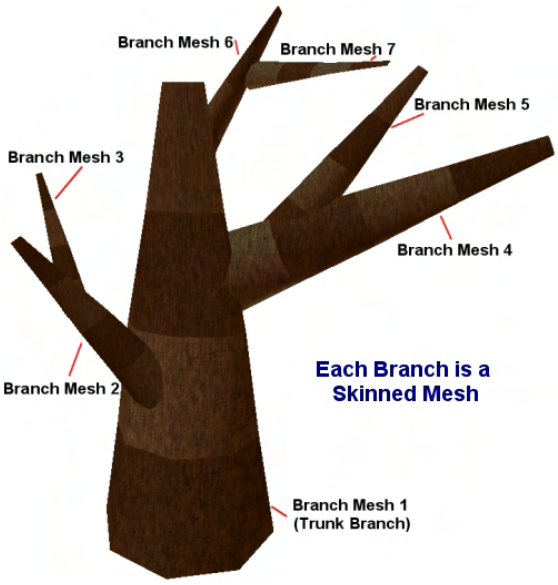

Figure 12.7

When we grow the tree, we initially start out with the root branch; more specifically, the root segment of the branch. We build the branch up segment by segment, at each step determining how big or wide that segment should be. We will also make a choice at each branch segment whether a new child branch (or multiple child branches) should be spawned from that segment. We can see in Figure 12.7, that at segment 2 of the trunk branch, a child branch was spawned off to the left, which itself set in motion a recursive procedure of building the child branch segment by segment in the same way. In this child branch we can see that while generating its third segment, another (smaller) child branch was spawned. After the recursive process ends for the child branches, the flow once again returns to the root branch, which is still half way through being built. On the third segment of the root branch it is determined again that another child branch should be spawned (this time off to the right), which itself spawns its own child branch during the construction of its second segment. When flow returns back to the root branch, and its fourth segment is added, the decision to split into a child branch is made yet again. This child also splits off into a separate child branch some way along its length.

We can definitely see the hierarchical pattern here. If we think about how we might represent this concept in a hierarchy (much like our frame hierarchy), in a way that is totally abstracted from any type of mesh data, we can think of the root segment of the trunk branch as being the root node in the hierarchy. The root node would have a child that would be the second segment in the root branch. This second level child would also have a child which would represent the third segment of the trunk branch, and the third segment would have a child that pointed at the data for the fourth and final branch segment in the trunk. So, each individual branch would be represented in the hierarchy as a list of N nodes arranged in a strict parent-child relationship that represented the N segments of that branch.

Now let us think about how the child branches could be stored. The first child node of the trunk branch in the hierarchy (which represents the second segment of the trunk) could have a sibling that is the first segment in the first child branch (the one that branches to the left). After all, the second segment of the trunk and the first segment of the child branch exist at the same level in the tree and should also exist at

the same level in the hierarchy. We then recur with that sibling pointer, such that each of its segments would be added in a parent-child relationship. So segment N of any branch is the parent of segment N+1 in the same branch.

In Figure 12.8, we see how this hierarchy might look in memory. To reduce clutter, we have only fully shown the trunk branch and the first child branch (protruding from the second segment of the trunk out to the left) in their entirety. When studying this image, do not concern yourself with meshes or bones for now; we are simply constructing a 'virtual tree' tree at this stage, where each branch segment has its own node in the hierarchy and the first segment in any child branch is connected as a sibling of the parent branch segment from which it was spawned.

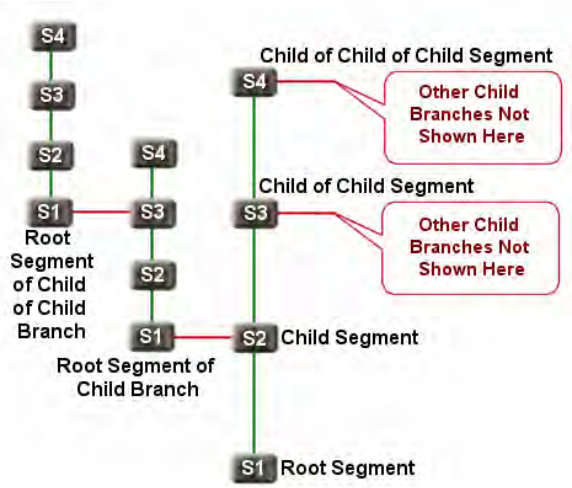

Figure 12.8

In Figure 12.8 we have inverted the diagram so that it reads bottom up. While this is not the typical way to draw a hierarchy, it corresponds better visually with the tree we saw in Figure 12.7. At the bottom of the image we see the root node of the hierarchy. This represents the first segment of the trunk branch. The parent/child relationship is depicted by vertical lines connecting the nodes, while the horizontal lines depict where a sibling relationship exists between two nodes. We can see that the root segment actually has two children arranged in a sibling list. The first child (S2) represents the second segment of the trunk branch, while a horizontal line connects node S2 to the root segment of a child branch. S2 of the root branch also has a child S3. S3 would also have a sibling but that is not shown here. The S3 node of the root branch has a child also (S4), which once again, would also have a sibling to the start of a child branch which is not shown here.

If we backtrack to node S2 of the root branch, we can see that it is in a sibling list with node S1 of a child branch. This tells us that at node S2 in the root branch, a new child branch was spawned. Node S1 in the child branch has one child (S2), but node S2 of the child branch has two children arranged in a sibling list. It points to node S3 (the third segment) in the child branch and node S1 in a new child that is spawned from this child branch at this third segment.

Study the diagram and make sure you understand the relationships as this will all be very important moving forward. If our tree was a single branch with four segments for example, this would create a four level deep hierarchy where each child (except the root) would be a child of the previous node. Each

level in the hierarchy would contain a single node. Any child branches that are spawned at a given branch segment, are arranged in a sibling list with that parent branch's segment node.

It is very important that you consider the node hierarchy shown in Figure 12.8 abstracted from the concept of meshes, vertices, or bones. We are currently just generating a hierarchy of data structures (nodes) that will describe to us the shape of the tree we need to generate. We might consider each node in the tree containing such information as the tree space position of that node and the direction it is facing. In fact, this is exactly how we will build our tree. We will essentially do it in two phases.

In the first phase, we will grow (node by node) a hierarchy of data structures describing the virtual tree. Then, once the shape of the virtual tree has been created, we will traverse this node hierarchy in a second phase and use the information to build the meshes and add the bones. This approach is preferable because it allows us to abstract the shape of the tree that we generate from the procedure used to skin it. After we have built the node hierarchy, we will traverse it in a second phase, and insert a ring of vertices at each node adding another segment to the branch. Of course, at a later time, you could decide to build the mesh data in a completely different way still using the same virtual tree information. For example, you might decide to use the node information to build the tree out of curved surfaces or even decide to drop the resolution such that a ring of vertices is only inserted every three nodes. These are just examples, but hopefully you understand why it is helpful to abstract the virtual tree generation process from the process that turns that virtual representation into a discrete polygonal representation.

As stated above, in our code, when we build the mesh, we will insert a ring of vertices at every node we generated in the virtual tree creation process. This means, with the exception of the first node of every branch, every other node we encounter will cause another branch segment (cylinder) to be generated. Obviously, the first node in a branch cannot possibly add another segment by itself as we need two rings of vertices to create a cylinder. Therefore, it is not until the second node is encountered and another ring of vertices is inserted that the first segment of the branch is complete. The ring of vertices we add at the second node however, also forms the bottom row of vertices for the next branch segment. So when we encounter the third node and add a third ring of vertices to the branch, this (along with the vertices from the second node) forms the second branch segment of the current branch being built.

Thus, our recursive procedure will initially grow a virtual tree out of a hierarchy of nodes, where each node contains data about that node. What information would we need to store in each node? First we will need to store the position of the node in tree space. In tree space, the root node of the trunk branch would be positioned at (0, 0, 0) in the coordinate system. However, what might not seem obvious at first is that in order to grow this node and spawn child nodes, we will need each node to also have a direction vector. This direction vector is a vector pointing in the direction of where the next node will be placed. More importantly, the direction vector can be thought of as a normal to a plane that passes through that node. When we generate the actual mesh for the branch, this is the plane upon which we will place the ring of vertices generated by that node.

To better understand the need to store the direction of a node, let us first just consider a four segment branch that forms the trunk of a tree growing directly upwards. In this case, the direction vector of each branch would simply point straight up to the next node (0,1,0). When we generate the mesh for the vertical tree, this direction vector also describes the normal to the plane on which the node is sitting. In this instance, each node would sit on an XZ aligned plane offset some distance vertically from the origin

of the coordinate system (except the first node which would exist on the XZ plane). As Figure 12.9 demonstrates, when we generate the mesh for a branch, the direction vector describes the normal of a plane. The node is assumed to be positioned at the center of a circle defined on that plane. Using the plane normal we can also generate two tangent vectors (vectors that lay on the plane forming an orthogonal axis with the normal vector). Essentially, once we have the three axes of the node, we can generate the N vertices at the node position and then push them out along the tangent vectors by some radius to form a circle of vertices that lay on the node's plane.

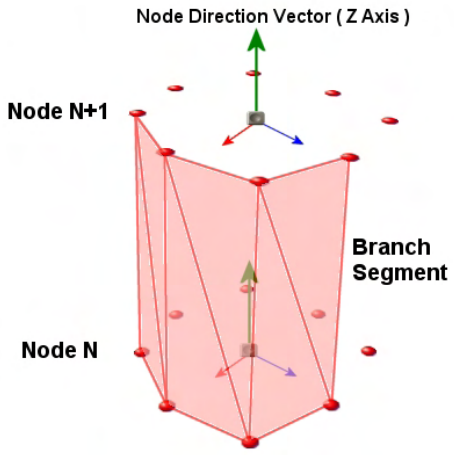

Figure 12.9

You might be wondering why each node would need its own direction vector if the tree is going to grow straight up most of the time anyway? Well, let us consider child branches that are spawned from a node of the trunk branch. They will almost certainly need to have their direction vectors deviated from the parent node's direction vectors, otherwise, all branches spawned would grow vertically straight up inside the trunk of the tree (we would not even see them).

One of the major aspects of the virtual tree generation process will involve deviation of a child's direction vector from that of its parent. For example, let us assume we start at the root node and assign it an initial 'straight up' direction vector of (0, 1, 0). Imagine that we continue to add child nodes with the same direction vector to the same branch, but then we hit a node where a random calculation says we need to add a new child branch. We know that this child branch must not share the same direction vector as the parent, so we will take the parent node's direction vector and rotate it (deviate it) by some amount. The maximum and minimum angles by which we deviate the child node's direction vector from its parent will be controlled by input parameters to the system. We will essentially use two angles to define a deviation cone. When a child branch is spawned and a new node is added to the parent node's child list, its direction vector will be generated by randomly deviating the parent direction vector within a specified range. As we have control over the deviation range via its input parameters, we can use fairly small ranges such that the child branches, while deviating from the parent direction, still follow the overall growth direction of the tree (appropriate for most trees). Alternatively, by specifying a larger random deviation range, we can have child branches growing off at wild angles and even coming back down against the initial growth direction of the root branch (useful for modeling some tree types).

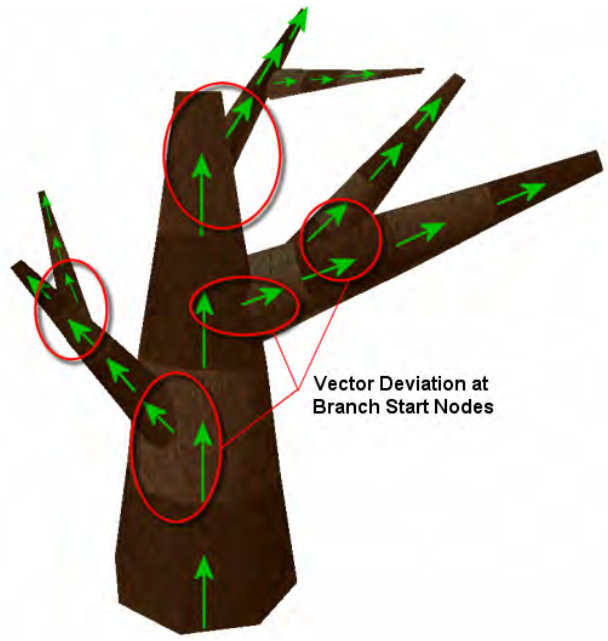

Figure 12.10 : Deviated Direction Vectors

Do not worry about how we deviate a vector within certain restraints as we will get to that in a moment. Figure 12.10 clearly shows why the nodes of each branch will need to have deviated direction vectors from that of its parent branch segments.

Looking at the tree in Figure 12.10, we see that it still is not quite there yet. While the branches shoot out at their own directions, the individual segments within a given branch are all still far too uniform. That is, all nodes within a given branch share the same direction vector. If we study the branch of a real tree, we know it is far from perfectly straight. Usually, it bends multiple times along its length. As we have already added the functionality to deviate a branch node's direction vector, we can widen the application of this technique to deviate every node in the tree from its parent's direction vector.

We will want to control the deviation such that, the deviation applied to a normal branch node's vector is not as strong as the one applied to a node that is the start of an entirely new branch. After all, if every single node in every single branch could deviate by a large amount, we might end up with branches that look more like springs. We can control this with two sets of deviation input parameters to the system. The first pair of input parameters describes the deviation cone that can occur between segments within the same branch. The second pair of parameters describes the deviation cone that can occur for the root node (the starting segment) of any branch. Typically, we will want the deviation cone used for segment deviation within the same branch to be quite small, as shown in Figure 12.11.

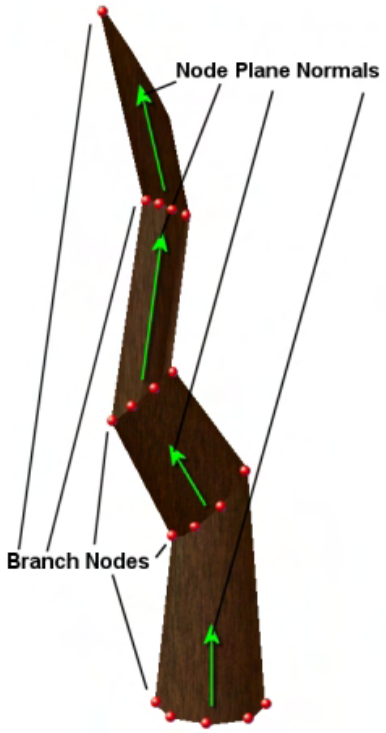

Figure 12.11

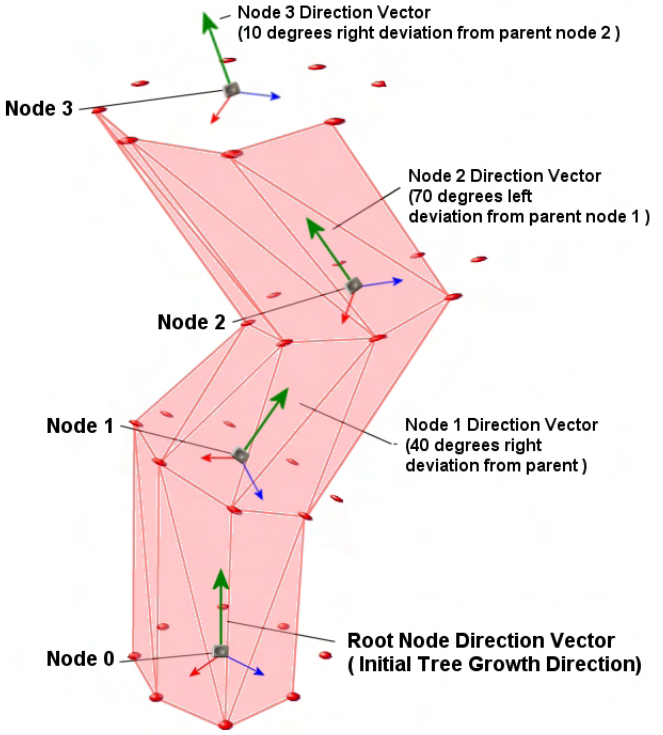

Figure 12.12

Note: Figure 12.11 and 12.12 show two different branches. They are not intended to depict the same vector deviations at each segment.

Figure 12.11 shows how a single branch mesh would be constructed if per-node direction vector deviation was used during the creation of the virtual tree hierarchy. In this diagram, you can see that the initial node had a direction vector (0,1,0) and thus a ring of vertices was inserted and aligned to the XZ plane. However, when a new node is generated to extend the branch, its direction vector is calculated by deviating the parent node by some random amount (within a range specified by input parameters). In this example, you can see that the second node deviated the parent node direction about 35 degrees to the left. Notice that when we come to insert the vertices for this node, the direction vector (along with the two tangent vectors), describes the plane on which the vertices must be positioned. Once again, we can imagine that the node position describes the initial point on the plane at which we add vertices, before then translating them out along the plane (using the tangent vectors) into their positions in the ellipse shape (see Figure 12.12). Looking at the third node (third row of vertices) in Figure 12.11, we can see that this node was deviated from its parent about 45 degrees to the right. This process is repeated for every node of every branch.

So we have learned that when we build our node hierarchy, we will start with the initial growth direction vector of the root node. This vector will be passed through a recursive procedure and deviated for the next node, which will pass its new direction vector onto its child node where it will be further deviated, and so on. Each iteration of the node hierarchy building process will involve, in simple terms, positioning a new child node, and calculating a direction vector for that node by deviating the parent vector.

When we combine the lesser per-segment deviation with the more extreme deviation performed to calculate the direction vector for each starting node in a new branch, we end up with a virtual tree representation that. when converted to mesh form, is a lot more pleasing (see Figure 12.13).

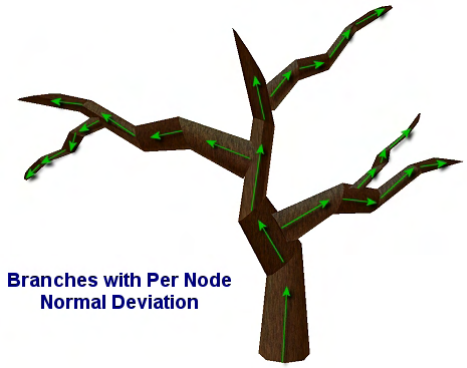

Figure 12.13

Figure 12.14 depicts how the node hierarchy for this tree might look after it has been created. For reasons of image clarity, we have slightly offset the nodes that start new branches from the position of their sibling nodes. In reality however, they would occupy the same position.

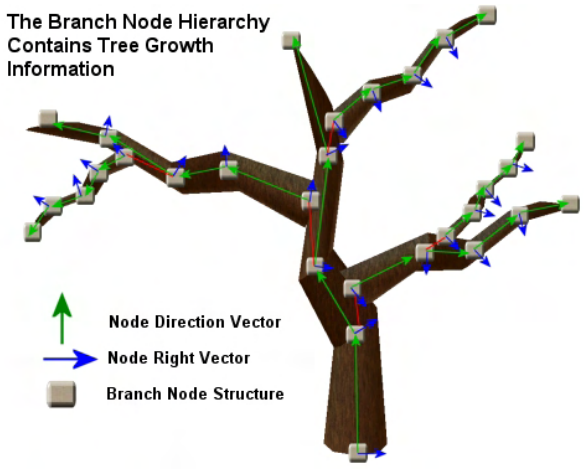

Figure 12.14

If you examine Figure 12.14 you will notice that each node contains a direction vector depicted by the green arrows, and a right vector that is perpendicular to the direction vector. We will also pass the right vector of the initial segment into the system in addition to the direction vector. Why do we need to pass this right vector through the tree? We need it in order to deviate the direction vector of each node during the recursive process. This will be explained in the next section.

12.2 Direction Vector Deviation

Before we examine the source code, we have one major process left to discuss on a theoretical level. Given a vector A, how do we generate a new random vector B that is contained within a specified cone set up around the original vector? It is easy in the two dimensional case since we merely have to rotate the new vector either left or right of the original vector by a random number of degrees. However, when working in three dimensions, simply rotating the vector left or right, or backwards or forwards will not allow us to generate a new vector that is anywhere within the specified cone.

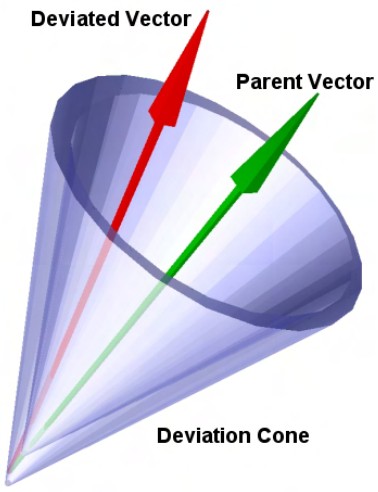

Figure 12.15 : We need to generate a random vector anywhere within the deviation cone.

Figure 12.15 demonstrates the problem we need to solve. The green arrow running down the center of the cone is assumed to be the parent vector (i.e., the vector we wish to deviate). The cone itself represents the range over which the vector can deviate. The goal is to generate a totally random vector anywhere within this deviation cone (the red arrow is one example of a possible solution). As can be seen, simply rotating the original vector clockwise or counter clockwise about a single axis will not provide us with a means to accomplish our objective.

You will see in a moment, when we discuss the structures that we are going to use in our code, how the size of this cone is specified using an angle. However, we will also have another variable that influences vector deviation called *deviation rotation*. Describing what this variable is will allow us to also understand the question at hand, "How do I generate a random vector with a cone?" The answer to this question will explain why we need to calculate a right vector at the root node and pass it through the recursive process. Each node will have its own right vector which will be used in the deviation process of its child nodes.

We will use a simple example to demonstrate the process of deviating the vector. While the same deviation function is used for the deviation of normal segment nodes and for nodes starting new child branches, in this example, we will show how a new branch is spawned from a node and how that node's direction vector is deviated to create the direction vector of the new branch start node. To give clarity to these examples, we will show the mesh data that will eventually be created from the virtual node. However, just remember that the node hierarchy that we generate will not contain any mesh data; it will be a hierarchy of data structures containing positional and directional information that will later be used to describe a tree shape to the mesh building process.

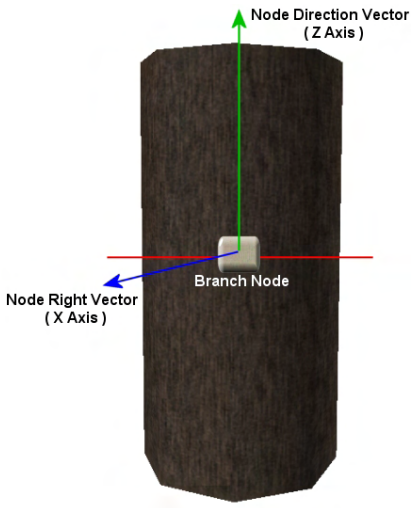

Figure 12.16

In Figure 12.16 we see a single node that is situated at some arbitrary position along a branch. We will assume this is a node in the root branch. Notice how the node stores a direction vector (the local Z axis of the node) and a right vector (the node's local X axis).

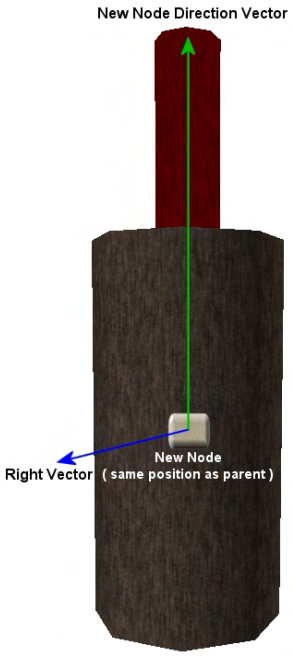

Figure 12.17

Next, let us assume that while processing this node we determine that we would like to create a new branch at this node. In Figure 12.17, the new node is added at the position of the parent node and currently has inherited its direction vector. In the diagram the red cylinder mesh sticking out of the top of the parent segment would not actually exist at this point, but will make our explanation easier. We can think of this for now as being the branch segment that will eventually be built from the branch start node we have just created.

In this diagram, the right vector of the parent node is assumed to be coming out of the page. You will notice that this provides an axis around which we can rotate the new branch node's direction vector. For example, if the cone deviation angle was 90 degrees, then we could generate a matrix that will rotate the new node's direction vector about the parent node's right vector by some angle between 0 and 90 degrees (to allow randomness). In fact, that still is not quite what we want since that would only rotate the vector one way (right for example). What we want to do instead is choose a random number between –cone angle/2 and +cone angle/2. For example, if our input parameters describe to the system that a new child branch node should be deviated by 90 degrees, we would generate a random number between –45 and +45 and use this value to build an axis rotation matrix around the parent node's right vector. This will allow for counter-clockwise and clockwise rotations within the cone.

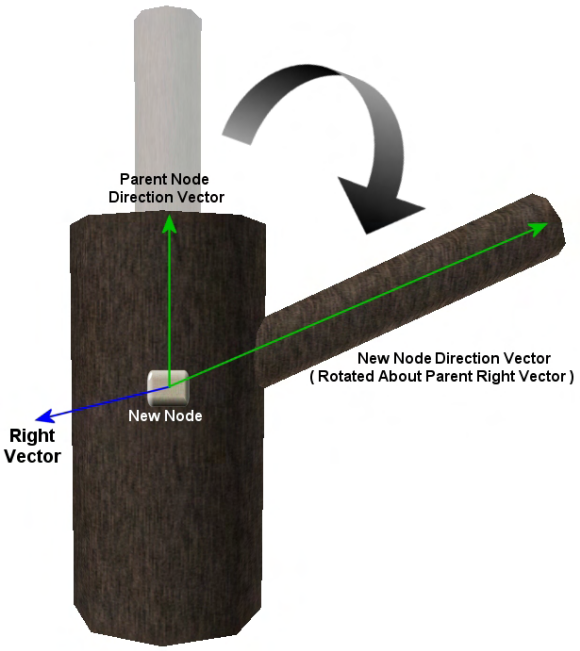

Figure 12.18

After rotating the child node's direction vector about the parent node's right vector (Figure 11.18), we will perform a second random rotation of that vector about the parent node's direction vector. This vector acts as a local up vector for the child node allowing us to rotate its newly rotated direction vector to any position around the circumference of the parent branch (see Figure 12.19). This means, our vector deviation routine will require an additional angle range that describes the permissible rotation that can be applied to the child node's direction vector when generating its random position on the branch. Usually, we will want to give branches an equal chance of shooting out from the parent at any angle, and as such, would set the up axis rotation range to 180 degrees. Then, when we need to rotate the child direction vector about the parent direction vector, we simply choose a random angle between 0-180 to rotate the new node into its final position.

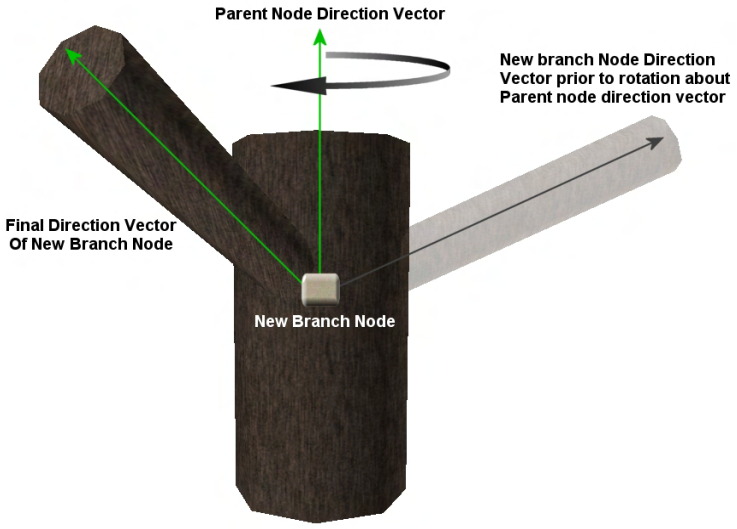

Figure 12.19 : Polar Rotation

Why do we only need to rotate 180 degrees in the second rotation step instead of 360? Remember that in the first step we will rotate the branch either counter-clockwise or clockwise depending on whether a positive or negative angle is used for rotation about the right vector of the parent node. Therefore, this first step essentially rotates the child node's vector into either the negative or positive half of a circle surrounding the parent node. Therefore, the first step chooses the semi-circle which the branch will grow from, and the second step allows us to access any random angle within that semi-circle. Of course, you can limit the rotation angle if you want branches limited to a smaller range of values on either side of the circle. Usually though, in the case of deviating the vector of a new branch start node, you will want to allow full 180 degree rotation on either side so that the branch can grow from anywhere. It should be noted that the same deviation procedure is used for deviating both the direction vectors of new branch start nodes and for the deviation between nodes within the same branch. However, as we will usually want segment to segment deviation within the same branch to more closely follow the overall growth direction of the branch, we will generally use much smaller deviation angles for both rotation steps in the process. With this two step deviation approach we essentially describe a virtual cone with the parent node's direction vector at the center. The new deviated vector will exist somewhere within this cone (Figure 12.20).

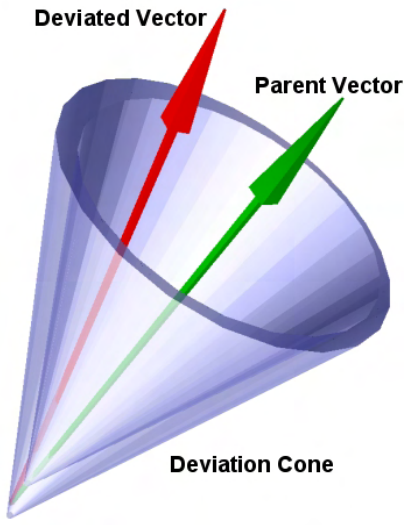

Figure 12.20

In the data structure that we feed into our CTreeActor::SetGrowthProperties function (prior to calling the CTreeActor::GenerateTree function), we will specify two sets of ranges. We will set an axis rotation range for both up and right vectors for node to node deviation within the same branch, and we will also set an axis rotation range for both of the vectors that the deviation process will use when calculating the direction vector of the node that is to become the first node in a new branch. By separating these into two separate deviation cases, we can easily control new branch and inter-branch deviation.

Looking at Figures 12.18 and 12.19 we can see that having the right vector stored at every node is important during the initial growth of the virtual tree as it is needed to deviate the directions of any child nodes. Therefore, while we have shown that the direction vector of each node must be deviated from the parent to create a new direction vector for the child node, once this has been accomplished, we must also calculate the right vector of the new node.

As it happens, updating the right vector in the deviated node is simple since we have already generated the matrix to rotate it into its new position. When we performed rotation on the child nodes direction vector, we would have rotated about the parent node's direction vector by some random amount. We will use 90 degrees in this example. So all we have to do is rotate the parent node's right vector around the parent node's direction vector and we have the new right vector for the child node. The basic node building process now looks like this:

We start the process by passing in a single growth direction vector for the tree (e.g., <0,1,0>). We will perform the cross product with this vector and the world axis that is least aligned to it to create the right vector. We now have the growth direction vector and the right vector for the first node in the tree. From this point on the recursive process starts and works as follows:

1) Will this node generate another child node in the same branch (another branch segment)?
    a) Generate a new segment node and attach it to the parent as a child
    b) Deviate the parent node's direction vector and right vector using (small random values)
    c) Store deviated vectors in the child node

2) Will this node generate a new branch?
    a) Generate a new branch node and attach it to the child list
    b) Deviate the new node's direction vector and right vector using (large random values)
    c) Store deviated vectors in new child node
    d) Repeat steps a-c for each new branch generated at this node
3) Repeat steps 1 and 2 for newly generated node(s)

When we set the deviation properties for our system, we will in fact have three range values we can specify for each of the two deviation types (segment deviation and new branch deviation). We will have a minimum cone angle, a maximum cone angle and the polar rotation angle. The minimum and maximum cone angles (which are a pair) are used to influence the first rotation step (the rotation around the parent's right vector). These values instruct the deviation function to generate a random deviation angle for the first rotation step that is no greater than the maximum cone angle, but also, no smaller than the minimum cone angle. This allows us to set a minimum level of deviation to ensure that we always get at least some deviation. When setting the minimum and maximum cone angle for the new branch deviation settings, the variables can greatly effect the shape of the tree. For example, by using a large minimum angle and only a slightly larger maximum angle, you can generate a tree that has a very uniform looking branch growth direction (like a conifer tree).

By introducing a minimum cone angle variable combined with the polar rotation step, we essentially specify a region inside the cone where vectors can be produced. It is perhaps more accurate to say that we define a region at the center of the cone where random vectors *cannot* be produced (Figure 12.21).

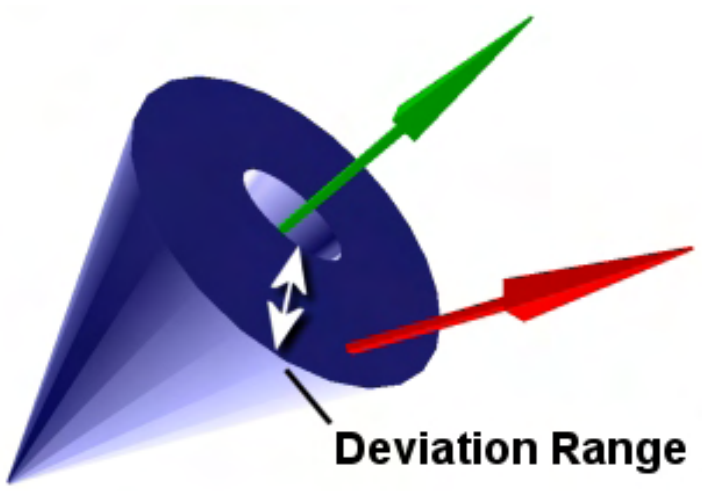

Figure 12.21

While this might sound like a complicated process, you will see shortly that the CTreeActor::DeviateNode method is only a few lines of code long.

12.3 Building the Virtual Tree

We now have all the theoretical knowledge at our disposal to discuss the code to the first part of the tree generation process. This will be the process that essentially grows the virtual tree one node at a time. Remember, at this point we are not dealing with mesh or bone data at all; we are simply building a hierarchy of data structures that contain direction vectors, right vectors, and dimensions.

Let us first see how the application might generate a tree using our new CTreeActor class.

```
// Create a new CTreeActor
CTreeActor * pTree = new CTreeActor;

// Fill out a TreeGrowthProperties Structure
TreeGrowthProperties tgp;

// Fill in the TreeGrowthProperties structure here
// NOT SHOWN HERE AS WILL DISUCSS THESE PROPERTIES IN A MOMENT

// Send out properties to the actor
pTree->SetGrowthProperties ( tgp );

// Build everything
D3DXVECTOR3 RootSegSize( 2.0 ,2.0 ,2.6 );
pTree->GenerateTree ( RootSegSize )
```

That is all there is to it. We create an instance of CTreeActor and then we fill in a TreeGrowthProperties structure. We will look at all the members in this structure in a moment. For now just know that it influences the way the nodes of the virtual tree are grown. We then send this structure to our CTreeActor so that it will have access to these properties during the tree generation process. Finally, we call the one function that makes it all happen: GenerateTree. This function first builds the virtual tree of information nodes (which we call *branch nodes*). Note that we pass in a vector of dimensions that describe the three radii of an ellipsoid that will contain the first branch segment (the root node). The X and Y components describe a box that will bound the ring of vertices generated for that node. If X and Y are equal, the branches will be perfectly circular. However, if we assign X and Y different values such as 2 and 5 for example, the thickness of the root segment of the root branch would be two tree space units in the X dimension and 5 tree space units in the Y dimension. As tree space is essentially the world space coordinate system, but with the tree at the origin, these dimensions directly describe the thickness of the root segment in world space (provided you do not transform the actor into world space using a scaling matrix). The Z component of the dimension vector describes the length of the root segment of the root branch. That is, when building the root branch (the trunk), this is the distance along the root node's direction vector that the second node will be positioned. This equates to the location of the second ring of vertices during the mesh building process. You will see when we examine the recursive tree building process, that the dimensions of each branch node are scaled down versions of the dimensions inherited from their parent. This ensures that branches get thinner and shorter as they near their end.

When the virtual tree has been completely built, we will then enter the second phase of tree construction. We will traverse the virtual tree hierarchy, creating vertices at each node and adding them to the meshes for the branch to which that node belongs. While building the meshes for each branch, we also assemble (using the node hierarchy) a D3DXFRAME hierarchy that will be used as the bone system for the tree.

Finally, when the actor's hierarchy and meshes have been built, we create the actor's animation controller and add optional animations to simulate the tree branches swaying in the wind. Once the GenerateTree function returns, the tree is complete and we can use it in our application just like a regular actor, or we can save it out to an X file for import it a world editor. Using the CTreeActor class within your application (should you wish not to save the generated tree out to an X file and load it in as a regular actor) is no different from using a normal actor. That is, you call its AdvanceTime method to update its animations each frame update and use its DrawSubset methods to render it. The virtual tree hierarchy is no longer needed at this time since it was only used to generate the frame hierarchy of bones and the mesh data for each branch.

12.3.1 The TreeGrowthProperties Structure

So that we get a better feel for the system, the best place to start is the TreeGrowthProperties structure since it defines the behavior of the CTreeActor during the virtual tree building process. This structure is pretty large as the system has many variables that you can tweak to provide you with a means to generate a vast number of different tree configurations. Not all of the members of this structure will make immediate sense until we see them being used. So a detailed discussion of some of them may be deferred until the actual mesh building process is covered.

```
typedef struct _TreeGrowthProperties
{
    USHORT      Max_Iteration_Count;
    USHORT      Initial_Branch_Count;
    USHORT      Min_Split_Iteration;
    USHORT      Max_Split_Iteration;
    float       Min_Split_Size;
    float       Max_Split_Size;

    float       Two_Split_Chance;
    float       Three_Split_Chance;
    float       Four_Split_Chance;
    float       Split_End_Chance;

    float       Segment_Deviation_Chance;
    float       Segment_Deviation_Min_Cone;
    float       Segment_Deviation_Max_Cone;
    float       Segment_Deviation_Rotate;

    float       Length_Falloff_Scale;

    float       Split_Deviation_Min_Cone;
    float       Split_Deviation_Max_Cone;
    float       Split_Deviation_Rotate;

    float       SegDev_Parent_Weight;
    float       SegDev_GrowthDir_Weight;
```

```
    USHORT      Branch_Resolution;
    USHORT      Bone_Resolution;

    float       Texture_Scale_U;
    float       Texture_Scale_V;

    D3DXVECTOR3 Growth_Dir;
} TreeGrowthProperties;
```

This structure may seem a little daunting at first, so we will examine the members one at a time. You will see that many of them relate to the concepts we have already discussed. They act as a means for setting ranges in which certain behaviors can and cannot happen during the growth process.

USHORT Max_Iteration_Count

The maximum iteration member allows us to control the overall depth of the virtual tree hierarchy we create. We start at the root node with an iteration count of 1. Every time a new segment/node is generated for a branch, the iteration count is increased and assigned to the child node. This recursive process continues such that, with every node within a given branch, the segment count is increased. As soon as (or if) the iteration count of the current node reaches the Max_Iteration_Count, no new segments/nodes will be generated along the branch and the branch will be capped and ended. One thing to watch out for is that when new child branches are spawned, the first node in that branch inherits the same segment count as the sibling node of the parent branch. Remember, if a node spawns three child nodes, there will be a sibling list of four nodes in the hierarchy -- three branch start nodes and the node that spawned the branches (the next segment of the current branch being processed). All nodes within the sibling list will contain the same iteration number (see Figure 11.22).

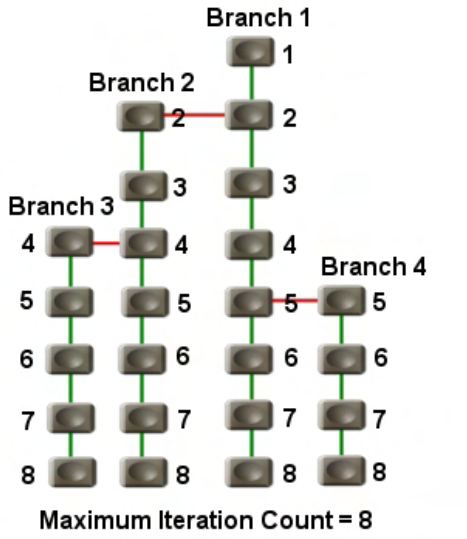

Figure 12.22

Figure 12.22 shows an example hierarchy for a tree that is constructed from four branches. The first branch is, of course, the trunk; but notice that when we add the second node of the trunk we also decide to start a new child branch. The second node of the trunk and the first node of the child branch are in a sibling list, both with an iteration count of 2. This iteration count is then continued down each branch. As you can see, the fourth branch starts with an iteration count of 5 and terminates at 8, being only four segments in length. In this example, we use a maximum iteration count of 8, so the virtual tree hierarchy will never be deeper to traverse than eight levels.

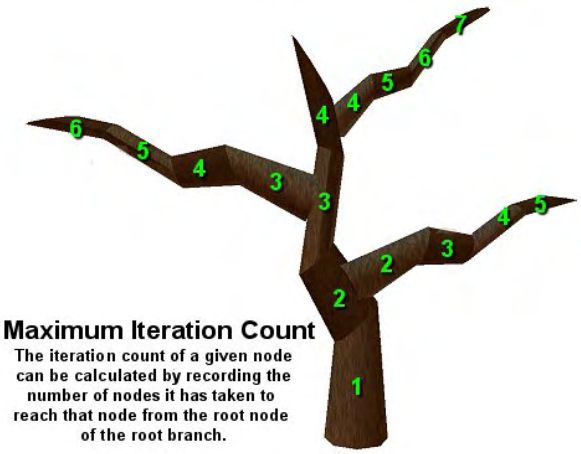

Figure 12.23

Figure 12.23 shows the tree in mesh form so that we can see how the iteration counts apply to the various segments. We are using a bit of artistic license here since we are placing the node iteration count values in the branch segments. We know that in reality however, the nodes that will contain those iterative values will be positioned at the branch segment boundaries (two of which create a branch segment). Nevertheless, this should provide an easy way to see how the iteration count can be used to set a maximum tree depth on the recursive procedure during the generation of the virtual tree.

It should be noted, that while Figure 12.22 clearly shows each branch terminating at the maximum iteration count threshold, this will not always be the case. There are many factors that are considered when deciding to add another segment/node to a branch or whether to terminate the branch at the current node. Such factors are the current branch thickness and of course a random element thrown in for good measure. Therefore, if we set the maximum iteration count to 20, we will not generate a tree where all branches end at the 20^{th} level in the hierarchy. Some branches may be terminated much sooner due to other factors. However, it is one of the many limiting factors that we will place on the procedure to control the depth of our hierarchy and the ultimate the size and complexity of our tree. There will never be a single path of branch segments from the root segment in the root branch to any branch's terminating segment that will cross segment boundaries more times than the value we set here.

USHORT Initial_Branch_Count

In all the example trees we have examined so far, we have assumed that the tree had a single initial branch (the trunk) from which all others were spawned. However, there is no reason why this has to be a strictly followed rule. While it is clear that your trees will require one initial branch (the trunk), you may wish to model trees that have multiple trunks (Figure 12.24). This parameter allows us to specify the number of initial branches we would like to tree to have.

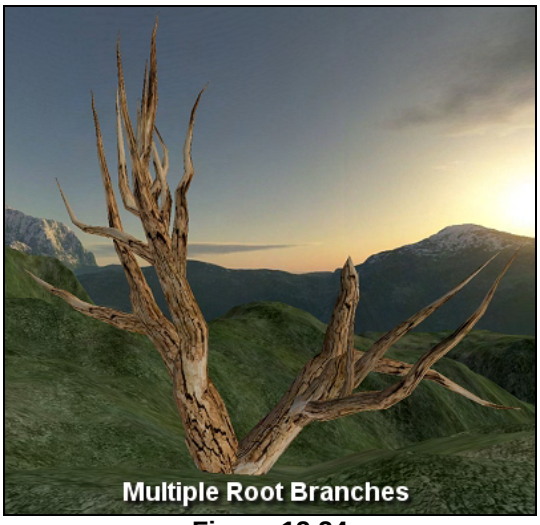

Figure 12.24

When multiple initial branches are enabled, all initial branches start at the same position (0,0,0) in tree space. Normally, when a single initial branch is being used, the direction vector we pass into the CTreeActor::GenerateTree function will be used 'as is' for the direction of the first node in that branch. When multiple initial branches are being used, each initial node in each trunk branch we create will be randomly deviated from the initial vector passed in. For example, we might imagine when looking at Figure 12.24, that when GenerateTree was called, an initial growth direction vector of <0,1,0> was specified. However, we cannot assign this same initial vector to the first node in each root branch or they would be created in exactly the same position and facing the same direction (thus, we would only see one branch). So instead, the passed vector is randomly deviated to create the actual initial direction vectors of each branch root node. In Figure 12.24 you can see that the node direction vector for both root branches has been rotated left or right to some degree from the initial direction vector passed in.

From the perspective of our virtual tree hierarchy, it simply means that there will no longer be only a single root node in the first level of the hierarchy (describing the start node of the only trunk). Instead, the first level of the hierarchy may consist of a sibling list of nodes, where each node in the list describes the start node of a trunk branch. By default, the Initial_Branch_Count member is set to 1 (in the constructor). By setting it to higher values, we are able to model foliage that grows in a more clustered manner (e.g., a rhubarb plant).

> **Note:** CTreeActor can be used to model foliage types beyond trees (bushes, shrubs, etc.) using the same methodology. If you did not want to include the overhead of all of the hierarchy and animation and skinning for small shrubs, you can still use CTreeActor to generate the shrub and then save it as an X file. When you load it back in, you can load it as a standard mesh (CTriMesh) rather than as an actor. We will talk more about this later.

USHORT Min_Split_Iteration
USHORT Max_Split_Iteration

These two members provide us with a means to control the range in which child branches are allowed to be spawned. For example, we will often *not* want a child branch to be spawned at the first segment of the trunk (during the first iteration of the recursive process).

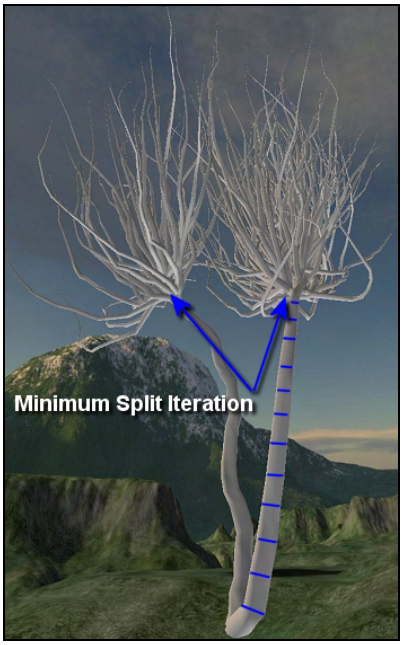

Figure 12.25

As discussed above (see Max_Iteration_Count), the iteration value is increased as each child node is added to the virtual tree hierarchy and it is directly related to the current branch segment that will be added to the mesh. We can think of the iteration count of a given node as indirectly describing the level in the hierarchy at which it resides. Figure 12.25 shows an example where we have set the minimum split iteration count quite near to the maximum iteration count of the tree such that splits into child branches only occur at the very top of the tree. Simply put, when a new node is added to the virtual tree hierarchy, we will decide whether or not we should split at this node and create multiple child branches. Splits will never happen if the iteration count of the current node being processed is smaller than Min_Split_Iteration or larger Max_Split_Iteration. Therefore, a node will only be considered for splitting if its iteration count (its depth in the hierarchy) is within the range described by these two members.

float Min_Split_Size
float Max_Split_Size

These two values allow us to further define a range of branch sizes with which child branches can be spawned from a node. When we call CTreeActor::GenerateTree, we will pass in a vector describing the size of the initial root node. As previously discussed, the X and Y components of this vector will describe the radii of the circle/ellipse that will be used to position the vertices at that node when we build the mesh. With each iteration, when we add new child node, we will subtract a small amount from this vector so that the vertices placed at each node define a smaller ellipse the further along the branch we move. This will produce a tapering effect. At the very end of a branch, the ellipse becomes a single point defining the tip of the branch. Essentially, by dividing the dimensions vector of the root branch node by the maximum number of iterations of the tree, we have a value that we can subtract from the dimensions of a parent node to generate the dimensions of the new child segment. By using this value, we can be sure that any branch will get progressively smaller as its length is traversed, with the final end node in a branch being the tip.

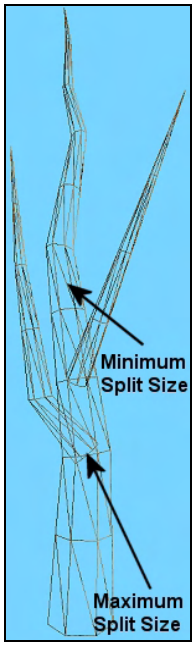

Figure 12.26

Near the end of a branch, its segments will typically be very thin, and as such, generating new child branches from these would result in extremely slim branches. They would be so thin that it would be a waste of time rendering them, especially when we consider that we will eventually add leaves to this tree that will completely obscure such microscopic detail. These two values allow us to define a thickness

range. If a node's dimensions are within this range, then it is possible for it to split into a child branch at this node. However, if the node thickness is smaller than the minimum split size or larger than the maximum split size, splitting the node will not be considered.

Figure 12.26 shows an example of a very simple tree where the Min_Split_Size and Max_Split_Size properties have been set to a very limited range in the center of the tree. As you can see, the Max_Split_Size variable allows us to control child branches not being spawned too close to the base of a branch, while the Min_Split_Size allows us to cease splitting the branch once its thickness has decreased past a sensible level.

These two members and the previous two members can be used together to provide a very flexible control mechanism for determining when and where child branches are spawned (and thus, control the shape and complexity of the tree).

float Two_Split_Chance
float Three_Split_Chance
float Four_Split_Chance

When building our virtual tree hierarchy, at every node we will need to decide whether or not we wish to introduce a new child branch. Of course, if the current iteration (tree depth) is such that it is outside the range described by the Max_Split_Iteration and Min_Split_Iteration members, then the node will not be considered for splitting. Furthermore, if the thickness of the node (its X and Y dimensions) is outside the range described in the Min_Split_Size and Max_Split_Size members, then once again, the node will not be considered for splitting. If however, the node is within the specified ranges for a possible split to occur, then we will use a random procedure to decide whether a split will occur at this node. In fact, we will perform three tests to decide whether the node should spawn two, three, or four branches (or just the one default).

These three properties each contain a percentage score that describe the probability of each node splitting into two, three, or four branches respectively. The tests are actually performed in order; we first perform a test to see if two branches should be spawned, then we perform a test to see if three branches should be spawned and finally we test to see if four branches should be spawned. The following pseudo code should give you the basic idea until we get the actual code.

```
// Generate Random Number Between 0 and 100
if ( RandomNumber < Two_Split_Chance)    NewNodeCount=2;
if ( RandomNumber < Three_Split_Chance)  NewNodeCount=3;
if ( RandomNumber < Four_Split_Chance)   NewNodeCount=4;
```

A random number will be generated between 0 and 100. Our three split chance members should be defined in that range too. Note above that all tests are always performed, so we always fall back to the highest number of splits should more than one of the tests succeed. For example, assume that we set our Four_Split_Chance member to 40 (40% chance) and our Two_Split_Chance to 80 (80% chance) and that at a given node the random number generated is 10. 10 is smaller than 80 so we have passed the two split chance and NewNodeCount is set to 2. However, when we perform the last test we also find that 10 is smaller than 40 so the Four_Split_Chance case wins out and we introduce four new branch nodes (three new branch segments plus the next branch segment of the current branch we currently processing). A different random number is generated for each test, so this is not as redundant as it

sounds. The reason we have ordered the test such that the highest number of splits takes precedence if multiple tests pass, is because typically we will set the probabilities of the four split case much lower than the two split case. Therefore, the two split case will often succeed when no others do. In the rare cases where the four split test does succeed, we want it to override the results of any previous tests.

By setting these values to different percentage values, we can influence how many branches are generated at each node. If all the tests fail, then no split will happen at this node and just the one node (the continuation of the branch) will be added.

float Split_End_Chance
This member is another percentage [0, 100] that describes the probability that each node has of ending the branch to which it belongs if it spawns one or more child branches. When it is determined that a branch node we are adding to the current branch will also spawn new child branches, we will generate a random number between 0 and 100 to determine whether the current branch we are adding should be terminated when the new branches are spawned. If the random number we generate is smaller than the Split_End_Chance probability, the current node will terminate the current branch, allowing the new child branches it spawned to continue. This value is not considered when a branch node is added that does not spawn new child branches. It really is just used to determine what the chances are of a branch terminating at the point where it forks into multiple child branches. We can think of it as the probability that the branch has been pruned at that node.

float Segment_Deviation_Chance
float Segment_Deviation_Min_Cone
float Segment_Deviation_Max_Cone
float Segment_Deviation_Rotate
These members control the range of random vector deviation that is applied to a child node's direction vector. As previously discussed, when a new node is added to continue a branch (not a branch start node), we will typically want to randomly deviate the direction of the new node so that all the segments in the branch do not end up sharing a perfectly uniform direction. The Segment_Deviation_Chance member should be set between 0 and 100 and will be used to determine the probability that a given node will deviate from its parent node's direction. If you set this to 100 for example, then a child node's direction vector will always be deviated from its parent node's direction vector making the branches of the tree look much more organic. Setting this to a value of 0 will generate a tree where all segments within the same branch share the same direction and no deviation will occur between segments within that branch.

Once it is determine that a child node's vector will be deviated, we will deviate it in two steps as discussed earlier in this lesson. First, we will rotate the child node's direction vector (initially inherited from the parent node) around the parent node's right vector. The amount we rotate this vector is described in degrees by the Segment_Deviation_Min_Cone and Segment_Deviation_Max_Cone properties. For example, if we set the minimum cone angle to 60 and the maximum cone angle to 110, then a random deviation angle will been chosen between 60 and 110 degrees. However, we do not always want the rotation to happen in the same direction around the parent node's right vector, otherwise our trees will have a tendency to all lean one way. So we convert the random angle into either a negative or positive number based on a random decision. This would allow us in this example to create a rotation between either –60 and –90 degrees or +60 to +90 degrees. Below we see the code that would

generate the rotation angle used in the first step. It generates a rotation angle between the minimum cone angle and the maximum cone angle in either the clockwise or counter-clockwise direction.

```
float fAzimuth = (float)rand() / (float)RAND_MAX;

fAzimuth = Segment_Deviation_Min_Cone +
          ((Segment_Deviation_Max_Cone – Segment_Deviation_Min_Cone) * fAzimuth);

if ( RandomNumber > 50% ) fAzimuth = -fAzimuth;
```

The first line generates a random number between 0.0 and 1.0. The second line essentially uses this value to scale the delta value between the minimum cone angle and maximum cone angle which is then added to the minimum cone angle. At this point we have a positive angle in the correct range, so the third line generates a random number between 0 and 100 and basically flips the sign if the random number is in the second half of its range. This ensures we have a 50/50 chance that each deviation will be either positive or negative in direction.

Let us plug in some values to see how that works. Let us imagine that we have set the minimum cone angle to 40 degrees and the maximum cone angle to 110 degrees. Let us also imagine that the initial random value (fAzimuth) is 0.5. This essentially means we wish to perform either a positive or negative rotation to a position halfway between 40 and 110 degrees (+/- 75 degrees).

```
float fAzimuth = 0.5; // Half way between min and max

fAzimuth = 40 +(( 110 – 40) * 0.5);
//       = 40 +(( 70) * 0.5 )
//       = 40 +( 35  )
//       = 75 degrees

if ( RandomNumber>50% ) fAzimuth = -fAzimuth;
```

That works perfectly. Once we have a value of 75 degrees in the above example, the second random number would be generated to decide whether or not to flip the sign and make this a +75 rotation or a –75 rotation.

As another example, if the random fAzimuth value we initially generated was 0.0, this means we wish to apply the minimum deviation. The minimum deviation we can perform is defined by the Segment_Deviation_Min_Cone angle. Using the same example values above, this was set to 40, which means the minimum we should deviate is 40 degrees. Let us plug it in and see if it works.

```
float fAzimuth = 0.0; // Apply minimum deviation

fAzimuth = 40 +(( 110 – 40) * 0.0);
//       = 40 +(( 70) * 0.0 )
//       = 40 +( 0  )
//       = 40 degrees

if ( RandomNumber>50% ) fAzimuth = -fAzimuth;
```

As you can see this would generate a rotation of either –40 degrees or + 40 degrees.

With the first deviation phase out of the way, our next task (having rotated the new node's direction vector left or right) is to rotate it in a circular fashion about the parent node's direction vector. This allows us to rotate the direction vector of the child so that is can protrude from the parent branch at any angle. Setting this value to 180 degrees will allow for a vector with total freedom of deviation in a 360 degree circle about the parent node.

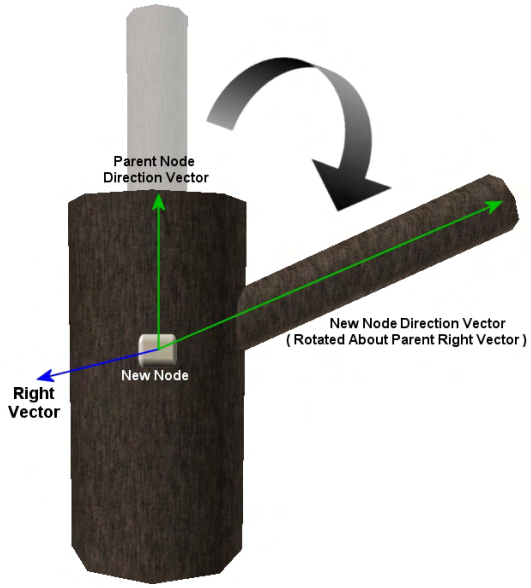

Figure 12.27
Phase 1: Random +/- rotation about parent node's right vector in the range defined by the minimum and maximum cone angles.

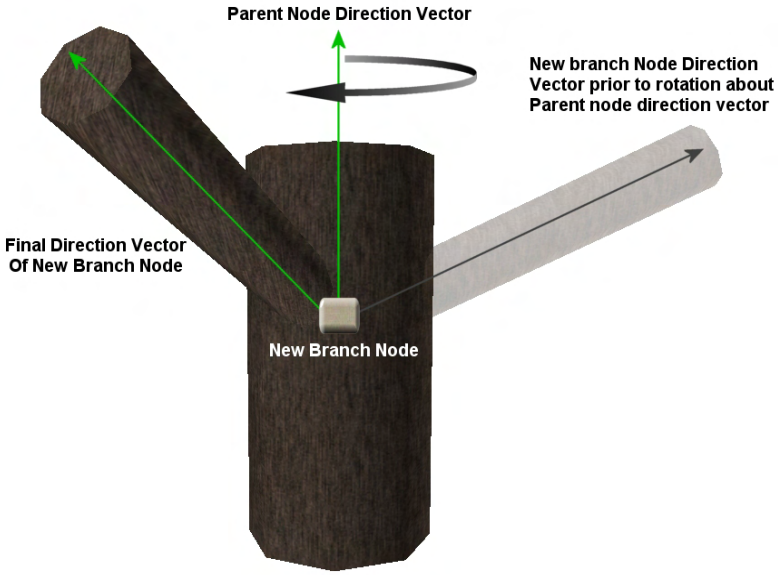

Figure 12.28
Phase 2: Random +/- rotation about the parent node's direction vector within the range: – (Polar Angle/2) to +(Polar Angle/2)

Once again, if this polar angle was set to 40 degrees, it would mean a random angle would be generated between 0 and 40. However, we do not always want to rotate about the parent node's direction vector in the same direction, so we will map it into the -/+ range. In this instance, we would want to generate a value between –20 and +20 instead of 0 to 40 using the code shown below.

```
fPolar  = (float)rand() / (float)RAND_MAX;
fPolar  = (Segment_Deviation_Rotate * fPolar) - (Segment_Deviation_Rotate / 2.0f);
```

To generate the random polar rotation angle we first generate a random number in the range of 0.0 to 1.0. We then use this value to generate an angle that is mapped into a -/+ range.

For example, let us imagine that we had set Segment_Deviation_Rotate to 30 degrees. Let us also assume that we generated an initial random number of 0.0. This should perform a negative rotation 15 degrees left as shown below.

```
fPolar  = 0.0;
fPolar  = (Segment_Deviation_Rotate * fPolar) - (Segment_Deviation_Rotate / 2.0f);
//      = ( 30 * 0.0 ) – ( 30 / 2 )
//      = 0.0 - 15
```

```
//      = -15 degrees
```

Likewise, an initial random number of 1.0 will generate a positive 15 degree rotation.

```
fPolar  = 1.0;
fPolar  = (Segment_Deviation_Rotate * fPolar) - (Segment_Deviation_Rotate / 2.0f);
//      = ( 30 * 1.0 ) – ( 30 / 2 )
//      =  30 - 15
//      =  15 degrees
```

Finally, an initial random number of 0.5 is halfway between the range and should therefore generate a rotation of 0.0 degrees (no polar rotation).

```
fPolar  = 0.5;
fPolar  = (Segment_Deviation_Rotate * fPolar) - (Segment_Deviation_Rotate / 2.0f);
//      = ( 30 * 0.5 ) – ( 30 / 2 )
//      =  15 - 15
//      =  0 degrees
```

And that is all there is to node deviation. We then use these two rotation values to build the rotation matrices with which to rotate the direction and right vectors of the child node.

float Length_Falloff_Scale

This member is one of those members that will make more sense when we look at the code. It controls how the length of each segment gets smaller as the segments near the end of the branch (the tapering effect). As discussed above, as we add each new node to our hierarchy, each node inherits the dimensions of its parent node which then has some small value subtracted from it. In the case of the X and Y dimensions of a node, these describe the radii of an ellipse on the plane described by the node, and thus the size of the ring of vertices that will be generated there. We also discussed how the value we subtract from each node is the dimensions of the root node divided by the maximum iteration count. This allows us to scale the radii of each node such that the ellipse of vertices inserted at each node will get progressively smaller towards the end of the branch (and thus the overall tree). We also do the same for the Z dimension of each node, which essentially describes the length of the cylinder segment formed by that node and its child node (the length of a branch segment). This means branch segments will not only get thinner as the tree approaches its branch tips, but also shorter.

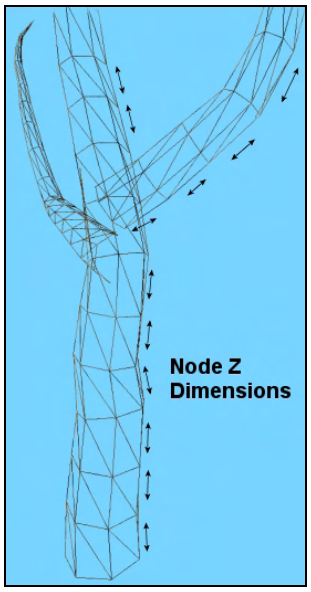

Figure 12.29

However, if you look at Figure 12.29, you can see that while we usually wish the thickness of the branch to get smaller towards its end quite quickly, usually we will not wish to scale the length of each segment at quite the same rate. In Figure 12.29 you can see that the length of each segment diminishes only slightly from segment to segment while the thickness of the each segment (the X and Y dimensions) falls off quite quickly.

The Length_Falloff_Scale allows us to control how the length of each segment (the Z dimension) gets decreased from node to node with respect to how the X and Y dimensions are scaled. For example, if we

set this value to 1.0, then the length of each segment in a branch will get smaller by the same ratio as the reduction in the thickness from segment to segment. A value of 0.5 would mean that the reduction in length from segment to segment would be half the reduction in branch thickness from segment to segment. Lower values in this member make the tree more spindly looking (long and thin) while higher values will result in tree with shorter, stumpy looking branches.

float Split_Deviation_Min_Cone
float Split_Deviation_Max_Cone
float Split_Deviation_Rotate
These values should look familiar to you. They define the cone and polar rotation used to deviate the vector of a node that is the first node in a new branch. The exact same deviation technique is used as has been previously described, and as such, these parameters are used in exactly the same way as the Segment_Deviation_Min_Cone, Segment_Deviation_Max_Cone and the Segment_Deviation_Rotate members discussed earlier. These values are used when deviating the vectors for start nodes of a new branch. This allows us to provide a much larger deviation range for new child branches which will usually sprout off from the parent at quite arbitrary angles. Contrast this with segment to segment deviation within the same branch where we usually keep vector deviation more conservative.

float SegDev_Parent_Weight
This member is used to set a weight (usually between 0.0 and 1.0) which describes how much the deviated vector of a child node should be influenced by the direction vector of its parent. Essentially, once we have deviated the vector of a node, we will add to that vector the direction vector of the parent scaled by this weight, before normalizing that vector.

```
DeviatedVector        = This is the vector that has just been randomly deviated
pNewNode->Direction   = DeviatedVector+( pParentNode->Direction*SegDev_Parent_Weight );
D3DXVec3Normalize    ( &pNewNode->Direction, &pNewNode->Direction );
```

If this value is set to zero then segment to segment vector deviation will be completely random and sporadic (within the specified ranges). By assigning this weight a value, we allow each new segment added to a branch to be randomly deviated while still following the overall direction of the branch.

It is very important to realize that the parent nodes direction vector and this weight are only used to influence the deviated vector of a child node during segment to segment deviation within the same branch. Whenever a new branch is generated, the direction vector of the first node in that branch (the root node of the branch) is not influenced by its parent node's direction vector at all. This makes sense as we often want new branches to shoot off at random angles from the parent branch. However, once the new random vector for a branch start node has been generated, all child segments/nodes of that branch will have their vectors influenced by their parent direction vectors, the first of which is the direction vector of the branch's root node. Therefore, new branch nodes are the links where parent influence is temporarily discarded (for the generation of that node only).

If you were to set this weight value to 1.0, the final vector for a new node would be the average of the deviated vector (generated in the steps discussed previously) and the parent node's direction vector.

D3DXVECTOR3 Growth_Dir
float SegDev_GrowthDir_Weight

These two members further allow us to control the overall growth direction of the tree. When we call CTreeActor::GenerateTree we pass in a vector describing the direction of the first node in that tree. From this point on, the direction vectors are passed from parent to child and deviate at each step. Therefore, even if you passed in an initial direction vector of <0, 1, 0>, this does not mean that your tree would grow in that direction at all. This only tells us that the first segment will point in that direction. As discussed in the previous parameter, we can certainly factor in the parent vector of any node into the generation of its child node's vector, however this does not always do what we want.

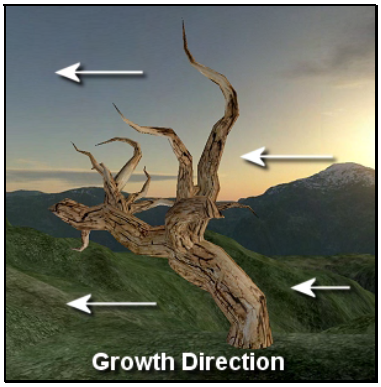

Figure 12.30

For example, if we used an initial direction vector of <0,1,0> for the root node and also set the SegDev_Parent_Weight to some non-zero value, we know that the direction vector would influence all the other segments in the root branch to some degree. This means, the root branch would generally grow in an upwards direction as described by our initial direction vector. However, what we must consider is that as soon as a new branch is spawned, the influence of the root parent branch direction vector is lost. That is, if a new branch is generated, the first node in that branch will have a totally random deviation applied to it (not influenced by its parent). From that point on, all the child nodes of that branch will be influenced by that direction vector and not the vector that we initially passed in. This is not a design flaw, since we absolutely want branches to have directions independent of their parent branches. But it would be nice if we had another level of control; a direction vector that could globally influence the direction of all nodes in the hierarchy. That is what the Growth_Dir and the SegDev_GrowthDir_Weight properties are for. These values are very useful for shaping the overall growth direction of a tree.

If you take a look at Figure 12.30 you can see a tree that has been generated with a growth direction vector of <-1,0,0> to make the tree segments generally grow in the direction of the negative X axis of tree space. In this example, a SegDev_GrowthDir_Weight of 0.2 was used. As you can see, even though we passed in an initial direction vector of <0,1,0> for the root node, as the segments are generated, the growth direction vector is still influencing the direction of every branch node. Once again, the only time that the growth direction does not influence the vector generated for a node is when the node is a root node of a branch. For example, you can see in Figure 12.30 how initially, new branches deviate in a totally random direction. As we begin to add nodes to those branches however, those child nodes are influenced by the growth direction vector and as such, the branches begin to curl round in the direction of the growth vector specified.

Let us say for example that you wanted to model a tree growing out of the side of cliff face. The growth direction for the tree could be set to <0,1,0> but the initial direction vector of the root node of the entire tree set to <1,0,0>. The tree would start growth horizontally out of the cliff face and then gradually start to grow upwards. How quickly this change in growth direction takes place depends on how you set the SegDev_GrowthDir_Weight member and the SegDev_Parent_Weight members. These members directly control, at each node, how strongly the parent node influences the node direction, and how strongly the overall growth direction of the tree does.

USHORT Branch_Resolution

This member is used to control how many vertices will be used in our node rings (and thus, our whole tree). As mentioned previously, after we have generated our virtual node tree, we will traverse that tree and insert a ring of vertices at each node. How many vertices we insert into this ring directly controls smoothness of the branches. Figure 12.31 shows the circle of vertices inserted for two nodes with a branch resolution setting of 8. As you can see, the Branch_Resolution member defines how coarse and angular the cylinder of each branch segment will be.

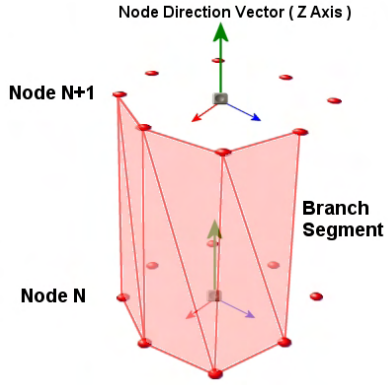

Figure 12.31

The default value is 8, which means each branch segment cylinder will be using 16 vertices -- 8 vertices at each node that form its bottom and top boundaries. Note however that vertices are shared between segments. For example, the ring of vertices inserted at node 2, form the top of cylinder 1 (Node1 ->Node2) and the bottom of cylinder 2 (Node2->Node3).

USHORT Bone_Resolution

Once we have completed the first phase of tree creation, we will have a Virtual Tree described by a hierarchy of branch node structures. This tree representation is abstracted from mesh or bone data at this point. The second phase of tree creation will involve generating the meshes for the branches themselves and building the actor's internal D3DXFRAME hierarchy which will describe the bones of the tree used to render and animate the actor.

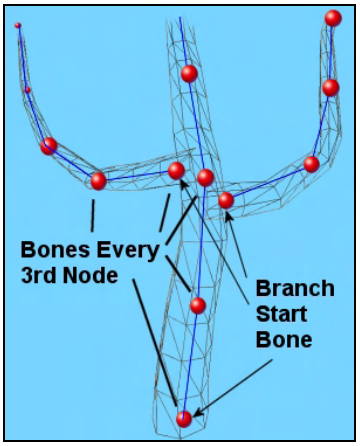

Figure 12.32

When building the meshes for the tree, we have decided that every node in the virtual tree should describe a plane that will contain a ring of vertices that both end and begin each branch segment. Therefore, each node in our virtual tree represents the actual location where vertices will be placed. We could take the same approach when building the actor's frame hierarchy, although having bones placed at every node is probably overkill for what will simply be an animation that gently moves the tree back and forth in the wind. The more bones we create for the tree, the more traversal and transformation will have to be done when rendering the tree and animating the hierarchy. Therefore, this member allows us to define the bone resolution of the tree.

The bone resolution is simply a value N that describes to the tree creation process that bones should be inserted every N nodes. The default bone resolution is 3 which means, starting from the root node, bones

will be inserted every third node that is encountered along a branch. If you look at Figure 12.32 you can see how the bones might look if placed at every third node. We have found during testing that this provides more than enough joints to move the tree in a convincing manner. In fact, the tree will still move nicely even with fewer bones than this, so you could set this member based on the end user's system to get better performance if you intended to use CTreeActor in your actual game code. As you can see by looking at Figure 12.32, the actor's frame hierarchy will contain a lot fewer frames than the node hierarchy of the virtual tree that we create. Therefore, we can think of the actor's frame hierarchy as being a discrete version of the virtual node hierarchy. This is similar to how curved surfaces are eventually turned into a discrete polygonal representation based on a continuous curve. The more polygons you allow to model the curve, the more closely the final mesh will resemble the mathematical model of that curve. While our virtual tree hierarchy is not nearly as abstract as a curved surface, it does allow us to de-couple the virtual tree generation process from the bone and mesh resolutions we ultimately end up using the build the final representation.

float Texture_Scale_U
float Texture_Scale_V

The final two members in our structure will be used to set the scale of the texture used to map the branch meshes. We learned in Module I of this series how we can assign texture coordinates values outside the [0.0, 1.0] range to allow us to repeat a texture image multiple times over the face of an object. For example, we know that if we have a texture mapped to a quad that has its texture coordinates in the 0.0-4.0 range along both its U and V axes, the texture will be mapped to the surface of the polygon sixteen times. It will be mapped four times along the U axis and four times along the V axis.

In Figure 12.33 we can see a quad that has a texture mapped to it once because its UV range is in the [0.0, 1.0] range both horizontally and vertically. In Figure 12.34, the same quad has texture coordinates in the range of [0.0, 4.0] which tiles four rows and four columns of the texture image.

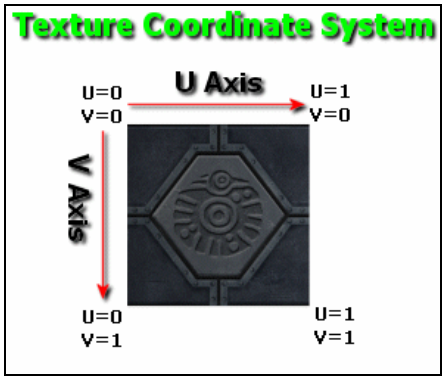

Figure 12.33 (UV range 0-1)
Texture mapped once to a quad.

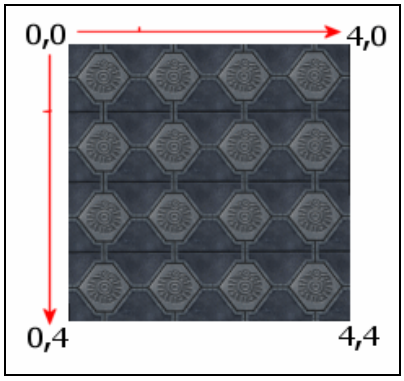

Figure 12.34 (UV range 0-4)
Texture mapped sixteen times to quad

The Texture_ScaleU and Texture_Scale_V properties of our tree allow us to apply the same scaling of the texture that we use for the branches of our tree. That is to say, the higher we set these values, the more times the texture will be tiled over the entire range of the tree. In order to understand how these properties work, we need to discuss how we will in fact generate the texture coordinates for the vertices of the tree.

Calculation of the U texture coordinate for a vertex in our branches is delightfully easy because it is a function of the branch resolution (the number of vertices we will use to form the ring at each node in our virtual tree). If the branch resolution is 8 for example, then we simply wish to assign each vertex in the ring one of 8 positions across the U axis of the texture. If we forget about the texture scaling members for the time being, we could see that the calculation of the U texture coordinate for a vertex in the ring is simply its position within that ring divided by the total number of vertices in the ring (branch resolution)

generating a value in the [0.0. 1.0] range. For example, if we have a branch resolution of 8, then we simply have to do the following calculation for each vertex in a ring:

```
for (int i=0; i< BranchResolution; i++)
{
     Vertex[i].U = i / BranchResolution-1; // zero based vertices
}
```

Let us have a look at the values this generates for each vertex in the ring.

Vertex[0].u = 0 / 7 = 0.0
Vertex[1].u = 1 / 7 = 0.142
Vertex[2].u = 2 / 7 = 0.285
Vertex[3].u = 3 / 7 = 0.428
Vertex[4].u = 4 / 7 = 0.571
Vertex[5].u = 5 / 7 = 0.714
Vertex[6].u = 6 / 7 = 0.857
Vertex[7].u = 7 / 7 = 1.0

As you can see, we have essentially unrolled the ring of vertices at that node and laid them flat across the texture. If you imagine those vertices then being pulled back into the shape of a cylinder, we have in fact wrapped the texture around the cylinder's width exactly once.

Calculating the V coordinate for each vertex is a slightly different matter but certainly no more difficult. We decided that the V coordinates should be mapped over the entire range of the tree. Essentially, vertices at the bottom of the tree will have V coordinates of 0.0 while vertices at the ends of branches will have V coordinates approaching 1.0.

We decided to do this because it allows us control over changing the color of the tree as a function of height. We could for example, have a bark texture that is very dark brown at the bottom but slowly faded to a light brown near the top. When mapped to the tree, the segment at the bottom of the tree would receive the dark brown texture colors, but as we move up the tree, the branch segments would receive the lighter portions of the texture. This might be to simulate that the branch tips are in direct sunlight and their color has been bleached. You could also generate a texture such that at the top of the texture, the bark texture has little green shoots or leaves, which once again, when mapped to the tree, the greener areas would only show up towards the branch ends.

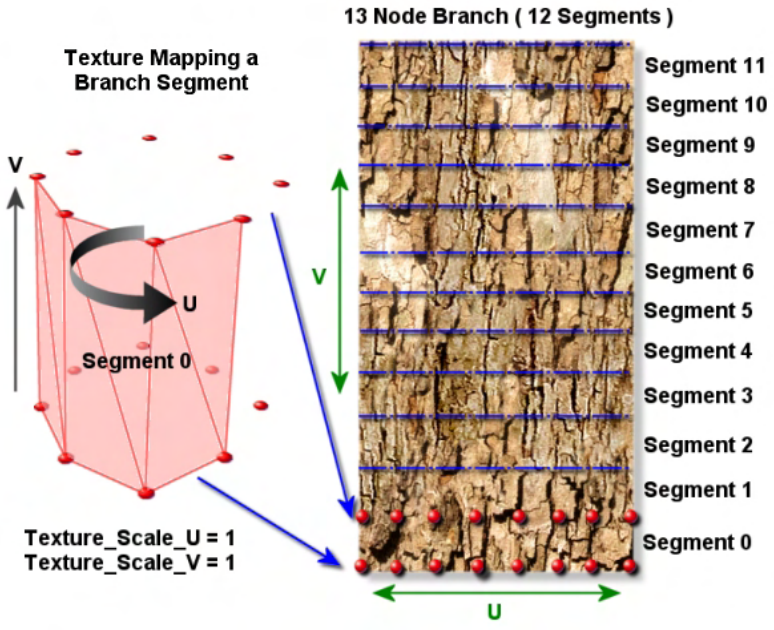

Figure 12.35
U Scale =1 : V Scale =1 : Max Iteration Count=13

In order to achieve the mapping of vertices such that the texture is mapped vertically over all segments of the tree, the generation of the V coordinate for each ring of vertices at a node, should be a function of that node's iteration count (its level in the virtual hierarchy) divided by the total hierarchy depth (maximum iteration count of the tree). Figure 12.35 shows this relationship clearly, which currently assumes a U and V texture scale of 1.0 (no scaling).

In Figure 12.35 we are shown the mapping of a texture to the first two rings of vertices (the first two nodes in the tree) which form the first segment in the root branch of the tree. For simplicity, we will also assume this tree consists of just a root branch which is constructed of 13 nodes (12 segments). If you look at the base of the bark texture, you can see how the two rings of vertices are mapped horizontally across the face of the texture using the U calculation texture we described previously. However, we can see that each node's vertices should be assigned different V coordinates which increase as the iteration of the node approaches the maximum iteration count of the tree. Using this technique, the V coordinates of the two rings of vertices forming the root segment are assigned low V values. It is also clear by looking at the segment boundaries marked on the texture that as we move up and calculate the V coordinates for the nodes deeper in the hierarchy (higher in the tree) the higher portion of the texture is mapped to the vertices of these nodes.

> **Note**: We have inverted the direction of the texture coordinate system V axis in the diagram so that it is more intuitive for this explanation. As we know, the V axis from runs top to bottom and not from bottom to top as shown here, so lower branch segments in the tree would actually be assigned the higher portions of the texture shown in this diagram, and the opposite is true.

By studying what we wish to achieve in Figure 12.35, the solution is easy. The V coordinate of any vertex is simply the iteration value of the node divided by the maximum iteration count of the tree (a property that we discussed earlier). The following snippet of pseudo code demonstrates the calculation of texture coordinates for a ring of vertices at an arbitrary node. In this example, the vertex structure is assumed to have a pointer to the branch node from which it was created. We will not implement it in this way, but this is to clearly establish the relationship between the node in the virtual tree and the vertices that are being created for it. In a moment when we look at the BranchNode structure, you will see how each node contains the iteration value that was generated during the virtual tree creation process and describes the level of that node in the virtual tree hierarchy.

```
for (i=0; i< BranchResolution; i++)
{
   Vertex[i].U = i / BranchResolution-1;
   Vertex[i].v = Vertex.pNode->Iteration / Max_Iteration_Count;
}
```

So we now know how to generate the texture coordinates for the vertices of all the branches in our tree. But what are the Texture_Scale_U and Texture_Scale_V members of the TreeGrowthProperties structure used for?

As you might imagine, they are simply used to multiply the result of the two texture coordinate calculations shown above so that we can tile the texture over the tree with a desired regularity. This upgrades our calculation code to the following final UV calculation.

```
for (i=0; i< BranchResolution; i++)
{
   Vertex[i].U = (i / BranchResolution-1) * Texture_Scale_U;
   Vertex[i].v = (Vertex.pNode->Iteration/Max_Iteration_Count) * Texture_Scale_V;
}
```

If both scaling factors are set to 1.0 then no texture scaling is done; a ring of vertices is simply mapped once horizontally across the face of the texture, and all the vertices comprising the tree are mapped once vertically along the face of the texture. By multiplying the texture coordinates by some scale value, we push them outside the 0.0 to 1.0 range, which we know will cause the texture to tile (unless texture tiling has been disabled in the API).

For example, we know that if we set the Texture_Scale_U property to 3.0, then each segment of a branch would have the texture's width wrapped around it not once, but three times. Obviously, for this to look good you must use a seamless tile-able texture. By performing scaling in this manner, the tree texture will look much higher resolution. If we were to set the Texture_Scale_V property to 2.0, then the texture would be mapped twice over the entire height of the tree. In other words, if we had a tree consisting of a single branch of 16 nodes, the entire vertical range of the texture would be mapped in its entirety to the first 8 nodes of the tree and repeated again for the second 8 nodes.

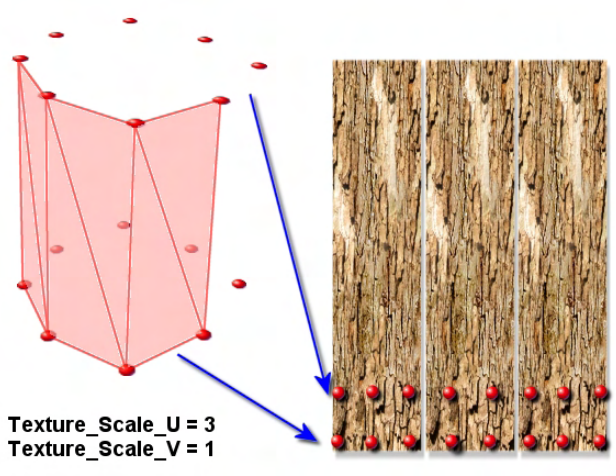

Figure 12.36

Figure 12.36 shows a simple example of tiling a bark texture with a Texture_Scale_U value of 3 and a Texture_Scale_V value of 1 (no scaling vertically). Once again, we are showing the vertex mapping for the first two rings of vertices (first segment) of the root branch. Notice how the 8 vertices now span three copies of the bark texture.

Figure 12.37 shows screenshots of the same section of the root branch of a tree mapped with this texture using different U and V texture coordinate scale values. Notice that the texture being used here is not a great texture for tiling but actually aids us in teaching this subject as it is clear that the texture is repeating across the width and height of the tree.

We can certainly see while examining the three example mappings in figure 12.37 how the U_Scale value is wrapping the texture multiple times around the section of the branch we are looking at. Of course, we are only looking at one side of the tree so we cannot see all the repeats. However, if you look at the center image, we can see a pattern starting to repeat which is much more obvious in the rightmost image. As mentioned, this texture is not ideal for tiling. But what should be clear is the extra detail that tiling seems to give the surface of our branches. The left most image, with no scaling being performed, looks quite blurry and out of scale by comparison. Of course, setting the correct texture scaling values in the TreeGrowthProperties structure will often only bear fruit by experimentation. Some textures look great when applied with no scale and some textures look awful when repeatedly tiled. Detail mapping can also be used to significantly improve the look and feel of the tree (see Module I).

U_Scale = 1 V_Scale = 1 | U_Scale = 5 V_Scale = 5 | U_Scale = 10 V_Scale = 10

Figure 12.37

We have now discussed the members of the TreeGrowthProperties structure. While that may have seemed daunting, remember that most of the last section was spent discussing how the tree will use these values in its construction. So by discussing this structure in such detail, we have also learned a great deal about how the tree will be built. This will make our job a lot easier when we examine the code. Remember, these values are set via the CTreeActor::SetGrowthProperties function, which simply assigns them to internal member variables which are accessible during tree creation. It is important that we set any tree properties before we issue the call to CTreeActor::GenerateTree since it is this function that builds the tree using the growth property information. Calling CTreeActor::SetGrowthProperties will have no effect if called after the CTreeActor::GenerateTree function.

12.3.2 The BranchNode Structure

When our application calls CTreeActor::GenerateTree method, the first task of this function is to build the virtual tree hierarchy. The nodes of this hierarchy will be arranged like D3DXFRAME structures in a frame hierarchy in that each node will contain a pointer to a linked list of children and another pointer to a linked list of sibling nodes that share the same parent. We are certainly used to this hierarchical arrangement by now. What is very important to grasp is that the hierarchy will not contain any mesh or bone data. Each node in the hierarchy is simply a packet of information, describing the position, orientation and scale of the tree at certain points. Later, this hierarchy of nodes will be used to build the actual meshes of the tree. As previously discussed, each node in this hierarchy will represent a branch segment boundary where a ring of vertices will be placed. Each node in our hierarchy will be represented by a BranchNode structure (defined in CTreeActor.h) whose members we will discuss momentarily.

It might strange that we would not build our virtual tree hierarchy out of D3DXFRAME derived structures. After all, this is the structure we are used to using and it has the child and sibling pointers that we need. It would at first seem an ideal choice to use for the nodes of this hierarchy. It is true that we will need to store much more information than a vanilla D3DXFRAME structure, but we could derive a class from this structure and add the extra members. So why do we not do this? There are several reasons we have decided to use a completely new structure for the building of our virtual tree.

The **first** reason is clarity. After our virtual tree has been constructed, we will traverse this hierarchy and build the actor's skeleton. We already know the actor's skeleton is just a D3DXFRAME hierarchy where each frame structure represents a bone. Therefore, we will be using one hierarchy (the virtual tree) to build another hierarchy (the actor's skeleton). If we implemented both of these as D3DXFRAME hierarchies, we might introduce confusion as to which hierarchy a given frame belongs to. By using two completely different hierarchy types, we eliminate the potential for bugs that could arise from accidentally connecting a D3DXFRAME structure to the wrong hierarchy.

The **second** reason is consistency. Although we can use the D3DXFRAME structure to store whatever information we choose, typically the matrix of this structure describes the position and orientation of that frame as a parent relative transformation. In order to convert that into an absolute transformation we must combine the matrices of all frames that precede it in the path down the hierarchy. We will be building our virtual tree hierarchy one node at a time using a random process and we certainly do not want to be adding nodes in parent relative space at this point. It makes much more sense to assign all the nodes a position and direction in a space shared by all nodes (tree space) so we are not constantly having to traverse the tree and perform transformations from one node's space to another. In short, we wish to store absolute positions and orientations at each node (not parent relative ones). Now it is true that we could simply use the matrix of each D3DXFRAME structure in the virtual tree hierarchy to store absolute transformations in this instance; but that is not consistent with what an application would usually expect the matrix of this structure to contain and may lead to incorrect assumptions about the matrices stored in this hierarchy if accessing frames directly.

The **third** and final reason is ease of use. It makes a little extra work for ourselves if we represent the position and direction of each node in matrix form during the building process. We have seen how we often need to work with the direction and right vectors in isolation when calculating the direction of a node and the deviation of its child nodes. Therefore, rather than having to extract the position and direction vectors from the matrix, modify them and store them back in the matrix, we will just store them in separate vector variables in the branch node structure.

The BranchNode structure also has a constructor and destructor which take care of initializing its member variables to zero and deleting its child and sibling lists, respectively. Below, we see the BranchNode structure and then discuss its member variables. Each node in our virtual tree will be a structure of this type.

```
typedef struct _BranchNode
{
    D3DXVECTOR3     Position;
    D3DXVECTOR3     Direction;
    D3DXVECTOR3     Right;
    D3DXVECTOR3     Dimensions;
```

```
    BranchNodeType  Type;
    _BranchNode    *Parent;
    _BranchNode    *Child;
    _BranchNode    *Sibling;
    USHORT          Iteration;     // The iteration at which this was generated
    USHORT          BranchSegment;
    USHORT          VertexStart;
    ULONG           UID;
    bool            BoneNode;
    LPD3DXFRAME     pBone;

    // Auto Hierarchy Destructor
    ~_BranchNode() { if ( Child ) delete Child; if ( Sibling ) delete Sibling; }

    // Auto clearing constructor
    _BranchNode()  { ZeroMemory( this, sizeof(_BranchNode) ); }

} BranchNode;
```

Let us discuss those member variables.

D3DXVECTOR3 Position
This member is where the tree space position of the node will be stored. We can think of tree space as a coordinate system where the root node/nodes of the trunk branch exist at the origin. The position, direction vector and right vectors of a node define a plane on which the ring of vertices that the node represents will be placed.

D3DXVECTOR3 Direction
This vector will contain the direction of the node. We can think of this vector as pointing in the direction of the next segment (child) in the branch. The direction vector can also be thought of as a normal to a plane on which the ring of vertices that this node represents will be placed.

D3DXVECTOR3 Right
This is where we will store the right vector of the node. This is a vector that is tangent to the plane on which the vertices will be placed and describes the direction in which the node's local X axis is pointing in tree space. That is to say, the Direction vector and the Right vector of a node represent the local coordinate system of the node (the Z and X axis respectively). By performing the cross product on these two vectors we can generate the third axis (the Y axis) of the local coordinate system for that node. This is used during mesh creation to position the ring of vertices on the node's plane.

D3DXVECTOR3 Dimensions
This vector stores the dimensions of the node. The X and Y components of the vector represent the two radii of an ellipse that has the node's position at its center. This is used to place the ring of vertices in a circle surrounding the node's position. The Z component of the vector describes the distance along the node's dimension vector to its child node (if it exists). We can think of the Z component of node N as defining the world space length of the branch segment (cylinder) formed by nodes N and N+1.

BranchNodeType Type
Each node in the tree will be one of three types of node which we must distinguish between when deviating vectors and building the mesh data. A node can either be a Branch Begin node, which means it

is the first node in a new child branch. It may alternatively be a Brand End node which means it is the terminating node in a branch and the node at which we will create only a single vertex (instead of a ring of vertices) forming the tip of the branch. Most nodes in the tree will be nodes of the third type: Branch Segment. These are nodes at some position in a branch between the branch begin and end nodes. It will become obvious when we cover the code why we must distinguish between the three node types in many places during the tree building process.

This member will be assigned one of three members of the BranchNodeType enumeration, which is defined in the CTreeActor namespace as:

```
enum BranchNodeType { BRANCH_BEGIN = 1, BRANCH_SEGMENT = 2, BRANCH_END = 3 };
```

_BranchNode *Parent
_BranchNode *Child
_BranchNode *Sibling
These three pointers are used to connect the branch node to the hierarchy. The Child and Sibling pointers mirror the functionality of the D3DXFRAME structure members of the same name. The Child pointer points to the first branch node in a linked list of child nodes in the next level of the hierarchy. If this node had a child node which had three siblings, this pointer would point to a linked list of four branch nodes. The parent node's Child pointer points to the child node at the head of the linked list, and each of the child nodes are connected by their sibling pointers. Likewise, the Sibling pointer will point to branch nodes that share the same parent node. The Parent pointer is not available in the D3DXFRAME structure and simply points to the node's parent branch node. This allows us to traverse up and down the levels of the hierarchy with ease from any given node.

As shown in Figure 12.22, the child pointer will point to a linked list of sibling nodes in the next level down in the hierarchy. This child list contains the next node in the current branch and any Branch Begin nodes of branches that start at that child node. The Sibling pointer will point to a list of nodes that exist at the same level and share the same parent. For example, let us imagine that node N in a branch has a child pointer to node N+1 which represents the next node in the branch. Also imagine, that at node N+1 two child branches are started. Node N would have a child pointer that would point to a linked list of three nodes: Node N+1 in the current branch and the two Branch Begin nodes for the new branches spawned at node N+1. These nodes would be connected via their sibling pointers.

USHORT Iteration
As discussed previously, as we step through a branch adding child branch nodes, the iteration count will be incremented and passed to the child nodes. The iteration basically describes the level in the hierarchy that the node exists at. For example, Node N would have an iteration count of N and any child nodes would have an iteration value of N+1, and so on down the tree. The Iteration of a node is also used in calculating its V texture coordinate as discussed in the previous section.

USHORT BranchSegment
This member will contain the Branch Begin relative index of the node. In other words, it stores the zero based node index from the start of the branch to which it belongs. Whenever a new branch begins, a new Branch Begin node is added with a BranchSegment value of zero. The next node of this branch will have a value of 1 assigned to its BranchSegment value, etc. We can think of this in many ways as being the branch local equivalent of the node's Iteration member. The node's iteration describes the number of

nodes that would have to be traversed from the root node of the root branch to reach the current node in the tree. The BranchSegment value describes the number of nodes that would have to be traversed from the first node (Branch_Begin node) in the current branch to reach the current node. This value will be useful when generating the mesh data for a given branch. Remember, each branch will be a separate skinned mesh.

USHORT VertexStart
This variable will be used when adding the vertices to at each branch node to aid in the building of branch segment indices. It will contain the vertex index where the current node's ring of vertices begins in the branch mesh. Remember that each branch will be a separate mesh, so this value will be the index where the ring of vertices starts in the branch mesh's vertex list. We will need to know this when adding branch segments to our mesh.

A branch segment is a cylinder of faces formed from the vertices at the parent node and the vertices at this node. To build these indices we will need an easy way of knowing the position at which a node's ring of vertices is placed in the branch mesh's vertex buffer. If a node had this value set to 50, and the branch resolution property of the tree was set to 8, we would know when generating the indices that this node's vertices will be positioned at 50 through 57 in the branch mesh's vertex buffer. This is a value we will generate when adding the vertices to each branch mesh in the second phase of creation.

ULONG UID
Every branch node in the virtual tree will contain a unique ID that identifies the node. This will start off at a value of zero for the first node of the hierarchy and will be incremented for each new node generated. The UID of the N^{th} node created will simply be N-1 because we start at 0 for the root node. So if the UID of a branch node had a value of 45, this would mean it was the 46^{th} branch node created during the virtual tree creation process. Why would we need to know this?

We will need this information when we build the skeleton for the actor in the second phase of tree creation. Certain nodes in the virtual tree hierarchy will become bones in the actor's frame hierarchy and as we know, frames that we wish to animate must be assigned names. We also need frames to have names in order to set up the skinning information. When a branch node is determined to be a candidate for a bone, we will need to give that frame a name. We also need to know that the name we assign the frame is unique with respect to any other frames in the hierarchy. We will assign a name to each frame using the format Branch_N where N is the UID of the branch node from which the bone is being created. Therefore, if we determine during the creation of the actor's skeleton that a branch node with a UID of 231 is to be used to create a bone for the actor's frame hierarchy, the name given to that frame will be Branch_231, which is guaranteed to be unique from any other frames we add.

bool BoneNode
When we discussed the TreeGrowthProperties structure, we examined a member called Bone_Resolution. By default it was set to 3. We discussed how this defines a ratio describing the number of bones we should create compared to the number of branch nodes in our virtual tree. The default value 3 means that we will create a bone for every third node in the branch node hierarchy. When building the actor's frame hierarchy (after the virtual tree of branch nodes has been constructed), we will traverse the branch node hierarchy starting at the root node. The Branch Begin node of every branch will always have a bone created for it. From that point on, we will create a bone using every third

node in the branch. Branch End nodes will never have a bone constructed from it, as it makes little sense to stick a joint at the tip. This second phase is where the frame hierarchy will be constructed.

The bones that we create from branch nodes between the Branch_Begin and Branch_End nodes form the skeleton for that mesh. Remember, each branch is a separate mesh and therefore will have its own bones connected into a larger hierarchy of bones for the entire actor. That is, the actor will have a skeleton that will represent the bones of the entire tree, but any given branch mesh will only use a localized set of those bones.

After the branch node hierarchy has been constructed in the initial phase, we can traverse that hierarchy and easily calculate which branch nodes should become bones and add them to the actor's frame hierarchy. This second phase is where the actor's frame hierarchy gets constructed from the virtual tree. Whenever we decide to make a bone from a branch node, we will set its BoneNode boolean member to true. This will be useful later on when building the skins for the various branches because we will need the original information stored in the branch node to calculate the bone offset matrix for a given bone in the hierarchy. It allows us to easily traverse a branch and find the branch nodes that have been used to construct bones.

As the BranchSegment member of a branch node contains the zero based index of that node within a given branch (a mesh), we can easily determine if a branch node will be a bone during the building of the actor's frame hierarchy. Simply put, every time the modulus of the branch node's BranchSegment member and the BoneResolution member equals zero, we have skipped the correct number of bones and it is time to mark the next new node as a bone node and create the accompanying frame in the hierarchy. Example code to determine if a newly created node (pNode) is a bone node is shown below.

```
if ( pNode->Type == BRANCH_BEGIN ||
   ((pNode->BranchSegment % m_Properties.Bone_Resolution)==0 && pNode->Type!=BRANCH_END))
{
        pNode->BoneNode = true;
        …
        …
}
```

As you can see, if this is a Branch_Begin node, then it is a node that starts a new branch and will become the first (root) bone of that branch mesh. In such a case we always make it a bone node. Otherwise, the only time we make a node a bone node is when the modulus of the local branch index of the node and the bone resolution wraps back around to zero (i.e., we have skipped the correct number of nodes). Notice as well that this is only true if the node in question is not a Branch_End node.

LPD3DXFRAME pBone

This member is also used during the creation of the actor's frame hierarchy in the second phase, and as such, is related and set using the same conditions as described for the previous member. As discussed, after building the virtual tree, we will enter the second phase where we construct the frame hierarchy (the skeleton) of the actor. We will traverse the branch node hierarchy and determine that certain nodes are bone nodes. For each one that we find, we will allocate a new D3DXFRAME, calculate its relative matrix based on the information stored in the branch node, and assign the frame (bone) a name before attaching it to the actor's hierarchy. We will then assign the new frame pointer to the source branch node's pBone member and set the branch node's BoneNode boolean to true. This establishes a

connection between the frame we have just added to the hierarchy and the branch node it was originally created from. This connectivity information will be used later when we manually build the ID3DXSkinInfo object for the branch mesh.

We have now discussed all there is to discuss about the structures used by CTreeActor and the properties that the tree generation process will use. While this has been an awful lot to take in without any code to look at, it is important that you understand the process overall before viewing the highly recursive code.

12.4 Source Code Walkthrough - CTreeActor

It is now time to look at our CTreeActor class, which is derived from CActor. Below you can see how the class is defined in CTreeActor.h. We will discuss the various new member variables of the actor in a moment. We will not immediately discuss the various methods of the class now as we will cover each one when we encounter it in the general flow of explaining the tree creation process.

```
class CTreeActor : public CActor
{
public:

    enum BranchNodeType { BRANCH_BEGIN = 1,BRANCH_SEGMENT = 2,BRANCH_END = 3 };

    // Constructors & Destructors for This Class.
             CTreeActor( );
    virtual ~CTreeActor( );

    // Public Functions for This Class
    void                SetGrowthProperties (const TreeGrowthProperties & Prop );
    TreeGrowthProperties GetGrowthProperties ( ) const;
    void                SetBranchMaterial ( LPCTSTR strTexture,
                                            D3DMATERIAL9 * pMaterial = NULL );

    HRESULT   GenerateTree( ULONG Options,
                            LPDIRECT3DDEVICE9 pD3DDevice,
                            const D3DXVECTOR3 & vecDimensions,
                            const D3DXVECTOR3 & vecInitialDir
                                              = D3DXVECTOR3( 0.0f, 1.0f, 0.0f ),
                            ULONG BranchSeed = 0 );

    HRESULT                 GenerateAnimation   ( D3DXVECTOR3 vecWindDir,
                                                  float fWindStrength,
                                                  bool bApplyCustomSets = true );

    virtual void            Release             ( );

private:

    // Private Functions for This Class
```

```
    HRESULT     GenerateBranches    ( const D3DXVECTOR3 & vecDimensions,
                                      const D3DXVECTOR3 & vecInitialDir
                                          = D3DXVECTOR3( 0.0f, 1.0f, 0.0f ),
                                      ULONG Seed = 0 );
    void        BuildBranchNodes    ( BranchNode * pNode,
                                      ULONG & BranchUID, ULONG Iteration = 0 );

    bool        ChanceResult        ( float fValue ) const;
    void        DeviateNode         ( BranchNode * pNode,
                                      float fAzimuthThetaMin,
                                      float fAzimuthThetaMax,
                                      float fPolarTheta = 360.0f ) const;

    HRESULT     BuildFrameHierarchy ( ID3DXAllocateHierarchy * pAllocate );
    HRESULT     BuildNode           ( BranchNode * pNode,
                                      D3DXFRAME * pParent,
                                      CTriMesh * pMesh,
                                      const D3DXMATRIX & mtxCombined,
                                      ID3DXAllocateHierarchy * pAllocate );

    HRESULT     BuildSkinInfo       ( BranchNode * pNode,
                                      CTriMesh * pMeshData
                                      LPD3DXSKININFO * ppSkinInfo );

    HRESULT     BuildNodeAnimation  ( BranchNode * pNode,
                                      const D3DXVECTOR3 & vecWindAxis,
                                      float fWindStrength,
                                      LPD3DXKEYFRAMEDANIMATIONSET pAnimSet );
    HRESULT     AddBranchSegment    ( BranchNode * pNode, CTriMesh * pMesh );

   // Private Variables for This Class
    ULONG                   m_nBranchSeed;
    TreeGrowthProperties    m_Properties;
    BranchNode             *m_pHeadNode;

    D3DMATERIAL9            m_Material;
    LPTSTR                  m_strTexture;
};
```

While the list of new member variables we have added is extremely small (only five), do bear in mind at all times that this class is derived from CActor and thus has access to all of its member variables and functionality as well. That is why you cannot see (for example) a member variable that points to the root frame of the tree's frame hierarchy. As you know, the frame hierarchy member variables (and the method to traverse them) are all inherited from the base class (CActor). Let us now discuss these new member variables one at a time.

ULONG m_nBranchSeed

As you certainly aware by now, the assembling of our tree will call for a lot of randomly generated numbers. For example, we will generate random angles for direction vector deviations between nodes in a branch and we will also use random numbers to decide whether or not a branch node currently being processed should spawn a new child branch. You will see when we cover the code in a moment that random number generation is used literally throughout the entire tree generation process.

We generate random numbers using the rand function (part of the standard C runtime libraries). Of course, a computer cannot generate a truly random number since this is essentially like asking the computer to make a real choice. Only sentient beings that are self aware can make random choices. So, the rand function (and its sibling function, srand) just generates and returns numbers using a simple calculation that returns a string of numbers that seem random to a human being. All the rand function is actually doing is performing a calculation where the srand function is used to set an initial value (a seed) that is used in that calculation. Each time the rand function is called, the initial seed value we set is updated to new value which is then used to influence the value returned in the next rand call. For example, lets us imagine that the C runtime library stores some global value called 'next' which is initially set to 1. That is, the default seed for the rand function is 1.

```
unsigned long int next = 1;

/* rand: return pseudo-random integer on 0..32767 */
int rand(void)
{
    next = next * 1103515245 + 12345;
    return (unsigned int) (next/65536) % 32768;
}
```

As you can see, the rand function does not generate anything randomly. The first time it is called the 'next' variable will be set to the seed value (1 by default). The rand function simply multiplies this value by a very large number. Notice however that the 'next' value is updated with the result so that each time the rand function is called a different value will be returned. It then simply returns the number divided by 65536 and has a modulus performed with 32768 to snap the value into the correct range of an unsigned integer.

We use the srand function to seed the C random number generator (i.e., change the initial value of the 'next' variable in the above code). What is vitally important to note is that this list of pseudo-random numbers generated will *never* change. So if we use the same seed at the start of our application, the random numbers generated will be exactly the same every time the application is run. After all, every time the application is run, the same starting point in that list of random numbers is used. Thus ten calls to the rand function will generate the same ten random numbers every time the application is run. In terms of our tree, this means regardless of how many times we use the rand function in our generation process, our GenerateTree function will create the same tree each time the application is run. This may or may not be desirable.

Often it is not desirable. If a game uses random numbers to generate random events, we do not want these events to happen on cue every single time at the exact same place every time the application is run. Therefore, usually the value used to seed the random number generator is taken from a value that is unique every time the application is run (e.g., the timestamp of the current system time or the number of microseconds that have passed since the computer was switched on). We take such a value and use the srand function to seed the random generation process. Below we can see that the call to srand simply sets the initial value of the 'next' value used in the rand calls. If we use a different seed every time the application runs (system time for example), the random numbers generated will be different every time also.

```
/* srand: set seed for rand() */
void srand(unsigned int seed)
{
    next = seed;
}
```

That fact that using the same seed will generate the same string of pseudo-random numbers can actually be beneficial in our tree creation process. When the application calls the CTreeActor::GenerateTree method we can optionally pass in a seed value that will be used to seed the random number generator prior to tree creation. We will use the timeGetTime function call to seed the random number generator if the application passes no seed. As this value will change each time a tree is generated, we will get different trees every time the function is called. However, you also have the option to pass in any seed value that you like so that the same tree is generated. This allows you to continually generate trees using different seed values until you find a tree that you really like. You can then remember those seeds and use them to generate the trees for your game, knowing exactly what the trees that will be generated will look like.

The m_nBranchSeed member of the class will contain the seed that was used to generate the tree. This will be either the seed value passed in by the application or the value returned from timeGetTime. If you see a tree that was randomly generated that you really like, you can examine the contents of this member and use this seed in the future to create that same tree.

TreeGrowthProperties m_Properties
This member contains the creation properties used to generate the tree. We set the members of this structure using the CTreeActor::SetGrowthProperties and can also retrieve it using the CTreeActor::GetGrowthProperties methods. We have already discussed all the members of this structure in detail..

BranchNode *m_pHeadNode
This member stores a pointer to the root branch node of the virtual tree hierarchy that was generated during tree creation. Remember, this is not the root frame of the actor's hierarchy (stored in a base class member variable). The hierarchy of branch nodes is used to grow a virtual tree representation and then used to build the frame hierarchy and meshes of the actor.

D3DMATERIAL9 m_Material
LPTSTR m_strTexture
Our branches will need to have a texture and material applied to them. We set these values using the CTreeActor::SetBranchMaterial function. Notice that we do not pass in an actual texture, only the filename. Essentially, this is the same information our actor is passed by D3DX when we load a material from an X file. This is certainly by design because from the CActor's perspective, there will be no difference. What do we mean by this?

After we have generated our virtual tree we will step through that hierarchy and generate the frame hierarchy similarly to how D3DX does it when we call D3DXLoadMeshHierarchyFromX. Every time we wish to allocate a new frame for example, we will call the actor's CAllocateHierarchy::CreateFrame method, just as D3DX does during the loading process. Our CAllocateHierarchy object is already written, so we use it again in exactly the same way. Similarly, every time D3DX encounters a mesh

during the loading process, it will call our CAllocateHierarchy::CreateMeshContainer method which is responsible for loading textures and materials (via registered callbacks) and for generating the actual skinned mesh. We will follow this exact same technique so that all the code we have developed in that function can be re-used without modification to generate our tree meshes.

When we traverse the virtual tree hierarchy generating mesh data, we will do two things. We will generate a regular mesh and we will also populate an ID3DXSkinInfo object with bone information. Once we have done that, we will simply call the CAllocateHierarchy::CreateMeshContainer method passing the regular mesh we have generated for the branch being processed and its skin info. We will also pass it the material and the texture filename that has been set for the tree. As we know, the CreateMeshContainer method will generate a skinned mesh from the regular mesh passed in and will also take care of calling any callback functions to handle the loading and processing of textures and materials. From the perspective of CreateMeshContainer, nothing is different from the case where the mesh data is being loaded by D3DX. We still pass it a regular mesh, texture filename and material structures, the same format in which the D3DXLoadMeshHierarchyFromX provides the mesh information.

It is actually quite a complex relationship when you examine it. In our application, our CTreeActor is set to non-managed mode prior to tree generation (the application registers an attribute callback function). As we know, this callback function is responsible for loading textures from filenames and storing those textures and their accompanying materials in the scene database. We also set the texture filename and the material the tree should use immediately afterwards. Next we make the call to the GenerateTree method to generate the actual meshes. So, for each branch mesh we create, the texture filename is passed to the CreateMeshContainer method which then sends that same texture filename back to the application defined callback which loads the actual texture used by the actor. So, the application supplied the actor with a texture filename which is later passed back to its callback function where it will load that texture.

Constructor - CTreeActor

The constructor of CTreeActor simply initializes the tree's growth properties to some default values that will be overridden as soon as the application calls the SetGrowthProperties method. It also sets a default material in case the application does not call the SetBranchMaterial method to specifically set one. The constructor is shown below. Please note that the values assigned to each of the tree growth properties may differ in the actual source code. At the time of this writing, the development team was still experimenting with their preferred defaults.

```
CTreeActor::CTreeActor()
{
    // Call base constructor
    CActor::CActor();

    // Reset all required values
    m_nBranchSeed = 0;
    m_pHeadNode   = NULL;
    m_strTexture  = NULL;
```

```
    // Setup some useful initial growth properties
    m_Properties.Max_Iteration_Count        = 21;
    m_Properties.Initial_Branch_Count       = 1;
    m_Properties.Min_Split_Iteration        = 2;
    m_Properties.Max_Split_Iteration        = 20;
    m_Properties.Min_Split_Size             = 0.8f;
    m_Properties.Max_Split_Size             = 20.0f;

    // 25% Chance of splitting in two
    m_Properties.Two_Split_Chance           = 15.0f;

    // 25% Chance of splitting in three
    m_Properties.Three_Split_Chance         = 5.0f;

    // 1% Chance of splitting into four
    m_Properties.Four_Split_Chance          = 1.0f;

    // 5% Chance that a branch will end when a split occurs.
    m_Properties.Split_End_Chance           = 5.0f;

    m_Properties.Segment_Deviation_Chance   = 60.0f;    // 60% chance of deviation
    m_Properties.Segment_Deviation_Min_Cone = 0.0f;     // Min Cone Angle
    m_Properties.Segment_Deviation_Max_Cone = 30.0f;    // Max Cone angle
    m_Properties.Segment_Deviation_Rotate   = 10.0f;    // Max Polar rotation

    m_Properties.Length_Falloff_Scale       = 0.1f;     // Segment Length falloff
                                                        // happens 10 times slower
                                                        // than branch thickness
                                                        // fall off

    // Deviation properties for new child branch
    m_Properties.Split_Deviation_Min_Cone   = 10.0f;    // Min Cone Angle
    m_Properties.Split_Deviation_Max_Cone   = 70.0f;    // Max Cone Angle
    m_Properties.Split_Deviation_Rotate     = 360.0f;   // Max Polar rotation

    m_Properties.SegDev_Parent_Weight       = 0.0f;     // Weight with which the
                                                        // original direction of
                                                        // the segments parent is
                                                        // averaged with the
                                                        // deviation

    m_Properties.SegDev_GrowthDir_Weight    = 0.4f;     // Weight with which the
                                                        // growth direction vector
                                                        // is averaged with the
                                                        // deviated segment
                                                        // direction

    m_Properties.Branch_Resolution          = 8;        // Number of vertices used
                                                        // for each branch mesh
                                                        // segment ring

    m_Properties.Bone_Resolution            = 3;        // One bone every 3 nodes

    m_Properties.Texture_Scale_U            = 1.0f;
    m_Properties.Texture_Scale_V            = 1.0f;
```

```
    // Growth direction of tree
    m_Properties.Growth_Dir                 = D3DXVECTOR3( 0.0f, 1.0f, 0.0f );

    // Setup default material properties
    m_Material.Diffuse   = D3DXCOLOR( 0.8f, 0.8f, 0.8f, 0.8f );
    m_Material.Emissive  = D3DXCOLOR( 0.0f, 0.0f, 0.0f, 1.0f );
    m_Material.Ambient   = D3DXCOLOR( 0.0f, 0.0f, 0.0f, 1.0f );
    m_Material.Specular  = D3DXCOLOR( 0.0f, 0.0f, 0.0f, 1.0f );
    m_Material.Power     = 0.0f;

}
```

What is important to note is that the first thing we do in this constructor is issue a call to the base class constructor so that CActor can perform its own initialization. Remember, the base class sets a default skinning method and initializes the actor's callback array. It also sets some default parameters for the animation controller.

Destructor – CTreeActor

Like all of our destructors, this destructor is also very simple due to the fact that it hands off the clean-up to its Release method (which can also be called by the application to force a clean up). What we do release in this function is any texture filename string that may exist.

When we look at the CTreeActor::SetBranchMaterial method in a moment, you will see that the texture filename passed in is duplicated and stored in the m_strTexture member variable (using _tcsdup). Therefore, we must make sure on destruction that we clean that memory up in the appropriate way. We then issue a call to the CTreeActor::Release method to do any final clean up.

```
CTreeActor::~CTreeActor()
{
    // Release any allocated memory
    Release();

    // Release the properties.
    if ( m_strTexture ) free( m_strTexture ); // Allocated by _tcsdup

    // Reset variables
    m_strTexture = NULL;
}
```

Release – CTreeActor

The Release method is small because the derived class has very few resources to clean up. What we must do however is call the base class Release method so that the frame hierarchy and meshes managed by the base class are released. We know the CActor base class performs quite a bit of clean up, such as releasing interfaces to animation controllers, destroying CTriMesh objects, and de-allocating the entire

frame hierarchy. Once we have called the base class's Release method, the only additional information that needs to be released in CTreeActor is the virtual tree hierarchy. When we looked at the BranchNode structure earlier, we also saw how its constructor took care of deleting its sibling and child pointers. Therefore, all we have to do is delete the root branch node (m_pHeadNode), which will delete its child, which will delete its child, and so on, causing a traversal and deletion of the entire branch node hierarchy.

```
void CTreeActor::Release()
{
    // Call base release
    CActor::Release();

    // Destroy the tree hierarchy data
    if ( m_pHeadNode  ) delete m_pHeadNode;

    // Clear variables.
    m_pHeadNode  = NULL;
}
```

SetGrowthProperties / GetGrowthProperties – CTreeActor

One task that the application will want to perform before generating the actual tree, is setting the growth properties that will influence the tree generation process. This function takes as its only parameter a TreeGrowthProperties structure whose values will be stored in the CTreeActor's m_Properties member. We also supply a function for retrieving the properties of a CTreeActor. Both the 'Set' and 'Get' functions are shown below.

```
void CTreeActor::SetGrowthProperties( const TreeGrowthProperties & Prop )
{
    // Store the properties
    m_Properties = Prop;
}
```

```
TreeGrowthProperties CTreeActor::GetGrowthProperties( ) const
{
    // Return the properties
    return m_Properties;
}
```

It is important that you set the growth properties of the tree prior to calling the GenerateTree method since it uses the values stored in the m_Properties structure to influence tree generation. Setting the properties after the tree has been generated will have no effect.

SetBranchMaterial – CTreeActor

Another task that you will probably want to perform before calling GenerateTree is informing the tree about the texture and material you would like to have applied to its mesh faces. We do this using the CTreeActor::SetBranchMaterial function. The function accepts two parameters. The first should be a string containing the filename of the texture you wish to use and the second parameter should be a pointer to a D3DMATERIAL9 structure containing the light reflectance properties that should be applied to the faces of the tree.

```
void CTreeActor::SetBranchMaterial( LPCTSTR strTexture, D3DMATERIAL9 * pMaterial )
{
    // Free any previous texture name
    if ( m_strTexture ) free( m_strTexture );
    m_strTexture = NULL;

    // Store the material
    if ( pMaterial ) m_Material = *pMaterial;

    // Duplicate the texture filename if any
    if ( strTexture ) m_strTexture = _tcsdup( strTexture );
}
```

If the tree already has a texture name set, then its memory is released. The material passed is then copied into the m_Material member variable, replacing the default values we assigned to it in the constructor. Finally, we use the _tcsdup function to make a copy of the texture filename. A pointer to this copy is stored in the m_strTexture member variable.

GenerateTree - CTreeActor

We are now ready to examine the GenerateTree method, which is invoked by the caller to build the entire tree. We can think of this method as being the replacement to the regular actor's LoadActorFromX method in that on function return, the actor will have a fully populated frame hierarchy (and potentially even some animation data). This function is actually just a front end function for the caller since the tree building mechanism is mostly done through helper functions called from this method. We will examine each of the helper functions one at a time afterwards. However, by looking at the GenerateTree function first, we will be able to see the overall order in which the various processes are invoked.

GenerateTree accepts five parameters (the final two are optional). The first parameter is a combination of one or more D3DXMESH flags which instruct the tree in which of the device's resource pools the vertex and index buffers for the branch meshes should be allocated. The second parameter is a pointer to the device that will essentially own the actor and its meshes. The third parameter is the initial dimensions for the root node in the branch node hierarchy. For example, passing a vector of (2, 3, 6) means the thickness of the root branch segment is defined as an ellipse that has radii X=2 and Y=3 in world space. These values are used to place the ring of vertices at the root branch node of the correct

size. The size of each branch segment will get smaller as we step along the branch. That is why we only pass in the size of the root branch node which will then be automatically downsized in each recursive step. The Z component of this vector describes the length of the root branch segment. Using the vector specified above, this means after the root node has been inserted, we will move a distance of 6 units along the root node's direction vector before placing the next node in that branch. As both these nodes define the bottom and top of the same cylinder, this Z value really defines the length of the root branch segment. The fourth (optional) parameter is another 3D vector describing the initial direction vector of the root node of the virtual tree. If we were to pass a vector of <1,0,0> the initial segment of the root branch would grow horizontally along the X axis (e.g., out of a cliff face). If the growth vector of the tree has been set (in the tree properties) to <0,1,0>, the tree would start to grow upwards as each new node was added. If you omit this parameter, a default vector of <0,1,0> will be used. This is a very sensible default since you will usually want your tree to grow vertically upwards. The final (optional) parameter is an unsigned long integer that will be used to seed the random number generator. If omitted, the current system time will be used to seed the random number generator.

In the first section of the function, we allocate an instance of our CAllocateHierarchy class. This will be used later so that we can call its CreateFrame and CreateMeshContainer methods to generate the frames of the hierarchy and the skinned meshes. We return if a valid device was not passed.

```
HRESULT CTreeActor::GenerateTree( ULONG Options, LPDIRECT3DDEVICE9 pD3DDevice,
                                  const D3DXVECTOR3 & vecDimensions,
                                  const D3DXVECTOR3 & vecInitialDir ,
                                  ULONG BranchSeed )
{
    HRESULT            hRet;
    CAllocateHierarchy Allocator( this );

    // Validate parameters
    if ( !pD3DDevice ) return D3DERR_INVALIDCALL;

    // Release previous data.
    Release();

    // Store the D3D Device here
    m_pD3DDevice = pD3DDevice;
    m_pD3DDevice->AddRef();

    // Store options
    m_nOptions = Options;
```

Provided the device is valid we call the CTreeActor::Release method to release any previous data that may have been generated for this tree object. This allows us to use the same object to generate another tree simply by calling its GenerateTree method again. Remember, the Release method also passes the request to the base class Release method, ensuring that all frames, mesh, and attribute data is released before generating a new tree from scratch. Next we make a copy of the device interface, increment the interface's reference count, and store the mesh creation options in the m_nOptions member.

The final section of the function code builds the entire tree through the invocation of three other methods, each of which is responsible for one phase of the tree generation. We will look at the code to each of these three functions as we go along.

```
    // Generate the branches
    hRet = GenerateBranches( vecDimensions, vecInitialDir, BranchSeed );
    if (FAILED(hRet)) return hRet;

    // Build the frame hierarchy
    hRet = BuildFrameHierarchy( &Allocator );
    if (FAILED(hRet)) return hRet;

    // Build the bone matrix tables for all skinned meshes stored here
    if ( m_pFrameRoot )
    {
        hRet = BuildBoneMatrixPointers( m_pFrameRoot );
        if ( FAILED(hRet) ) return hRet;

    } // End if no hierarchy

    // All is well.
    return D3D_OK;
}
```

The GenerateBranches function is called first and completes the first phase of the tree building process. It is responsible to building the branch node hierarchy that contains our virtual tree representation. When the GenerateBranches method returns, we will have a virtual tree hierarchy, the root branch node of which will be pointed to by the m_pHeadNode member variable. At this point, the actor will not yet have had its frame hierarchy built and no mesh data will have been generated. That is what the next function BuildFrameHierarchy does. It accomplish phase two of the tree generation process.

BuildFrameHierarchy is responsible for building the actor's D3DXFRAME hierarchy and generating all skinned meshes. It does so by traversing the virtual tree hierarchy assembled in phase one and inserting vertices and frames for the relevant branch nodes. Once the BuildFrameHierarchy function returns, the actor's frame hierarchy will have been created and all the skinned meshes will have been created and attached to that hierarchy as well. However, at this point there is still one final step to perform which you should recall from the last chapter. During the building of the frame hierarchy, we cannot store the bone pointers needed for our mesh containers until the frame hierarchy has been created in its entirety. Therefore, just as we do in the CActor::LoadActorFromX function, after the frame hierarchy has been created, we traverse it and calculate the absolute matrices at each frame (the bone matrices) before storing all the bone matrices used by a given mesh container in its bone matrix pointer array. We looked at the code to the CActor::BuildBoneMatrixPointers function in the previous chapter's workbook.

Now we are ready to look at the first function called in the above code which implements phase one (i.e., the building of the virtual tree branch node hierarchy).

GenerateBranches - CTreeActor

This function is called from the GenerateTree method and is passed the dimensions of the root branch node, the direction of the root branch node, and (optionally) the random seed. The first thing the function does is seed the random number generator. The default value of the Seed parameter is zero if omitted from the parameter list, so the first thing we do if this is the case is set the seed value to the value returned from the timeGetTime function. We then store either the passed seed value or the seed value just calculated in the m_nBranchSeed member variable. Finally, we seed the random number generator via a call to srand.

```
HRESULT CTreeActor::GenerateBranches( const D3DXVECTOR3 & vecDimensions,
                                      const D3DXVECTOR3 & vecInitialDir ,
                                      ULONG Seed )
{
    ULONG i;
    ULONG BranchUID = 0;

    // Seed the random number generator with current time if not specified
    if ( Seed == 0 ) Seed = timeGetTime();

    // Store the seed value
    m_nBranchSeed = Seed;

    // Seed the generator
    srand( Seed );
```

This function is responsible for creating the root node of the branch node hierarchy. It will then pass this node to the BuildBranchNodes function (a recursive function that will repeatedly call itself to create new branch nodes for the hierarchy). However, as mentioned earlier, we do have the option of creating a tree that has multiple initial branches (multiple trunks), so we may have multiple nodes in the root level of the tree. While we will usually expect a value of 1 to be stored in the Initial_Branch_Count member of the tree's growth properties structure, this may not always be the case. Therefore, we will set up a loop that counts up to the value stored in the Initial_Branch_Count member and create a new branch node for each root branch. As we may be creating multiple branch nodes at the root level (one for each initial branch) we will connect these as siblings at the root level. Each root branch node will be passed into the BuildBranchNodes recursive function to generate the entire tree for that branch recursively.

In the next section of code we show the start of that loop. Each iteration allocates a new branch node. If a previous node has been created in a previous iteration then we attach the new branch node to the previous node's sibling pointer. If not, then this is the first node we have generated and will assign the m_pHeadNode member variable to point at this node. In other words, if the initial branch count was set to 3, in the first iteration we would generate a new branch node and assign it to the m_pHeadNode pointer. In the second iteration we would create a new branch node and assign it to the head node's sibling pointer. In the third and final iteration we would create a new branch node and assign it to the sibling pointer of the node we created in loop iteration 2, and so on. Thus, we are creating a sibling list of Branch_Begin nodes at the root level of the hierarchy.

```
    BranchNode * pPrevNode = NULL;

    // Generate the required set of head branches
    for ( i = 0; i < m_Properties.Initial_Branch_Count; ++i )
    {
        BranchNode * pNewNode = new BranchNode;
        if ( !pNewNode ) continue;

        // Store in the appropriate place
        if ( pPrevNode )
            pPrevNode->Sibling = pNewNode;
        else
            m_pHeadNode = pNewNode;

        // Setup the node
        pNewNode->UID        = BranchUID++;
        pNewNode->Type       = BRANCH_BEGIN;
        pNewNode->Direction  = vecInitialDir;
        pNewNode->Dimensions = vecDimensions;
        pNewNode->Iteration  = 0;
```

In the above code, you can see that for each root node we create we assign it a unique branch node ID (BranchUID). This value was set to 0 at the start of this function and is incremented with each new node we add. We also know that any branch nodes we create at the root level will be the start nodes of trunk branches, so we set the type of each branch node created in this loop to the type Branch_Begin. When building the meshes later, we will know that each of these nodes starts a new branch mesh. We also store the direction vector and the dimension vector passed into the function in the node. Finally, we set the iteration of the nodes to zero. This iteration will be passed down the branches and incremented at each level. Every branch node added at the root level however will be set to zero since they exist at the same level in the hierarchy and for all intents and purposes are the start nodes of separate trees linked at the root level. The position of each node is not set here as this will have been set to 0 in the constructor of the branch node structure. We wish each trunk branch to be positioned at (0,0,0) in tree space.

We know the direction vector of the nodes we are creating because it was passed into the function. However, we learned earlier that each node also needs a right vector. The right vector of the root node(s) will be passed down the tree and modified at each node so that it remains correctly orthogonal to the node's deviated direction vector. We do not require the application to pass in the right vector of the root node(s) as we can calculate that easily. All we have to do is find the coordinate system axis (X, Y or Z) that is least aligned to the direction vector. This will allow us to find a vector that is definitely not the same as the direction vector. We find this axis simply by taking the absolute values of the direction vector's components and searching for the smallest component. For example, we know that if the direction vector has a Z component of 0, then we can use the Z axis of the coordinate system since this is definitely not close to being aligned to the direction vector. All we are doing here is safely picking an axis which is not the direction vector. Once we have that axis vector, we can perform the cross product between the direction vector and that axis vector to create the right vector for the node. The following code shows how we find this axis vector and cross it with the direction vector to generate the right vector. The right vector is then stored in the branch node.

```
        // Get absolute normal vector
        float x = fabsf( pNewNode->Direction.x );
```

```
        float y = fabsf( pNewNode->Direction.y );
        float z = fabsf( pNewNode->Direction.z );
        float fNorm = x;

        // Find the best vector to use as right vector
        D3DXVECTOR3 vecCross = D3DXVECTOR3( 1.0f, 0.0f, 0.0f );
        if ( fNorm > y )
       { fNorm = y; vecCross = D3DXVECTOR3( 0.0f, 1.0f, 0.0f ); }

        if ( fNorm > z )
       { fNorm = z; vecCross = D3DXVECTOR3( 0.0f, 0.0f, 1.0f ); }

        D3DXVec3Cross( &pNewNode->Right, &pNewNode->Direction, &vecCross );
```

At this point we have successfully populated the new branch node with its information. However, if we are generating multiple branches at the root level (Initial_Branch_Count > 1) then we cannot simply assign the same direction and right vectors to each branch node; otherwise, each root branch node we create will be placed in the exact same position and with the same orientation as the other nodes in its sibling list. So, if we are only creating a single node, then our job is done and we pass this node into the BuildBranchNodes function to start the recursive branch building process. The branch node will have the exact direction vector that we passed into the function. However, if we are creating multiple root branch nodes, then we must deviate the direction vector of each node so that they are slightly different. This will allow us to generate a tree where multiple trunks sprout from the same location but with different directions. If deviation is needed, we call the DeviateNode function to perform that deviation. This function (which will be covered in a moment) is passed the node, the min and max cone angles and a rotation angle. This will deviate the vector a random angle about its right vector with a range of –180 to +180 degrees. It will also rotate the new deviated direction vector a random angle of 180 degrees about the original direction vector. Finally, it will rotate the node's right vector so that it stays orthogonal to the new deviated direction vector.

We covered how vector deviation is performed in theory earlier on in the chapter, so refer back if you need to brush up. After the DeviateNode function returns, we have modified the root node direction and right vectors and are ready to pass this node into the BuildBranchNodes function. This function is a recursive process that repeats until all the branch segments of the root node and any child branches it spawns are calculated. Suffice to say, when BuildBranchNodes returns program flow back to this function, the entire virtual tree for the current root node we are processing will have been created.

```
        // Deviate if we're starting with more than one branch
        if ( m_Properties.Initial_Branch_Count > 1 )
             DeviateNode( pNewNode, 0.0f, 180.0f, 180.0f );

        // Start the recursive build for this branch
        BuildBranchNodes( pNewNode, BranchUID );

        // Store previous node
        pPrevNode = pNewNode;

    } // Next Initial Branch
```

At the end of the loop shown in the above code, we assign the pPrevNode pointer to point at the node we have just generated. This way, in the next iteration (assuming multiple roots) of the loop, we have access to the node generated in the previous iteration so that we can add a new root node to its sibling list.

When the loop finishes, the entire virtual tree hierarchy will have been created. We will examine the BuildBranchNodes recursive function in detail shortly, as this is where all of the work happens for phase one.

In the next and final section of the code we test to see that the root node of the tree is valid and if not we return E_OUTOFMEMORY. If this is NULL, then the very first root node could not be allocated so we must return failure. Otherwise, we return success.

```
    // Fail if we failed.
    if ( !m_pHeadNode ) return E_OUTOFMEMORY;

    // Success!!
    return D3D_OK;
}
```

There are three functions called from the previous function that we need to discuss. The first one called is DeviateNode. It will be used many times throughout the tree building process to randomly deviate the direction vector of a child node from that of its parent node. Let us have a look at that function next.

DeviateNode - CTreeActor

DeviateNode is a small function that is called many times throughout the tree generation process to randomly deviate the vector of a child node from that of its parent over some given a range. It takes four parameters. The first parameter is the node whose direction vector we wish to deviate. The direction vector of a newly created node that is passed into this function will initially have its direction vector inherited from the parent node (or in the case of the GenerateBranches function, explicitly set to the direction vector passed by the application). Therefore, there is no reason to also pass in the parent node's vectors (direction and right) which we wish to rotate around, as initially, the vectors stored in the child node we pass will be equal to its parent vectors.

The second and third parameters specify the minimum and maximum deviation angles in degrees. This is the amount we wish to rotate the direction vector clockwise or counter-counter clockwise about the parent node's right vector. This forms a minimum and maximum cone of rotation. We can initially perform this rotation of the direction vector about the node's right vector, since at this point the right vector of the node will be equal to the right vector stored in its parent node. The final parameter is the maximum polar rotation angle we wish to rotate the (now rotated) direction vector around the parent's direction vector. Passing a value of 180 degrees will allow us to swing the direction vector to any position around the branch (90 degrees left or right from the rotated position). Here is the first section of the code followed by an explanation.

```
void CTreeActor::DeviateNode( BranchNode * pNode,
                              float fAzimuthThetaMin,
                              float fAzimuthThetaMax,
                              float fPolarTheta ) const
{
    // Cache direction
    D3DXVECTOR3 vecNormal = pNode->Direction;

    // Generate Azimuth / Polar angles
    float fAzimuth = (float)rand() / (float)RAND_MAX;
    float fPolar   = (float)rand() / (float)RAND_MAX;
    fAzimuth = fAzimuthThetaMin +
               ((fAzimuthThetaMax - fAzimuthThetaMin) * fAzimuth);

    fPolar   = (fPolarTheta * fPolar) - (fPolarTheta / 2.0f);
```

First we make a copy of the node's direction vector. This is important as this currently holds the direction vector of the parent node. Once we rotate this vector it will be overwritten and we will have lost our ability to rotate the rotated direction vector about the original direction vector of the parent.

We then generate two random rotation values for the fAzimuth and fPolar local variables. The rand function generates a random integer in the range [0, RAND_MAX], so dividing the result of rand by RAND_MAX gives a random float in the range [0.0, 1.0]. We calculate the fAzimuth angle using the [0.0, 1.0] random number to find the angle between the minimum cone angle and the maximum cone angle using interpolation. That is, to calculate the first rotation angle (around the parent's right vector), we the minimum cone angle with the difference between the min and max cone angles multiplied by our random float.

We now have an angle in degrees between the minimum and the maximum cone angle. Next we calculate the polar rotation angle. The 0.0 to 1.0 range random number represents an angle between 0 and the maximum polar rotation angle passed into the function. Therefore, scaling the maximum polar rotation angle by the random float will produce an angle value in degrees, in the range [0.0, Max Polar Rotation Angle]. If the passed polar rotation limit was 180 degrees for example, this means we wish to map it into the [–90, +90] range so that we have a random chance of rotating the direction vector clockwise or counter clockwise. Therefore, we subtract from the angle the maximum angle passed divided by two. This maps a value of (Polar Angle / 2) to a zero degree rotation, a value of 0 to –(Polar Angle/2) and a value of Polar Angle to (Polar Angle / 2). This is exactly what we want.

Now that we have our two rotation angles, we need to decide whether the first rotation angle (fAzimuth) is going to rotate the direction vector of the node clockwise or counter-clockwise around the parent's right vector. The following code uses a member function called ChanceResult to generate a number between 1 and 100. This function returns true if it generated a random number smaller than the value passed in (typically a value in the range of 0 to 100 also). We use this function frequently through the tree generation process to decide whether a branch node should be deviated or whether it should spawn child branches. Because we want an equal probability for each direction, we pass in a value of 50. The function will return true if it generates a random number between 0 – 49, otherwise, it will return false. As you can see, the parameter we pass into this function is really a probability value; the lower the value we pass in, the less chance the function has of returning true.

```
// Deviate in both directions to prevent a tendency to lean, whilst still
    // providing support for our 'dead zone' of rotation.
    if ( ChanceResult( 50 ) == true ) fAzimuth = -fAzimuth;
```

If the function returns true, we negate the rotation angle so that rotation happens in the opposite direction.

Now we have two final rotation angles, and it is time to perform the rotations. In the first step, we build a rotation matrix that will rotate vectors about the node's right vector (currently equal to the parent's right vector) by fAzimuth degrees. We then rotate the node's direction vector about the right vector by transforming it using this matrix. This step rotates the local Z axis of the new node into either the left or right semi-circle surround the parent node direction vector.

```
    // Rotate the normal
    D3DXMATRIX mtxRot;
    D3DXMatrixRotationAxis( &mtxRot, &pNode->Right, D3DXToRadian( fAzimuth ) );
    D3DXVec3TransformNormal( &pNode->Direction, &vecNormal, &mtxRot );
```

The first rotation has been performed and our node's direction vector will now be rotated either clockwise or counter-clockwise about the parent's right vector. Next we want to perform the polar rotation. In order to do this we must rotate the node's direction vector around the parent's direction vector (which is why we made a copy in vecNormal at the start of the function) by an angle of fPolar degrees. We build a matrix that performs this rotation and multiply both the node's direction vector and right vector by this matrix. This rotates the direction vector into its final position and also rotates the right vector by the same amount such that it remains orthogonal to the direction vector.

```
    D3DXMatrixRotationAxis( &mtxRot, &vecNormal, D3DXToRadian( fPolar ) );
    D3DXVec3TransformNormal( &pNode->Direction, &pNode->Direction, &mtxRot );
    D3DXVec3TransformNormal( &pNode->Right, &pNode->Right, &mtxRot );
}
```

Finally, we run some vector generation code to ensure that the right vector and direction vector are completely orthogonal. We discussed a similar technique in Chapter Four of Module I when dealing with vector re-generation for the camera class. Because we are passing a direction and right vector down through the recursive process and are repeatedly applying rotations to it, without this next step, floating point accumulation errors would build quite quickly and we would lose orthogonality. Since these vectors represent our node coordinate system which is used in many places during tree and mesh creation, we must not let this happen.

```
   // Ensure that these new vectors are orthogonal
   D3DXVec3Cross( &vecNormal, &pNode->Direction, &pNode->Right );
   D3DXVec3Cross( &pNode->Right, &vecNormal, &pNode->Direction );
   D3DXVec3Normalize( &pNode->Right, &pNode->Right );
```

ChanceResult - CTreeActor

Before continuing to cover the other functions called by GenerateBranches, let us have a look at the ChanceResult function which was called from DeviateNode (and called from various other places throughout the tree generation process).

The function generates a value between 0.0 and 1.0 by dividing the value returned from rand by RAND_MAX. We then multiply this float by 100 so that we have a value between 0.0 and 100.0. If this value is smaller than the probability value passed in (itself a value between 0.0 and 100.0) the function returns true (simulating that the probability has come true in this instance). Otherwise, false is returned.

```
bool CTreeActor::ChanceResult( float fValue ) const
{
    // REALLY simple percentage chance prediction
    if ( (((float)rand() / (float)RAND_MAX) * 100.0f) < fValue ) return true;
    return false;
}
```

BuildBranchNodes – CTreeActor

Recall that after GenerateBranches has deviated the direction vector for each root node (in the multiple root branch case) it passes the root node into the BuildBranchNodes function. This function is called once by GenerateBranches for each root node. The BuildBranchNodes function is really the heart of the tree generation process. Not surprisingly, it is a recursive function. When the initial call made from GenerateBranches returns, the entire branch node hierarchy for that root branch will have been created.

While recursive functions are often tricky to follow along with in your head, the tasks that this function must perform are really quite simple. The function is passed a branch node that has already been generated and it must create a new child node for that node. It must also decide whether the new child node (which continues the branch) should be a normal branch node or whether it should be a Branch_End node. It must also decide whether the child node it has generated will spawn additional child branches (new Branch_Begin nodes). Of course, when making these decisions, it will use the growth properties structure that the application passed in when starting the process.

When the function creates and attaches the new child node, it fills out all its information and then sends that new node into the BuildBranchNodes function with a recursive call. Therefore, each call to this function will generate a new node, attach it to the parent node (i.e., the node passed in) and recursively call itself passing in the new node as the parent node in the next recursive call. This process continues until an instance of the function determines the end of the branch as been reached and returns.

Recall from our discussion of GenerateBranches that this function was passed two parameters. The first was a root node of a root branch and the second was the current value of the BranchUID variable. The BranchUID variable was local to the GenerateBranches function and was incremented every time a root node was created. However, we want this value to be incremented for every node that is created, so we

pass this value by reference into the BuildBranchNodes call. This means that with each recursive call to BuildBranchNodes when a new branch node is created and attached to the tree, the same physical variable is accessed from each level of the recursion. The value will be increased with every node created and then assigned to that node as its unique ID.

What was not obvious in the GenerateBranches function is that BuildBranchNodes function accepts a third parameter: the current iteration count. Recall that in each node we store the current iteration which is incremented with each recursive call. This value represents the current depth of the tree where the node is stored. We use this iteration count for both determining when a branch has become too long (and should be terminated), and when calculating the texture coordinates for the branch meshes. We saw in the GenerateBranches function that each root node was assigned a value of 0. This is as we might expect because the nodes in the root level are in the first level of the hierarchy. However, that function did not pass in the iteration parameter when it called BuildBranchNodes for each root generated, which means the default iteration value of 0 will be used when adding the second node of each root branch to the tree. The result is that both the first and second nodes in a branch will have an iteration count of zero. For all nodes we add to the branch after that, it is incremented. Thus, the third branch segment will have an iteration count of 1 and the fourth will have an iteration count of 2, and so on. (it will always be incremented for all recursive calls from that point on). Is this a mistake? Not at all!

Although we have not discussed this concept previously, we do this because it is more intuitive during the tree building process if the iteration count of a branch node actually describes the index of the branch segment (cylinder) it creates. When we add the initial node, no segment is created because we need two nodes to make a segment. When the second node is added to the branch it is assigned an index count of 0 since its addition to the branch essentially adds the first segment to the branch. When we add the third node to the tree (node 2 because it is zero based), this is assigned an iteration count of 1 since its addition to the branch adds the second segment (segment 1), and so on.

Let us have a look at the code a couple of sections at a time.

```
void CTreeActor::BuildBranchNodes( BranchNode * pNode,
                                   ULONG & BranchUID,
                                   ULONG Iteration /* = 0 */ )
{
    ULONG NewNodeCount = 1, i;
    bool bEnd = false;

    // Bail if this is a branch end
    if ( pNode->Type == BRANCH_END ) return;
```

In the first section of code we set a local variable called NewNodeCount to 1. Keep in mind that, assuming the parent node we have been passed is not a branch end node, we will always add at least one node to this branch (even if it is just a Branch_End node that will cause the processing of this branch to terminate in the next recursive call). The reason we use this variable is due to the fact that we may increment this number throughout the body of the function if it is determined that the passed parent node should not only spawn another branch segment, but also one or more new branch start segments. If we decide later in the function that 2 new branches are going to be spawned from this node, this value will be set to 3. We can then create a loop that creates these three new nodes as siblings and attaches them to the parent node's (the node passed in) child list.

Notice how we initially set a boolean variable called bEnd to false. Provided the parent node is not already a branch end node, we will continue the branch by at least one more node. If at some point we determine that the child node we create should end the branch, we will set this boolean to true. This will be used to setup a branch end node instead of a normal branch node and ensure that when the next recursive call happens, and the parent branch node passed in is an end node, the recursive path will terminate all the way back to the last un-processed fork along the recursive road.

We can see this termination process being performed at the bottom of the code shown above. It tests the parent node to see if it is of type BRANCH_END. If it is, then the branch has ended and we should not add any more branch segments to that branch. In this case, we simply return. This terminates the recursive process of adding nodes to that branch.

If program flow gets past the code shown above, then it means the parent node passed into the function is not an end node and we need to continue this branch by at least one more node. What we must determine however is if this new node we are about to add to the branch is an end node. We perform a series of tests to determine this, and if any of these tests pass, the bEnd local boolean is set to true so that we know the new node we are about to create and add to this branch should be an end node.

First we test if the iteration value passed into the function (which is incremented every time the function is called and we step down another level in the hierarchy) is equal to the Max_Iteration_Count member of the tree's growth properties. This is a fixed termination level and our way of limiting the depth of the hierarchy that is ultimately created. If this is the case, then the recursive process has generated a tree that is of the maximum depth and the next branch node we add should be a branch end node. Thus, we set the branch end boolean to true, as shown below. Remember, the Iteration variable is a parameter to the function that is increased as the function repeatedly calls itself to step along the branch.

```
    // We've reached our end point here.
    if ( Iteration == m_Properties.Max_Iteration_Count ) bEnd = true;
```

Next we test to see if there is any chance of the node we are about to create spawning new child branches. In the TreeGrowthProperties structure we have several members that help us control the circumstances under which splits in the branch might happen.

First, we will definitely not want to create any splits if the iteration count passed is already larger than the maximum iteration count set for the tree. Otherwise, we would be generating a new branch at a level in the hierarchy that is deeper than we want the hierarchy to be. Therefore, we will certainly only consider splitting from this node if the current iteration count (tree depth) is smaller than the maximum iteration count set for the tree. Additionally, we only introduce new child branches at this node if the X and Y dimensions of the parent node (which are tapered as we step along the branch) are within the size ranges specified by the Min_Split_Size and Max_Split_Size tree growth properties. If either the X or Y dimensions fall outside this range, then the thickness of the branch is currently such that the application does not wish splits to happen. These properties are great for making sure that we do not spawn branches from very slim parent branches or that we do not spawn them from the base of a trunk branch where the branch is the thickest. The following code shows the conditional and the code block that will be executed only if we are allowed to spawn child branches from this node.

```
    // Chance of splitting into N ?
    if (  Iteration <  m_Properties.Max_Iteration_Count &&
          Iteration >= m_Properties.Min_Split_Iteration &&
          Iteration <= m_Properties.Max_Split_Iteration &&
          pNode->Dimensions.x >= m_Properties.Min_Split_Size &&
          pNode->Dimensions.x <= m_Properties.Max_Split_Size &&
          pNode->Dimensions.y >= m_Properties.Min_Split_Size &&
          pNode->Dimensions.y <= m_Properties.Max_Split_Size )
    {
        if ( ChanceResult( m_Properties.Two_Split_Chance ) )   NewNodeCount = 2;
        if ( ChanceResult( m_Properties.Three_Split_Chance ) ) NewNodeCount = 3;
        if ( ChanceResult( m_Properties.Four_Split_Chance ) )  NewNodeCount = 4;

        // Are we splitting here
        if ( NewNodeCount > 1 )
        {
            // Chance that a split will terminate this branch.
            if ( ChanceResult( m_Properties.Split_End_Chance ) ) bEnd = true;

        } // End if split here

    } // End if we've reached our limit
```

So what is happening inside the code block above? For starters, the fact that we are in the code block means that a new branch *can be* spawned from this node. Of course, it does not mean a new branch *will be* spawned since this will be decided using the split probability values stored in the tree growth properties structure.

Notice that we make three calls to the ChanceResult function (covered earlier). First we call it for the two split case. The chances of this test succeeding depend on the value stored in the Two_Split_Chance tree growth property. The higher the probability value we pass in, the better the odds that it will return true. We perform the two split, three split, and four split tests in that order such that higher branch splits (which typically have much lower probabilities assigned by the application) take precedence. As shown above, at the end of these tests, the NewNodeCount local variable will have been updated to contain the exact number of nodes that should be created at this level of the branch and attached to the parent node passed in as child nodes. This number is the sum of the new child branches we wish to add, plus one for the node that continues the current branch.

In the final section of the code above, you can see that provided we have introduced at least one new child branch at this node (NewNodeCount > 1), we will perform another probability test to see if the normal branch node we are about to add to the parent node (to continue the current branch) should be an end node terminating the current branch being processed. The Split_End_Chance growth probability variable is used for this test. This allows the application to control the likelihood that a branch will terminate at a node where new child branches are spawned (i.e., a fork in the branch).

At this point in the function, we know we have to create at least one new node to continue the branch, even if that node is an end node. In addition, we may also have to create one Branch_Begin nodes for each new branch starting at this new node. Forgetting about the new child branch nodes for now, let us first create a node that will be the continuation of the branch we are currently processing.

Before we create our new child branch node, we must calculate the size of this node. As discussed previously, every node in a branch will be smaller than the node before it (the parent node) so that our branches gradually taper off into tips by the time we reach the end node of that branch. In the next step we will calculate the dimensions of the new node we are about to create. How do we calculate the size of each node so that we have a gradual tapering from segment to segment such that the dimensions of the end node of the branch are zero?

We know that the dimensions of the root node describe the thickest part of the tree. That is, the X and Y dimensions of the root node describe the largest ring of vertices we will create. We also know that the TreeGrowthProperties::Max_Iteration_Count member contains the maximum depth of the hierarchy. Essentially, this tells us the iteration where the branch should have zero dimensions. Therefore, if we divide the X and Y dimensions of the root node by the maximum iteration count, we have a value that we can subtract from each node during each iteration. For example, if the root X dimension was 100 and the maximum iteration count was 25, we would calculate the amount to subtract from the dimensions of each node as follows:

SubtractAmount = 20 / 5 = 4;

So we would need to subtract 4 in each recursion from the X dimensions of the parent node when calculating the child node's dimensions. Remembering that in the next iteration, the child node will be the parent that will be reduced by another 4 units when calculating the dimensions of its child, we can see that the X dimension at each recursion would be:

Node 0 : X = 20
Node 1 : X = 16
Node 2 : X = 12
Node 3 : X = 8
Node 4 : X = 4
Node 5 : X = 0 (end node with single vertex)

As you can see, using this calculation we can recursively reduce the size of the nodes in each level of the hierarchy such that at the maximum iteration count, we have a branch tip node with zero size. We do this for both the X and Y dimensions since they may have different radii. We also do the same with the Z dimension since we want the length of each segment to get smaller as we traverse the length of the branch. However, we normally do not want the same level of downscaling from node to node as this would create very small stumpy segments at the ends of the branches. Unlike the X and Y dimensions, we are not aiming to get the length of the branch segment to be zero at the end node. To control the falloff in Z, we introduce an additional property (Length_Falloff_Scale) which can be used to allow the reduction in length from node to node to happen at a reduced rate. For example, if we set this property to 0.25, the length of the nodes will get smaller at a ratio of ¼ of the size reduction in branch thickness.

This next section of code calculates the three reduction values we need to subtract from the parent node's dimensions in order to calculate the dimensions of the new node.

```
    // Scale Ratio
    float ScalarX = (m_pHeadNode->Dimensions.x /
                    (float)m_Properties.Max_Iteration_Count);
```

```
    float ScalarY = (m_pHeadNode->Dimensions.y /
                    (float)m_Properties.Max_Iteration_Count);

    float ScalarZ = ((m_pHeadNode->Dimensions.z /
                    (float)m_Properties.Max_Iteration_Count) *
                     m_Properties.Length_Falloff_Scale );

    // Do we have enough room for another segment?
    if ( pNode->Dimensions.x < ScalarX) bEnd = true;
    if ( pNode->Dimensions.y < ScalarY) bEnd = true;
    if ( pNode->Dimensions.z < ScalarZ) bEnd = true;
```

As the above code demonstrates, after we have calculated the three reduction amounts (ScalarX, ScalarY and ScalarZ) we next test to see if any of these values are larger than the current dimensions of the parent node. If this is the case then it means the parent node is either too thin or too short to reduce by a suitable amount. When this happens, the child node we are about to add should end the branch (notice that we set the bEnd boolean to true).

At this point, we are ready to create the new child node that continues the current branch. We will deal with any new branch start nodes we may have decided to create in a moment. All we are dealing with here is the node that will continue the branch to which the parent node belongs. Here is the code that allocates a new child branch node and populates its members with the correct information.

```
    // Generate segment node (continuation of the branch)
    BranchNode * pNewNode  = new BranchNode;

    if ( !pNewNode ) return;

    // Store node details
    pNewNode->UID          = BranchUID++;
    pNewNode->Parent       = pNode;
    pNewNode->Dimensions.x = pNode->Dimensions.x - ScalarX;
    pNewNode->Dimensions.y = pNode->Dimensions.y - ScalarY;
    pNewNode->Dimensions.z = pNode->Dimensions.z - ScalarZ;
    pNewNode->Position     = pNode->Position +
                             (pNode->Direction * pNode->Dimensions.z);
    pNewNode->Direction    = pNode->Direction;
    pNewNode->Right        = pNode->Right;
    pNewNode->Type         = bEnd ? BRANCH_END : BRANCH_SEGMENT;
    pNewNode->BranchSegment= pNode->BranchSegment + 1;
    pNewNode->Iteration    = (USHORT)Iteration;
    pNode->Child           = pNewNode;

    // Clamp to minimum size, this is an end of branch
    if ( pNewNode->Dimensions.x < 0.0f ) pNewNode->Dimensions.x = 0.0f;
    if ( pNewNode->Dimensions.y < 0.0f ) pNewNode->Dimensions.y = 0.0f;
    if ( pNewNode->Dimensions.z < 0.0f ) pNewNode->Dimensions.y = 0.0f;
```

We increment the passed BranchUID member before assigning it to the node so that this node has a unique ID. We then store the address of the parent node (the node passed into this function) in the new node's Parent pointer. We also subtract the three scalar values we calculated previously from the parent node's dimensions before assigning them as the new dimensions of the child node.

Notice how we assign the new node its position. Its position is the product of adding the parent node's direction vector scaled by the parent node's Z dimensions (the length of the parent node) to the position of the parent node. Essentially, we are generating the new position by placing the child at the position of the parent, then sliding the child node along the direction vector of the parent by the Z length. This is an important concept to grasp. The Z dimension of any node actually describes the length of the segment for which that node forms its base ring of vertices. Next (in the above code) we copy the direction vector and the right vector of the parent into the child; we will deviate these in a moment.

The value we assign to the node's Type member depends on whether the local bEnd boolean was set to true in our tests. If it was, then the new node becomes a BRANCH_END type and will be the last node in that branch. Otherwise, it is assigned the BRANCH_SEGMENT type which means it is just another normal segment added to the current branch. We also store in the node's BranchSegment member the value stored in the parent node increased by one. Remember, this value will start off at zero in every BRANCH_BEGIN node so that it contains the local index of the node within the branch. The iteration value passed into the function (which would have been incremented in a previous call) is also stored in the node and then the parent node's child pointer is assigned to point at this new node. Finally, we test to see if any of the node's dimensions are smaller than zero and clamp them to zero if this is the case. This could only potentially be the case for a node that was already determined to be a branch end node.

The new node which continues the current branch has now been populated and attached to its parent, adding another segment to the branch and another level to this portion of the hierarchy. We now decide whether the child node should be randomly deviated using our ChanceResult function and the TreeGrowthProperties::Segment_Deviation_Chance member. This property holds the probability that segments within the same branch will deviate. The code that performs the deviation is shown below.

```
    // Chance of changing direction
    if ( ChanceResult( m_Properties.Segment_Deviation_Chance ) )
    {
        // Deviate the node
        DeviateNode( pNewNode,
                     m_Properties.Segment_Deviation_Min_Cone,
                     m_Properties.Segment_Deviation_Max_Cone,
                     m_Properties.Segment_Deviation_Rotate);

        // Weight with parent
        pNewNode->Direction += pNode->Direction *
                               m_Properties.SegDev_Parent_Weight;

        // Weight with growth direction
        pNewNode->Direction += m_Properties.Growth_Dir *
                               m_Properties.SegDev_GrowthDir_Weight;

        // Normalize
        D3DXVec3Normalize( &pNewNode->Direction, &pNewNode->Direction );

    } // Change direction
```

If the ChanceResult function returns true, we enter the code block that deviates the child node's direction vector. We first call the DeviateNode method passing in the minimum cone angle, the maximum cone angle, and the rotation properties for node deviation within the same branch. When this

function returns, the new node's direction vector will have been randomly deviated from its parent. However, we also have other properties to configure to restrain that deviation. For example, next we calculate how much the parent node's direction vector should be factored into the deviated vector. We add the new node's direction vector and the parent node's vector multiplied by the SegDev_Parent_Weight property (usually a value between 0.0 and 1.0). The lower this weight value, the less influence the parent node's direction vector will have over the direction vector generated for the child. Next, we add the Growth_Dir vector to the new node's direction vector. Growth_Dir is a tree growth property describing a general growth direction for the tree. The influence it will have is determined by the SegDev_GrowthDir_Weight property. After we have added these two vectors to the deviated direction vector, we renormalize it. The vector is now deviated and influenced to some degree by the parent node's vector and the general growth direction.

At this point, our child node is complete. All we have to do is continue to process the branch to which it belongs by calling the BuildBranchNodes function again in a recursive call. This time, the new child node we have just created is passed as the parent node. The current value of the BranchUID variable is also passed so that it can continue to be incremented and assigned to nodes in this branch when they are generated in future recursions. It is at this point that we also increment the current Iteration value before passing it into the next recursion. With each call into the recursive process, the Iteration value will be incremented so that as we step down the hierarchy from branch node to child branch node, the iteration values of the nodes stored at that level in the hierarchy are increased.

```
    // Generate this new branch segment
    BuildBranchNodes( pNewNode, BranchUID, Iteration + 1 );

    // Reduce NewNode Count
    NewNodeCount--;
```

One thing to bear in mind is that this function is recursively called until the parent node passed in is a branch end node, at which point it exits. When the function returns to the current iteration, all the child nodes (and any child branches spawned from those child nodes) will have been generated.

Of course, our job is not yet done for this node. We may have determined earlier in the function that additional child branches should be spawned from the node we have just created. Notice in the above code that after we have added our new node, we decrement the local NewNodeCount variable to account for the fact that we have already processed one of the new nodes we needed to add.

If the NewNodeCount value is still non-zero after the previous decrement, it means that one or more child branches (branch start nodes) will be spawned from this node. Note that these will need to be added to the node's sibling list since the new branch nodes we are about to create and the child node we just added all share the same parent.

Before we add these new branch child nodes, we must determine whether the thickness of the current branch can accommodate child branches which may be protruding at extreme angles. When we create a new node to continue a branch, we shrink its size from its parent by one step (where a step is the value contained in ScalarX, ScalarY, and ScalarZ). However, when a root node of a new child branch is about to be placed, it is likely to be deviated by a much greater angle than the deviation performed on nodes within the same branch. Since the ring of vertices at the start node of a new branch will essentially be

placed *inside* the parent branch (i.e., positioned at the same position as the child node we just generated) we want to make sure that the child branch is thin enough such that when rotated by 45 degrees for example, the vertices placed at its first node do not pierce the skin of the parent branch (Figure 12.38).

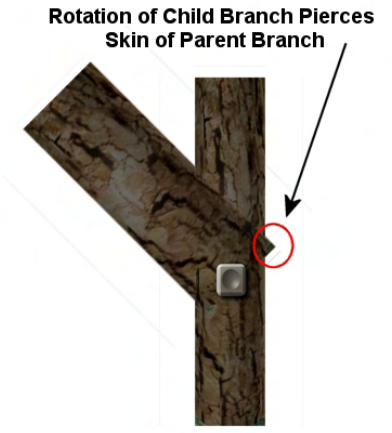

Figure 12.38

As you can see, our tree is a collection of disjoint meshes (one per branch). It is only the fact that we position the start nodes of those branches inside their parent branches that it looks like a single tree. However, as Figure 12.38 demonstrates, we need to make sure that any child branches we add are reduced enough in size with respect to the parent that we have room to rotate without the ring of vertices breaking the through the skin of the parent branch.

After some trial and error in the labs, we learned that by reducing the size of a new child branch by four steps (instead of one) we can generate children that can be freely rotated without much cause for concern. Therefore, instead of subtracting ScalarX, ScalarY, and ScalarZ from the size of the parent node as we did above when adding a node to continue the branch, when a new branch start node is spawned, we reduce its dimensions by four times that amount. So if we are at node N within a parent branch and a new branch is started at that node, the dimensions of that first node in the new branch will be equal to the thickness of node N+4 in the parent branch.

In the following code we assign this multiplier to a variable called fStepScale. We then perform tests to see if the dimensions of the parent node are smaller than the ScalarX, ScalarY, and ScalarZ values multiplied by the step scale. If the parent node is too thin to step down four levels in size, then we set the bEnd boolean to true.

```
    // Do we have enough room to split ?
    float fStepScale = 4.0f; // Reduce size by 4 times usual amount

    if ( pNode->Dimensions.x < (ScalarX * fStepScale) ) bEnd = true;
    if ( pNode->Dimensions.y < (ScalarY * fStepScale) ) bEnd = true;
    if ( pNode->Dimensions.z < (ScalarZ * fStepScale) ) bEnd = true;

    if ( bEnd ) NewNodeCount = 0;
```

If any of the dimensions of the parent node are so small that we would not be able to sufficiently reduce the size of the branch start nodes we are about to create, we set the NewNodeCount to zero. In this case, regardless of whether we determined a need to spawn child branches, no new branches will be started at this node.

If NewNodeCount is still larger than zero then we need to add one or more nodes to the parent node's child list in a loop. Each new node we are about to add in this step should be of the type BRANCH_BEGIN. For each node we allocate, we will assign it to the sibling pointer of the node that came before it in the loop, so we use the local pPrevNode pointer to store the address of the branch node that was allocated in the previous iteration of the loop. Initially we set the pPrevNode pointer to pNewNode, which is the node we allocated previously when adding another segment to the current branch. This node was assigned to the child pointer of the parent node, so any new nodes we add now should be attached to its sibling list.

```
    // Generate new split off branches ?
    BranchNode * pPrevNode = pNewNode;

    for ( i = 0; i < NewNodeCount; i++ )
    {

        BranchNode * pNewNode = new BranchNode;
        if ( !pNewNode ) continue;

        // Store node details
        pNewNode->UID          = BranchUID++;
        pNewNode->Parent       = pNode;
        pNewNode->Dimensions.x = pNode->Dimensions.x - (ScalarX * fStepScale);
        pNewNode->Dimensions.y = pNode->Dimensions.y - (ScalarY * fStepScale);
        pNewNode->Dimensions.z = pNode->Dimensions.z - (ScalarZ * fStepScale);
        pNewNode->Position     = pNode->Position +
                                 (pNode->Direction * pNode->Dimensions.z);
        pNewNode->Direction    = pNode->Direction;
        pNewNode->Right        = pNode->Right;
        pNewNode->BranchSegment= 0;
        pNewNode->Iteration    = (USHORT)Iteration;
        pNewNode->Type         = BRANCH_BEGIN;

        // Deviate the node
        DeviateNode( pNewNode,
                     m_Properties.Split_Deviation_Min_Cone,
                     m_Properties.Split_Deviation_Max_Cone,
                     m_Properties.Split_Deviation_Rotate );

        // Link the node
        pPrevNode->Sibling = pNewNode;

        // Generate this new branch
        BuildBranchNodes( pNewNode, BranchUID, Iteration + 1 );

        pPrevNode = pNewNode;

    } // Next New Branch Node
}
```

That was the final section of the BuildBranchNodes function. Notice that we assign each node a unique ID before incrementing the BranchUID variable. The dimensions we assign to each branch start node are the dimensions of the parent node reduced by four times the step reduction value used for inter-branch nodes. As before, the position of each node is simply calculated by sliding the new node from the parent node's position along the parent node's direction vector by the distance described in the parent node's Z dimension. The direction and right vectors are also copied straight from the parent node, and they will be deviated in a moment.

For each node we add in this loop we assign the BranchSegment member of that node to zero, because this member describes the index of the node relative to the start of the branch. Since we are adding branch start nodes here, the index of each new node we create will be zero. Of course, we also assign the type BRANCH_BEGIN to each node we create, as each one will begin a new branch mesh.

After we have assigned all the properties, we deviate the direction vector. We will usually want new branches to have a more obvious change in direction with respect to their parent branches so that we can see them sprouting out from the tree. When DeviateNode is called, we send in different minimum and maximum cone angles and polar rotation angles that we did before. These values specify the deviation range for nodes that start a new branch. Note that after we have deviated the direction vector of a new branch start node, we do *not* factor in the parent node's direction or the growth direction of the entire tree. The direction vector for this node will become the initial parent direction for the rest of the branch. The overall growth direction vector for the tree will be factored in eventually for the other nodes in the branch we are just starting. So even if the initial direction vector of the branch was (1,0,0), an overall growth direction of (0,1,0) would still make the other segments in the new branch start to grow upwards as they grow out.

Once the node has been created and populated, we attach it to the previous node's sibling pointer before the function calls itself recursively passing in the new node as the parent. When program flow returns back to the current instance of the function, the entire branch of nodes will have been created.

Before moving on, please make sure that you understand how the above function works by calling itself recursively to generate an entire tree of branches.

Phase One Complete

We have now covered all the code needed to implement phase one -- the building of the virtual tree. You will recall that phase one was initiated by CTreeActor::GenerateTree which was invoked by the application. The GenerateTree method called the GenerateBranches function to complete stage one. GenerateBranches called the recursive function BuildBranchNodes to build a virtual tree for each root branch node.

The GenerateTree function oversees the entire tree building process and we have only covered the first phase. Let us have another look at the GenerateTree method to remind ourselves of the functions it calls which we have yet to cover.

```
HRESULT CTreeActor::GenerateTree(   ULONG Options,
                                    LPDIRECT3DDEVICE9 pD3DDevice,
                                    const D3DXVECTOR3 & vecDimensions,
                                    const D3DXVECTOR3 & vecInitialDir ,
                                    ULONG BranchSeed /* = 0 */ )
{
    HRESULT            hRet;
    CAllocateHierarchy Allocator( this );

    // Validate parameters
    if ( !pD3DDevice ) return D3DERR_INVALIDCALL;

    // Release previous data.
    Release();

    // Store the D3D Device here
    m_pD3DDevice = pD3DDevice;
    m_pD3DDevice->AddRef();

    // Store options
    m_nOptions = Options;

    // Generate the branches
    hRet = GenerateBranches( vecDimensions, vecInitialDir, BranchSeed );
    if (FAILED(hRet)) return hRet;

    // Build the frame hierarchy
    hRet = BuildFrameHierarchy( &Allocator );
    if (FAILED(hRet)) return hRet;

    // Build the bone matrix tables for all skinned meshes stored here
    if ( m_pFrameRoot )
    {
        hRet = BuildBoneMatrixPointers( m_pFrameRoot );
        if ( FAILED(hRet) ) return hRet;

    } // End if no hierarchy

    // All is well.
    return D3D_OK;
}
```

After we have the virtual tree from phase one, it is time to move onto the phase two. Phase two is the construction of the actor's skeleton and branch skins and is initiated with a call to BuildFrameHierarchy

Notice how BuildFrameHierarchy accepts one parameter -- a pointer to an ID3DXAllocateHierachy interface. The CAllocateHierarchy class we developed has not been changed since our previous discussions. It contains both the CreateFrame and CreateMeshContainer methods that we need to allocate frames for our actor's hierarchy and convert any regular meshes we create for the branches into API compliant skinned meshes. Let us now follow the path of execution into the BuildFrameHierarchy function.

BuildFrameHierarchy – CTreeActor

The BuildFrameHierarchy function is the gateway to the recursive process for phase two of the tree generation process. It has only one task -- to call the BuildNode function with parameters that initialize the recursive process.

```
HRESULT CTreeActor::BuildFrameHierarchy( ID3DXAllocateHierarchy * pAllocate )
{
    D3DXMATRIX mtxRoot;

    // Initial frame is identity
    D3DXMatrixIdentity( &mtxRoot );

    // Build the nodes
    return BuildNode( m_pHeadNode, NULL, NULL, mtxRoot, pAllocate ) ;
}
```

The BuildNode function is passed the root node of the branch node hierarchy constructed in phase one. This function also needs to be passed a combined frame matrix that is initially set to identity (as the root node has no parent and we have not generated any frames yet). We also pass in the CAllocateHierarchy interface pointer so that the BuildNode function will be able to use its methods to generate meshes and frames. When this function returns, the entire frame hierarchy will have been constructed and populated with skinned meshes (one per branch).

BuildNode – CTreeActor

The BuildNode function is a function that recurses until the frame hierarchy and all its meshes have been created. Before we look at the code, let us briefly examine the design specifications so that we know what this function must do.

Frame Hierarchy Creation

This function will need to recursively step through the branch node hierarchy (the virtual tree) and examine each node. If a BRANCH_BEGIN node is encountered then we know that this node will be the root bone of a given mesh. Also, if we reach any type of node (except BRANCH_END) that has an iteration where Node->BranchSegment % Bone Resolution = 0, we know that we have skipped the correct number of nodes and it is time to add another bone. Remember, the bone resolution property tells this procedure how frequently it should convert branch nodes into actual bones. The BranchSegment member of a node contains its zero based index relative to the start of the branch.

Once the function determines that the current branch node is one that should be a bone, we have to allocate a new D3DXFRAME and attach it to the actor's frame hierarchy. Obviously, in the very first iteration the actor will have no hierarchy, so the first frame we create will be the root frame of the actor (the actor's m_pRootFrame member will point at this frame).

Once we have created a frame for a given node, we will also set that branch node's BoneNode boolean to true so that we will know later on that this node is a node that created a bone. This will be needed when building the skin and mesh data. We will also store a pointer to the frame we have just created in the branch node's pBone pointer. Once again, this is so we can access it later and pair branch nodes with frames.

Now that a frame has been allocated for this branch node, we need to populate it with information. Obviously, we wish this bone to be stored in the exact same position as the branch node it was created from. However, we cannot just copy over the position and orientation from the branch node into the frame's matrix. The branch node stores the position and orientation of the node as an absolute transformation from the origin of tree space, but we know that the frames must have their matrices defined in parent relative space. To address this, we will pass through the recursive process a combined frame matrix and the process will work as follows…

If we are currently adding a fifth frame to the actor's hierarchy, we will have a matrix that contains the combined transformations of the first four. We will also create a matrix for the current frame that contains the absolute position and orientation information copied over from the branch node. We now have matrix A (a combined matrix of frames 1 to 4) and matrix B (the absolute position of the current frame as taken from the branch node). We can calculate the relative matrix by inverting matrix A and multiplying with matrix B.

Relative Matrix = $B\ A^{-1}$

Essentially, we are subtracting the absolute position of the 4^{th} frame (the parent) from the absolute position of the 5^{th} frame (copied from the branch node) which leaves us with a matrix describing the transformation of the fifth frame relative to the fourth. Now you know how to construct relative matrices. Once we have this relative matrix, we will store it in the matrix of the frame.

Of course, we will need to pass the current combined matrix up to the point of the current branch node down to the child nodes. Therefore, using the above example, once we have calculated the relative matrix for frame 5, we will multiply that matrix with the combined matrix of frames 1-4 (passed into the function) so that we now have a combined matrix of transformations for frames 1 through 5. We will then pass that matrix into the next recursion so that it can be 'subtracted' from the absolute position of the 6^{th} frame to generate the relative matrix with respect to its parent, frame 5. Because not all branch nodes will become bones, we need to make sure that even when we do not add a frame to the hierarchy for a node that we are processing, we still pass the combined matrix into the next recursion.

For example, imagine we have a bone resolution of 5. At the first frame, we hit a BRANCH_BEGIN node, so we add a frame (the first frame) to the actor's hierarchy. Given the bone resolution, we will not be adding another frame for this branch until we traverse another five branch nodes. However, when we hit that next branch node where a frame must be added, we will need access to the combined matrix that was generated at the last branch node a frame was created for. We need it so that we can calculate the relative matrix for the new frame. Therefore, each time the function is called, we will pass in a combined frame matrix containing

the concatenation of all the frames we have added to the hierarchy up to that point. When the branch node we are processing is one that we will create another frame in the hierarchy for, that combined matrix will be updated by combining it with the relative matrix generated for the new frame. This updated combined matrix can then be passed down to the children and used further down the branch when another frame is added. If the branch node we are currently processing is a non-bone branch node, we will simply pass along the combined matrix un-modified to the children.

Mesh Creation

The function will do more than just create frames for the actor's frame hierarchy; it will also build a CTriMesh for each branch. Once again, the action taken by the function is slightly different depending on whether we are processing a BRANCH_START node or a normal branch node.

1. If the branch node is of type BRANCH_BEGIN, we have to create a new empty mesh. We then add the initial ring of vertices to this mesh before passing this mesh down to the child branch nodes.

2. If the branch node is not of type BRANCH_BEGIN then we are currently stepping down a branch for which a mesh has already been created. All we have to do is add another ring of vertices to that mesh at the position represented by the branch node.

Every time the function calls itself for a non-BRANCH_BEGIN node, it will be passed a pointer to the mesh that was allocated when the BRANCH_BEGIN node was encountered. Therefore, we use a similar transport mechanism for the mesh as we do for the combined matrix. The branch begin node allocated the mesh, and from that point on this mesh is passed down to each child node where rings of vertices are added. By the time the BRANCH_END node has been created, we will have added a ring of vertices to the mesh for every node in that branch.

Of course, when stepping through branch child nodes and building the mesh, we may find that a node exists in a child's sibling list. This tells us that one or more BRANCH_BEGIN nodes (new child branches) start at this node. For each of these BRANCH_BEGIN nodes, we must do the same thing as before -- create a new mesh and then recursively pass it down to each of its children so that they can add their vertices. So you can imagine that as the recursive process is underway, there can be many meshes allocated but only partially built.

For example, imagine a simple case where we have a root branch with six nodes. At the first node (BRANCH_BEGIN) we create a new CTriMesh and pass it down to each of the five children in the list. By the time we have reached the branch end node, the branch will have had five rings of vertices added and one tip vertex. However, let us also assume that this root branch has a child branch that starts at node 3 (another BRANCH_BEGIN node in a sibling list with node 3 of the root branch). We would travel into that branch and process its BRANCH_BEGIN node. This would mean allocating a new mesh for this second branch and stepping through its children adding their vertex rings.

At some point we will reach the branch end node of this second branch and all vertices will have been added. The initial mesh for the root branch is still only partially complete because we took a detour after processing node 3. When the recursive process returns, we find ourselves back in the instance of the function that was originally processing node 3 of the root branch. We would now continue down to the remaining branch nodes in the root branch and complete our adding of vertices to the root branch mesh.

Figure 12.39 shows the flow of the recursive process when walking the branch node hierarchy and building and populating branch meshes.

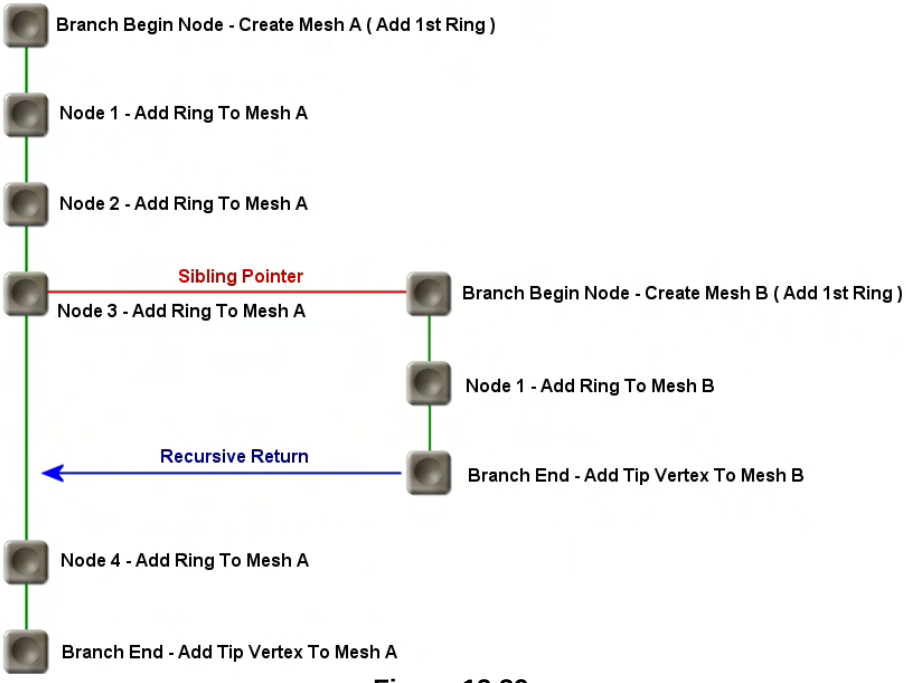

Figure 12.39

Regardless of how many branches your tree has and how many meshes it ultimately creates, the root mesh (the mesh of the trunk) will always be the first mesh allocated and the last mesh completed. We can see in Figure 12.39 that Mesh A was allocated first, but Mesh B was completed first. If you imagine more levels of recursion (child branches coming off of branch B), then you should be able to see that the last meshes to be allocated and the first to be completed are always the meshes for the smaller branches at the deepest levels of the tree.

When we add vertices to a mesh at a given node we will also add the indices to the mesh index buffer to create the branch segment (a cylinder of triangles) between the ring of vertices added at the current node and the ring of vertices added at the previous node. Remember, after the initial branch begin node, every node thereafter inserts vertices that create a new branch segment. Each ring of vertices inserted at a node (excluding the BRANCH_BEGIN node) forms the top row of vertices of the current segment being added and the bottom row of vertices for the next segment added when the child node is processed.

At the end of the BuildNode function we will once again test to see if the node we are currently processing is a BRANCH_BEGIN node. We know that if it is, then this instance of the function will have already recursively visited the child node, which would have visited its child node, and so on. Suffice to say, at this point, the recursive process has returned back to this instance of the function and the entire child branch will have had its vertices and indices added.

Recall that when we add vertices and indices to a CTriMesh, it stores them temporarily in its internal system memory arrays. Once we are sure that we have added all the vertices and index data, we call CTriMesh::BuildMesh to copy these arrays into vertex and index buffers and create the underlying D3DX mesh. Once done, we can pass the ID3DXMesh into the CAllocateHierarchy::CreateMeshContainer function to convert it into a proper skinned mesh before attaching it to the BRANCH_BEGIN frame in the hierarchy.

Of course, we must send other parameters into CreateMeshContainer, such as the material and texture lists the mesh uses. This list has only one element -- the material and the texture filename set by the application in the call to CTreeActor::SetBranchMaterial. CreateMeshContainer will take care of executing the relevant callbacks to load and store this texture and material combination.

When we covered the CAllocateHierarchy::CreateMeshContainer function, we also learned that if an intended skinned mesh is being passed in, we will also be supplied with a pointer to an ID3DXSkinInfo interface. It is this interface that provides the information needed to create the skin, such as which vertices are influenced by which bones and by what weight. It also contains the name of each bone and its accompanying bone offset matrix. For our tree, we will have to calculate all of this data ourselves, store it in an ID3DXSkinInfo object, and pass it to CreateMeshContainer. Therefore, before we call the CAllocateHierarchy::CreateMeshContainer method, we will issue a call to a helper function called CTreeActor::BuildSkinInfo to create this object for us. That allows us to treat this function like a black box until we have finished discussing the BuildNode function. We will then take a look at the BuildSkinInfo method and see exactly how we build the mapping information between vertices and bones and how we calculate the bone offset matrices for each frame used as a bone by the branch.

We are now ready to cover the CTreeActor::BuildNode function. First, let us have a look at its parameter list and describe what each parameter will be used for. This will make it much easier to then explain the code itself. The function accepts five parameters, which are listed below.

BranchNode *pNode
This is a pointer to the branch node that the instance of the BuildNode function will process. When the BuildNode function is initially called from the BuildFrameHierarchy function, a pointer to the root branch node of the virtual tree hierarchy will be passed. The function will recursively call itself using this parameter to step down to child nodes and along to sibling nodes.

It is this node that will contain the position and orientation of the ring of vertices that needs to be placed in this iteration of the function. If the node is of type BRANCH_BEGIN, the position and orientation of this node will be used to add a new frame to the actor’s frame hierarchy.

D3DXFRAME * Parent
This parameter will be NULL in the initial call. For all other recursive steps it will contain a pointer to the previous frame that was generated for the current branch (i.e., the frame that was last added to the hierarchy) and thus serves as the parent to the next frame being built along the branch. Not all nodes will create frames, so we must pass this pointer down to child nodes even if no frame was created for the current node.

CTriMesh * pMesh
This member will be set to NULL when the function is initially called from the BuildFrameHierarchy function. For all other iterations it will contain a pointer to the mesh that has been allocated for the current branch being constructed.

D3DXMATRIX &mtxCombined
This parameter will be set to an identity matrix when the function is initially called from the BuildFrameHierarchy function. For all other instances of the function, it will contain the combined (absolute) matrix of all the frames we have created so far along that path of the frame hierarchy.

When the function is processing a node that does not result in the generation of a new frame, this pointer should simply be passed unaltered into the child nodes. This allows us to continually pass the current combined matrix down through the branch node until it reaches a node where a new frame is to be generated. It is then used as part of the process to calculate that frame's relative matrix as discussed earlier in the chapter.

When the function recursively calls itself to process a sibling, it should also simply pass along the same combined matrix to the sibling that was passed into the function. The sibling frames will all share the same parent frame and therefore need to use the same parent absolute matrix to calculate their relative matrices.

ID3DXAllocateHierarchy * pAllocate
As we saw when we looked at the BuildFrameHierarchy function, this parameter always contains a pointer to an instance of our CAllocateHierarchy class. We use this object to call its CreateFrame and CreateMeshContainer callback methods whenever we wish to create a new frame in the hierarchy or build a (skinned) mesh.

With the parameter list now behind us, let us now look at the code a section at a time.

The first section of the code tests to see if the current node being processed is a node that should generate a new frame in the actor's hierarchy. The test for this is quite simple: if the node is of type BRANCH_BEGIN then this node represents the start of a new branch mesh and the initial bone of the branch. In this case, we definitely want to add a bone to the actor's hierarchy at this location. The other case in which we decide to create a new bone is if the modulus of the branch node's BranchSegment member with the tree's Bone_Resolution property is zero. Bear in mind that the BranchSegment member of a node contains the zero-based local index of the node within its branch. If a branch has 10 nodes, the BranchSegment member for each node would be in the range of 0-9, respectively. If the bone resolution was 3 for example, we would only add bones at the following nodes:

Node 1		BRANCH_BEGIN			(Bone Created)
Node 2	=	BranchSegment	Mod	Bone_Resolution	
	=	1	Mod	3 = 1	
Node 3	=	BranchSegment	Mod	Bone_Resolution	
	=	2	Mod	3 = 2	
Node 4	=	BranchSegment	Mod	Bone_Resolution	(Bone Created)
	=	3	Mod	3 = 0	
Node 5	=	BranchSegment	Mod	Bone_Resolution	
	=	4	Mod	3 = 1	
Node 6	=	BranchSegment	Mod	Bone_Resolution	
	=	5	Mod	3 = 2	
Node 7	=	BranchSegment	Mod	Bone_Resolution	(Bone Created)
	=	6	Mod	3 = 0	
Node 78	=	BranchSegment	Mod	Bone_Resolution	
	=	7	Mod	3 = 1	
Node 9	=	BranchSegment	Mod	Bone_Resolution	
	=	8	Mod	3 = 2	
Node 10	=	BranchSegment	Mod	Bone_Resolution	(Branch End = No Bone)
	=	9	Mod	3 = 0	

Remember that modulus operation returns the remainder of A divided by B as an integer. So as you can see, only when the modulus returns zero (evenly divisible) have we hit the bone resolution boundary where a new bone should be added. Of course, we always create a bone at the start of a branch. Notice that when we add the 10^{th} node, the modulus does indeed return zero, but we do not add a bone here. That is because it is the end of the branch and a bone would be unnecessary.

Let us have a look at the first section of the function and then we will discuss it.

```
HRESULT CTreeActor::BuildNode( BranchNode * pNode,
                               D3DXFRAME * pParent,
                               CTriMesh * pMesh,
                               const D3DXMATRIX & mtxCombined,
                               ID3DXAllocateHierarchy * pAllocate )
{
    HRESULT     hRet;
    CTriMesh   *pNewMesh  = NULL, *pChildMesh  = NULL;
    LPD3DXFRAME pNewFrame = NULL,  pChildFrame = NULL;
    D3DXMATRIX  mtxBranch, mtxInverse, mtxChild;
    D3DXVECTOR3 vecX, vecY, vecZ;
```

```
    TCHAR       strName[1024];

    // What type of node is this

     bool bIgnoreNodeForBone = (pNode->Type == BRANCH_END);
    if ( pNode->Type == BRANCH_BEGIN ||
        ((pNode->BranchSegment % m_Properties.Bone_Resolution) == 0 &&
         !bIgnoreNodeForBone) )
        {
        // We get here if either this is a new branch node, OR the
        // bone resolution is such that a new bone based frame is being
        // created here. Note: We don't drop here if this is an END node
        // since creating a new bone frame here would be pointless.

        // Generate frame name
        _stprintf( strName, _T("Branch_%i"), pNode->UID );

        // Allocate a new frame
        hRet = pAllocate->CreateFrame( strName, &pNewFrame );
        if ( FAILED(hRet) ) return hRet;

        // If there is a parent, store the new frame as a child.
        if ( pParent )
        {
            // Attach to head of parent's linked list
            pNewFrame->pFrameSibling  = pParent->pFrameFirstChild;
            pParent->pFrameFirstChild = pNewFrame;

        } // End if has a parent
        else
        {
            // Store at the actor's root
            pNewFrame->pFrameSibling = m_pFrameRoot;
            m_pFrameRoot             = pNewFrame;

        } // End if no parent found
```

In the above code we first determine whether a bone should be created for the current node using the techniques previously discussed. If it is determined that we should, we first build a name for that frame. Remember that in order for our frames to be animated, they must have names that will eventually match the animations inside an animation set. We need each frame in the hierarchy to have a name that is unique from any other frame, which was why we took the trouble to assign each branch node a unique numerical ID during the building of the branch node hierarchy. Thus, we build a name for the frame in the format Branch_*n* , where *n* is the ID of the branch node. We use the _stprintf (C standard runtime library) function to format the string and store the result in the local char array strName.

Now that we have the name for the frame we are about to allocate, we pass it into the CAllocateHierarchy::CreateFrame function. As we know, this is a method of our CAllocateHierarchy class that simply allocates a new D3DXFRAME derived structure, safely initializes its members and returns it. The new frame is returned to us in the pNewFrame local pointer.

Once we have our new frame, the code determines whether a parent frame currently exists (it will for all iterations of the function other than the first). If the pParent parameter is not NULL, then it contains a

pointer to the previous frame that was generated during the building process. When this is the case, we add our newly created frame to its child list. Of course, the parent frame may already have children (other branch start frames for example) so we are careful to simply add our new node to the head of the child list thus keeping the child list intact. In this case, we assign the new frame's sibling pointer to point at the current child pointer of the parent (which may point to a list of siblings), and assign the parent's child pointer to point at our new frame. In doing so, we have just added our new frame to the head of the list of child frames for the parent.

If the pParent pointer is NULL, then this is our first time through the function and the frame we have just allocated is the root frame. In this case we assign the actor's m_pFrameRoot pointer to point to our new frame, which is now the root frame for the actor's entire hierarchy. Notice however that we are still careful even in this case to attach the current value of m_pFrameRoot to the new frame's sibling pointer. Remember, there may be multiple root frames in our hierarchy that exist as siblings at the root level. Just because this frame has no parent does not mean that there is nothing useful being pointed to by the m_pFrameRoot pointer -- it may be the sibling root frame of another trunk branch -- so we should keep this list intact also.

Having created the new frame, we will also set the current branch node's BoneNode boolean to true so that we will know later that this branch node has had a bone created from it. We will also assign the branch node's pBone pointer to point at our new frame so that we have access later on.

```
        // For skin info building notify that this is the start of a new bone
        pNode->BoneNode = true;

        // Store which bone we're assigned to in the node
        pNode->pBone = pNewFrame;

        // Update the frame we will pass to the child with our new frame
        pChildFrame = pNewFrame;
```

Notice at the bottom of the above code, we assign a local pointer (pChildFrame) to the new frame we have just allocated. Because we have created a new frame, we know that it will be the parent frame of the next frame that is created further down the branch. So this pointer will serve as the frame that is passed to the child node as its parent.

We have now created a frame and attached it to the hierarchy but it currently requires initialization. Its matrix is just an identity matrix, so we need to compute the parent relative matrix. We do not know this information at the moment but we do have the absolute position of the current branch node the frame was created from, as well as the node's direction and right vectors. These vectors describe the alignment of the branch node's local Z and X axes with respect to tree space, and if we perform the cross product between the branch node's right and direction vectors we will generate the third axis of the branch node's local coordinate system.

```
        // Store / generate the vectors used to build the branch matrix
        vecX = pNode->Right;
        vecZ = pNode->Direction;
        D3DXVec3Cross( &vecY, &vecZ, &vecX );
```

At this point, we now know the orientation of the branch node's local axes as well as its position in tree space. This is all we need to build a tree space (absolute) matrix for the current frame.

```
        // Generate the frame matrix for this branch
        D3DXMatrixIdentity( &mtxBranch );
        mtxBranch._11 = vecX.x; mtxBranch._12 = vecX.y; mtxBranch._13 = vecX.z;
        mtxBranch._21 = vecY.x; mtxBranch._22 = vecY.y; mtxBranch._23 = vecY.z;
        mtxBranch._31 = vecZ.x; mtxBranch._32 = vecZ.y; mtxBranch._33 = vecZ.z;
        mtxBranch._41 = pNode->Position.x;
        mtxBranch._42 = pNode->Position.y;
        mtxBranch._43 = pNode->Position.z;
```

By placing the three axis vectors and the position into a matrix (using the specified format) we have created a single tree space matrix that describes the position and orientation of the branch node. In this coordinate system the tree root would be at the origin, but hopefully you can see that this matrix is no different from any other world matrix we would generate. Essentially, taking a point at the origin of the tree space coordinate system (0,0,0) and multiplying it with this matrix would transform the point to the position of the current node.

So, we have a matrix that describes the absolute position of our new frame, but we want it to be a parent relative matrix. We also have the combined matrix passed into the function (mtxCombined) which describes the absolute matrix of the parent frame. As discussed earlier, if we take the inverse of this combined matrix and multiply it with our current matrix, we will *essentially* subtract from our matrix all the combined transformations for all frames up to and including the parent frame. This will leave our matrix storing only the transformation 'difference' between the parent frame and the current frame's position/orientation. In other words, we have a matrix that describes our new frame as position and rotation offsets from the parent frame. In short, we have a parent relative matrix.

> **Note:** For a more technical description of what is happening here, you can refer back to Module I where we discussed the relationship between matrices, inverse matrices, and moving into and out of local coordinate systems.

```
        mtxChild = mtxBranch;

        D3DXMatrixInverse( &mtxInverse, NULL, &mtxCombined );
        D3DXMatrixMultiply( &mtxBranch, &mtxBranch, &mtxInverse );

        // Store the parent relative matrix in the frame
        pNewFrame->TransformationMatrix = mtxBranch;
```

As you can see in the above code we invert the current combined parent frame matrix and multiply it with our current absolute matrix (mtxBranch), storing the parent relative result back into mtxBranch. This is the matrix we need, so we assign our new frame's TransformationMatrix pointer to point at it. Our new frame has now been attached to the hierarchy and has received the correct matrix.

Note that the first step we took was making a copy of the absolute frame matrix (mtxBranch) to a local variable (mtxChild) before we modify it to become relative. Why? Well, think about what the mtxCombined matrix that was passed into this function contains -- the absolute matrix of the parent. When we recur down into the child node of the current node and generate a child frame, we will need

the combined matrix passed into that function to be the absolute matrix of the current frame we have just generated. Therefore, mtxChild will contain the combined matrix of the parent when processing the child node.

At this point we have created the new frame, attached it to the hierarchy, and assigned it a parent relative transformation matrix. We have also stored a local copy of the absolute transformation for our new frame so that it can be passed down to a child as the mtxCombined parameter and used to generate its relative matrix. The pChildFrame local frame pointer stores the address of our newly created frame so that it can be passed into the children of this branch as the pParent parameter. So between the mtxChild and pChildFrame local variables, we are ready for the next level of recursion into the child node.

> **Note**: At this point, please remember that we are still inside the code block that is executed only if a new frame is to be generated at this node.

In the next section of code we need to determine two things. If the current node we have just created a frame for is of type BRANCH_START then we know that this represents the start of a new branch mesh. We also need to determine what mesh we are going to pass down to the child node in the recursion. As with the mtxChild and pChildFrame local variables, we use a local variable called pChildMesh to store the mesh we need to pass down the branch.

If we are at a branch start node, we will ignore the mesh parameter passed into the function and create a new CTriMesh. We assign the pChildMesh local pointer to point at this new mesh. This will be the mesh we pass in as the mesh parameter when BuildNode calls itself for the child nodes in this new branch. If this is not a branch start node, then no new mesh needs to be created; it is just another node in a branch mesh that is already under construction. In this case, the pMesh parameter passed into the function will contain the address of the mesh that this node should pass down to its child, and the mesh it should add vertices to.

```
        // We only start creating the 'skin' mesh if this is a beginning branch
        if ( pNode->Type == BRANCH_BEGIN )
        {
            // We're going to start building a mesh, so create a new one
            pNewMesh = new CTriMesh;
            if ( !pNewMesh ) return E_OUTOFMEMORY;

            // Setup the new mesh's vertex format
            pNewMesh->SetDataFormat( VERTEX_FVF, sizeof(USHORT) );

            // Update the mesh we will pass to the child with our new mesh
            pChildMesh = pNewMesh;

        } // End if BRANCH_BEGIN
        else
        {
            // Reuse the mesh we were passed.
            pChildMesh = pMesh;

        } // End if other branch node type
```

At this point, whether we have allocated a brand new mesh, or are simply continuing the process of adding vertices to the mesh passed in for a current branch, the pChildMesh pointer will point to the mesh into which we will add the ring of vertices for this node.

Luckily for us in the short term, we use the CTreeActor::AddBranchSegment function to accomplish this task. It is passed the current node and the mesh we wish to add another ring of vertices to. We will discuss the code for the AddBranchSegment function next. Suffice to say, when it returns, a new branch segment will have been added to the branch mesh.

```
        // Add the ring for this segment in this frame's combined space
        hRet = AddBranchSegment( pNode, pChildMesh );
        if ( FAILED(hRet) ) { if (pNewMesh) delete pNewMesh; return hRet; }

    } // End if adding new frame
```

The curly brace at the bottom of the above code closes the code block that we have been examining so far. This is the code block that is only executed if the current branch node we are processing is a node for which a bone must be created and added to the hierarchy.

The next section of code is the else block of that conditional. It is executed if we are processing a node that will not add another bone to the frame hierarchy. However, we must still add a ring of vertices since every node (not just bone nodes) represents part of the branch.

```
    else
    {
        // Store which bone we're assigned to in the node
        pNode->pBone = pParent;

        // Add the ring for this segment in this frame's combined space
        hRet = AddBranchSegment( pNode, pMesh );
        if ( FAILED(hRet) ) { return hRet; }

        // Since no new frame is generated here, the child will receive
        // the same frame, mesh and matrices that we were passed.
        pChildFrame = pParent;
        pChildMesh  = pMesh;
        mtxChild    = mtxCombined;

    } // End if continuing build of previous mesh
```

As you can see, we call the AddBranchSegment function to add a ring of vertices to the mesh for this node. Notice that we pass in the pMesh parameter which contains the pointer to the mesh that has been passed into this function by the node's parent. Also notice how we set the local variables that will become the parameters for the child recursion. pChildFrame is set to the pParent frame pointer passed in since no new frame has been created and the parent frame should be passed unmodified into the child. The only time we ever wish to change the parent frame is when a new frame is inserted into the hierarchy. Finally, we set the mtxChild matrix to absolute parent matrix (mtxCombined) passed into the function. Since the parent frame is unchanged, so too is its absolute transformation. Thus, all we are doing is taking the input mesh, parent frame, and parent matrix, and preparing them to be passed down to the child.

At this point, we will now process the sibling list if a sibling exists at the current node.

```
    // Build the nodes for child & sibling
    if ( pNode->Sibling )
    {
        hRet = BuildNode( pNode->Sibling, pParent, pMesh,
                          mtxCombined, pAllocate );

        if (FAILED(hRet)) { if ( pNewMesh ) delete pNewMesh; return hRet; }

    } // End if has sibling
```

The BuildNode function calls itself recursively for the sibling node. It passes in the same parent and parent matrix as the current node (all siblings share the same parent) as well as the mesh pointer that was passed into the function.

Because of the way we organized our branch node hierarchy, the node of a branch will always be at the head of a sibling list. All other branch nodes in that sibling list (if any exist) will begin new branches. Therefore, strictly speaking, the mesh we are passing into the sibling will never be used, because as soon as we step into a sibling it will be of type BRANCH_START. This means that it will allocate its own CTriMesh for that branch and pass it down to each of its own children. However, just to safeguard against the fact that the application may have changed the order of the sibling list, we pass it the mesh. If a non-BRANCH_START node were it to exist somewhere in the sibling list, our code would still handle it correctly. The important thing to realize at this point is that when the above function call returns, all child branches that start at this node will have been *fully* built. Each sibling branch will have been traversed and created and so too will have any child branches of those child branches, and so on.

We still need to step though the remaining nodes of the current branch, so we issue the recursive call to the child pointer.

```
    if ( pNode->Child )
    {
        hRet = BuildNode( pNode->Child, pChildFrame, pChildMesh,
                          mtxChild, pAllocate );

        if (FAILED(hRet)) { if ( pNewMesh ) delete pNewMesh; return hRet; }

    } // End if has child
```

Notice this time that when we step into the child node, we pass in the pChildFrame, pChildMesh, and mtxChild local variables. What these variables store depends on whether a new frame and mesh was created at this node. Below we clarify what these variables will hold depending on the status of the current node:

Current Node = BRANCH_BEGIN node
pChildFrame = New frame added in this function
pChildMesh = New Mesh allocated in this function
mtxChild = Absolute matrix of the frame added in this function

Current Node = Normal Node (New Bone Node)
pChildFrame = New frame added in this function
pChildMesh = pMesh passed into this function from parent (pMesh)
mtxChild = Absolute matrix of the frame added in this function

Current Node = Normal Node (Non Bone Node)
pChildFrame = Parent frame passed into this function (pParent)
pChildMesh = pMesh passed into this function from parent (pMesh)
mtxChild = Absolute matrix of the frame added in this function (mtxCombined)

When the call to the child node returns, every remaining child node in the current branch will have been visited and will have added their rings of vertices to the mesh.

If the current node is not a BRANCH_BEGIN node then we have nothing left to do in this function. However, if the current node was a BRANCH_BEGIN node, then the CTriMesh for this branch will have had all the required vertices and indices added to it. It is then time to build the underlying ID3DXMesh and pass it to CAllocateHierarchy::CreateMeshContainer to have it converted to a skinned mesh. We will attach the returned mesh container to the branch start frame in the hierarchy.

```
    // If this was a 'begin' node, we can now build the mesh container
    // since all of the mesh segments should have been created by the
    // recursive calls.
    if ( pNode->Type == BRANCH_BEGIN )
    {
        D3DXMATERIAL        Material;
        D3DXMESHDATA        MeshData;
        D3DXMESHCONTAINER * pNewContainer       = NULL;
        DWORD             * pAdjacency          = NULL;
        LPD3DXBUFFER        pAdjacencyBuffer    = NULL;
        LPD3DXSKININFO      pSkinInfo           = NULL;

        // Generate mesh containers name
        _stprintf( strName, _T("Mesh_%i"), pNode->UID );

        // Generate the skin info for this branch
        hRet = BuildSkinInfo( pNode, pNewMesh &pSkinInfo );

        if ( FAILED(hRet) ) { delete pNewMesh; return hRet; }

        // Signal that CTriMesh should now build the mesh in software.
        pNewMesh->BuildMesh( D3DXMESH_MANAGED, m_pD3DDevice );
```

The first thing we do is call the CTreeActor::BuildSkinInfo function. We will look at this function shortly, but for now just know that it will create a new ID3DXSkinInfo object and will fill it with the vertex/bone mapping data. When the function returns, the pSkinInfo local variable will contain a pointer to the interface of this object. After building the skin info, we call CTriMesh::BuildMesh so that the vertices and indices we have been adding to the mesh (via the AddBranchSegment function) are used to construct the ID3DXMesh.

With our regular mesh now complete, we need to send it into the CreateMeshContainer function wrapped inside a D3DXMESHDATA structure. We set the Type member of the D3DXMESHDATA member to D3DXMESHTYPE_MESH so that the mesh container knows it is being given a regular ID3DXMesh.

```
        // Build the mesh data structure
        ZeroMemory( &MeshData, sizeof(D3DXMESHDATA) );
        MeshData.Type  = D3DXMESHTYPE_MESH;

        // Store a reference to our build mesh.
        // Note: This will call AddRef on the mesh itself.
        MeshData.pMesh = pNewMesh->GetMesh();

        // Build material data for this tree
        Material.pTextureFilename = m_strTexture;
        Material.MatD3D           = m_Material;
```

The CreateMeshContainer function also expects to be passed the texture filename and material for each subset. For our tree mesh, we have only one subset so we set up a single D3DXMATERIAL structure to store the texture filename and the material that the application set for the CTreeActor (via SetBranchMaterial).

Finally, before calling CreateMeshContainer we calculate the adjacency information for the mesh we are about to pass. We use the CTriMesh::GenerateAdjacency function, which generates the adjacency information and stores it internally inside an ID3DXBuffer object. We then call CTriMesh::GetAdjacencyBuffer which returns a pointer to its ID3DXBuffer interface and follow that with a call to ID3DXBuffer::GetBufferPointer to get a pointer to the actual adjacency information. We pass all this information into the CreateMeshContainer function which then creates a new skinned mesh (using the appropriate supported skinning method) and returns the results in the pNewContainer pointer passed in as the final parameter.

```
        // Retrieve adjacency information
        pNewMesh->GenerateAdjacency( );
        pAdjacencyBuffer = pNewMesh->GetAdjacencyBuffer();
        pAdjacency       = (DWORD*)pAdjacencyBuffer->GetBufferPointer();

        // Create the new mesh container
        hRet = pAllocate->CreateMeshContainer( strName,
                                               &MeshData,
                                               &Material,
                                               NULL,
                                               1,
                                               pAdjacency,
                                               pSkinInfo,
                                               &pNewContainer );

        // Release adjacency buffer
        pAdjacencyBuffer->Release();

        // Release the mesh we referenced
        MeshData.pMesh->Release();
```

```
        // Release the skin info
        if (pSkinInfo) pSkinInfo->Release();

        // Destroy our temporary child mesh
        delete pNewMesh;

        // If the mesh container creation failed, bail!
        if ( FAILED(hRet) ) return hRet;

        // Store the new mesh container in the frame
        pNewFrame->pMeshContainer = pNewContainer;

    } // End if beginning of branch

    // Success!!
    return D3D_OK;

}
```

When CreateMeshContainer returns, this branch will have been created as a skinned mesh and attached to a mesh container. We can then delete the original CTriMesh and the adjacency buffer before assigning the BRANCH_BEGIN frame's pMeshContainer pointer to our newly generated mesh container (which stores our branch skin).

While this was quite a complex function, remember that it is responsible for the entire hierarchy and mesh building process. When the initial instance of the function (called from BuildFrameHierarchy) returns the actor's hierarchy will be complete.

It is now time to look at the helper functions that were called from BuildNode to assist in accomplishing its required tasks. The first function we will look at is the AddBranchSegment method.

AddBranchSegment – CTreeActor

This method is passed a branch node and a pointer to a CTriMesh and it has two tasks it must perform. It must add the ring of vertices to the mesh that this node represents and it must add the indices to the mesh which connect vertices of the parent node to the vertices of the current node. This is how we form our cylinder (a branch segment) faces between the two nodes.

Things are not quite a simple as they first seem because the position of the node and the orientation of its vectors are defined in tree space. All node positions are relative to the root node of the virtual tree and therefore we might say that the node's positions and orientations are specified absolutely throughout the tree. The problem we must overcome is that each branch will be a separate mesh and we are going to want our vertex positions defined in the mesh's model space.

In the case of a branch mesh, we should consider the root node of that branch to be the origin of model space. Therefore, we want the vertex positions we add to this mesh to be defined relative to the root node of the branch, not to the root node of the entire tree. Essentially, we need to drag the root node of a

branch back to the origin of the coordinate system (dragging all its child nodes with it) so that the start node of the branch is at (0,0,0) and its local axes are aligned with the X,Y, and Z axes of the coordinate system. If we can do that, then we will have the positions and orientations of all its child nodes (in the same branch) defined in mesh/model relative space. In model space then, the start node of a branch is at the origin and all vertices are defined relative to the bottom of that branch (instead of the center of the branch which is often more typical).

Let us look at the code one section at a time.

```
HRESULT CTreeActor::AddBranchSegment( BranchNode * pNode, CTriMesh * pMesh )
{
    ULONG       i;
    USHORT      j, Index;
    D3DXMATRIX  mtxInverse, mtxRot, mtxBranch;
    D3DXVECTOR3 vecPos, vecAxis, vecRight, vecOrtho, vecNormal, vecVertexPos;
    D3DXVECTOR3 vecX, vecY, vecZ;

    // Back track until we find the beginning node for this branch
    BranchNode * pStartNode = pNode;

    while ( pStartNode->Type != BRANCH_BEGIN && pStartNode )
            pStartNode = pStartNode->Parent;

    if ( !pStartNode ) return D3DERR_INVALIDCALL;
```

In the first section of the code, we need to backtrack from the current node (which may not be a branch start node) to find the start of its branch. We will need access to this branch start node so that we can build a matrix that will transform the current node we are processing from tree space into model/branch space. As you can see in the above code, we simply start at the current node and use the pStartNode pointer to climb up through the parents of each node until we hit the start branch (a branch of type BRANCH_BEGIN). We now have the branch start node stored in pStartNode and the current node we wish to build a ring of vertices for stored in pNode.

Once we have the branch start node, we want to build a matrix for it like we did before. We perform the cross product on the right and direction vectors of the start node to get the third axis of the coordinate system. We then store the three axis vectors of the start node in a matrix along with its position.

```
    // Store / generate the vectors used to build the branch matrix
    vecX = pStartNode->Right;
    vecZ = pStartNode->Direction;
    D3DXVec3Cross( &vecY, &vecZ, &vecX );

    // Generate the frame matrix for this branch
    D3DXMatrixIdentity( &mtxBranch );
    mtxBranch._11 = vecX.x; mtxBranch._12 = vecX.y; mtxBranch._13 = vecX.z;
    mtxBranch._21 = vecY.x; mtxBranch._22 = vecY.y; mtxBranch._23 = vecY.z;
    mtxBranch._31 = vecZ.x; mtxBranch._32 = vecZ.y; mtxBranch._33 = vecZ.z;
    mtxBranch._41 = pStartNode->Position.x;
    mtxBranch._42 = pStartNode->Position.y;
    mtxBranch._43 = pStartNode->Position.z;
```

We now have a matrix (mtxBranch) that describes the position and orientation of the local axis of the branch start node relative to the origin of tree space. For example, if we place a vertex at the origin of the coordinate system and then multiplied it by this matrix, we would transform that vertex out to the position of the branch start node.

What we want is a matrix that does the exact opposite. We want a matrix that will undo the transformation of the branch start node from any vector we multiply with it. For example, if the branch start node was positioned at 100 units along the X axis and we have a vertex positioned at 110, we want a matrix that will subtract the branch start node from the position (and orientation) of the vector. If M was our desired matrix and V was our vector, V*M should equal 10. In other words, we need to know the position of the current node we are about to process as an offset from the branch start position. Likewise, we will also want to know the orientation of the current node's direction and right vectors as rotational offsets from the branch start node's direction and right vectors. Of course we have seen this all before. What we are saying here is that we want our current node defined in the local space of the branch start node. And as we learned back in Module I (and mentioned again earlier in the lesson), multiplication by the inverse of the matrix will do the trick.

```
    // Get the inverse matrix, to bring the node back into the frame's space
    D3DXMatrixInverse( &mtxInverse, NULL, &mtxBranch );
```

Now that we have this matrix what will we use it for?

We need to create a ring of vertices and place them on a plane described by the current node. This is a plane where pNode->Direction (made unit length) would describe its normal. We will see how we place the vertices on this plane in a moment, but for now just know that we will need the direction vector, the right vector and a vector orthogonal to the them both in order to slide the vertices from the node center point out to their correct positions on the plane. However, as we wish the vertices to be placed in model space and not in tree space, it stands to reason that both the current node's position and its local axis vectors (direction and right vector) which will be used to position the vertices, should also be transformed into model space (start branch relative space) prior to being used to position those vertices

In the next section of code we transform the current node's direction and right vectors into model space using the inverse matrix. We then store them in the local variables vecAxis and vecRight, respectively. We also transform the node's position into model space and store it in the vecPos local variable.

```
    // Build the axis in the frame's space
    D3DXVec3TransformNormal( &vecAxis, &pNode->Direction, &mtxInverse );
    D3DXVec3TransformNormal( &vecRight, &pNode->Right, &mtxInverse );
    D3DXVec3TransformCoord ( &vecPos, &pNode->Position, &mtxInverse );
```

To understand what we have just done take a look at Figure 12.40. The figure shows an arbitrary branch defined somewhere in the tree. Concentrate on just the first two nodes (N and N+1) which show the first two nodes of the branch as defined in tree space (prior to the transform we have just performed). Notice the green arrows at the two nodes showing the direction vector at each node prior to transformation.

In Figure 12.40, the blue lines indicate the planes defined by the nodes in tree space. The green arrows show the direction vector of each node, which essentially describes the normal of those planes. In this example, the first node in the branch is not assumed to be the root of the entire tree but is instead assumed to be a child of some other parent branch.

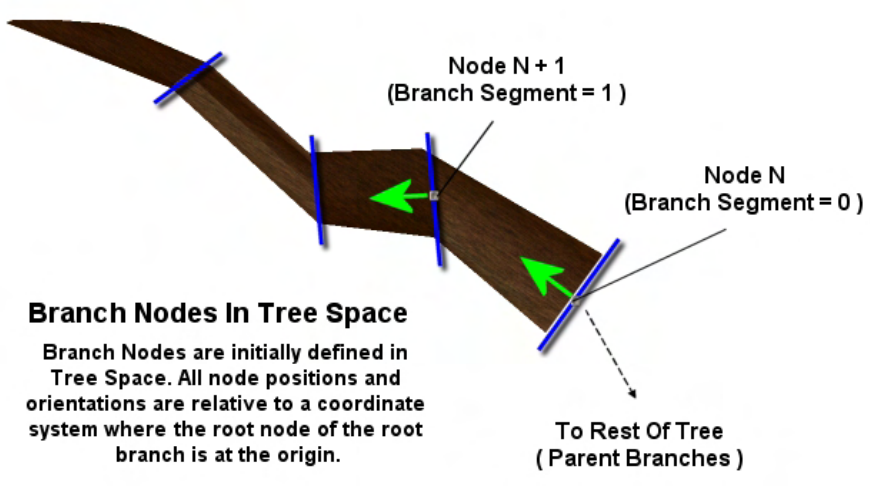

Figure 12.40 : Branch In Tree Space

In tree space, the position of each node is relative to the origin of the tree. So the position of the branch start node will not be (0,0,0) and thus is not the origin of the coordinate system. As discussed earlier, this needs to be rectified because we are going to want our children (and the vertices they represent) to be defined in the local space of the branch start node. So by applying the inverse matrix of the branch start node that we have just created to the position and orientation vectors of the current node we wish to add vertices for, we move the position and orientation of the node into the coordinate space defined by the branch start node. In Figure 12.41 you can see how all the nodes for the branch shown above look once transformed into mesh local (i.e., model) space.

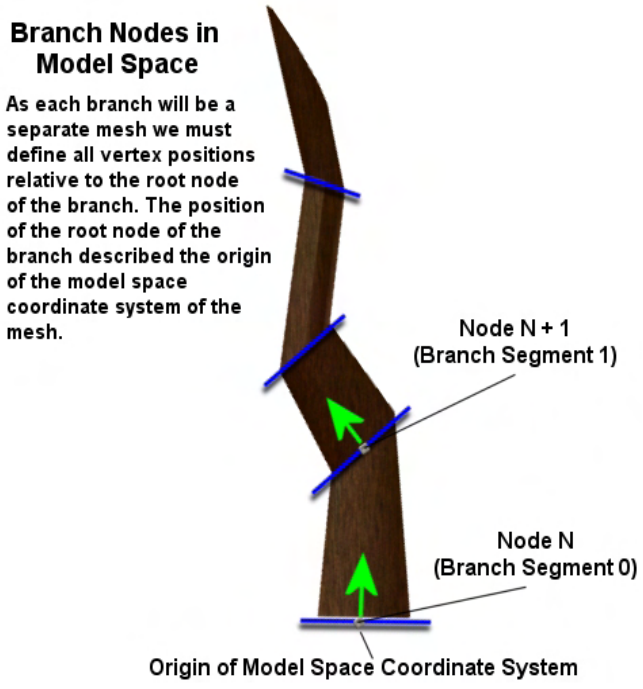

Figure 12.41 : Branch Nodes in Model Space

As you can see, in model space the nodes of the branch represent a unique mesh. The direction and right vectors of the branch start node form the Z and X axes of the coordinate system and the tree space position of the branch start node is mapped to the origin of the coordinate system.

Notice how the orientations and direction vectors in each node have changed. Yet while very different from their tree space counterparts, they still maintain the same inter-branch relationship.

It is the direction and right vector of the current node in this space which should be used to position the ring of vertices on the model space plane defined by each node. After all, when we created the start node for this branch we would have also added a frame to the actor's hierarchy. Remember, it is the frame matrices in the hierarchy that are responsible for ultimately transforming this model space branch into its proper tree space position at render time.

At this point, we now have the direction vector and the right vector of the current node in model space. The direction vector describes the normal of the plane on which the vertices should be added and the right vector is tangent to the plane (it lies on the plane). In order to position our vertices on this plane we will also need an additional tangent vector (often referred to as a binormal). If you imagine you are staring at a clock (with hands) that is currently showing 3 o'clock, think of the direction vector as an arrow coming out of the center of the clock pointing right at you. Now imagine that the little hand that is on the 3 is the right vector of the node. Finally, the binormal would be the big hand of the clock pointing at the 12 in this particular case.

If we have two tangent vectors, we have the ability to place vertices anywhere on that plane by combining those vectors and scaling. This should not surprise you since we are basically talking about a standard Cartesian XY plane here (where the direction vector is the Z axis). The X axis (1,0,0) and a Y axis (0,1,0) are both tangent vectors for the XY plane and they allow us to position vertices anywhere on that plane. If we want to place a point at position (40, 50) on the XY plane, we think of this as describing a point 40 units along the X axis and 50 units along the Y axis. However, what we are really saying is this:

Position X = 40 * (1, 0, 0) = (40, 0, 0)
+
Position Y = 50 * (0, 1, 0) = (0, 50, 0)
=
Position XY = (40, 50, 0)

This is a more mathematically correct way of thinking about what happens when we plot a coordinate. The reason we get the expected results is that our transformation matrices store an X axis and a Y axis with a length of 1.0 (unit length). But if our transformation matrix stored X and Y axis vectors with a length of 3.0 instead, the final position plotted on that plane is obviously entirely different:

Position X = 40 * (3, 0 ,0) = (120 , 0 , 0)
+
Position Y = 50 * (0, 3, 0) = (0, 150, 0)
=
Position XY = (120, 150, 0)

This is the mathematics of linear transformations and vector spaces. We do not need to get much more technical here in this course since we expect that you will cover such material in the Game Mathematics course. If you have not done so already, you should get used to viewing transformations in this way.

The point of this exercise was to demonstrate that if we have two unit length tangent vectors, we can use them to plot any point on the plane they define. When we position our vertices on the plane of the node, we will not be using the usual X and Y axis vectors as shown above. The plane of the node may be rotated and/or tilted in model space, so we will use the tangent vectors instead.

At the moment we currently have one tangent vector -- the node's right vector. We can think of this as the node's local X axis. We need a local Y axis also so that we can use these two vectors to position the ring of vertices on the plane.

Calculating this vector is easy and you should already know how to do it. The right vector is tangent to the plane and that the direction vector is perpendicular to the plane. The other tangent vector we wish to create should be orthogonal to these two, so all we have to do is rotate the model space right vector around the model space direction vector by 90 degrees and we have our second tangent vector (the binormal). This is shown in Figure 12.42.

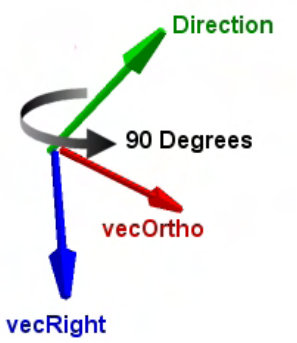

Figure 12.42

So let us build our node's third model space axis next:

```
    // Build the ortho vector which we use for our Y dimension axis
    D3DXMatrixRotationAxis( &mtxRot, &vecAxis, D3DXToRadian( 90.0f ) );
    D3DXVec3TransformNormal( &vecOrtho, &vecRight, &mtxRot );
```

We now have the node position and its local axis in model space so it is time to start adding our vertices. The second section of the function is divided into two code blocks. The first is executed only if the current node is not of type BRANCH_END. It adds a ring of vertices on the model space node plane and adds the indices to the mesh to stitch them into faces with the previous node's ring of vertices. The second code block is executed only if we are currently processing the BRANCH_END node. When this is the case, only a single vertex is added at the node position (not a ring) and the indices are added to stitch this final vertex into faces using the previous node's ring of vertices. The end result is the branch tip.

Let us first have a look at the code block that is executed for nodes that are not BRANCH_END nodes (adding rings).

```
    // If this is a beginning / segment node
    if ( pNode->Type != BRANCH_END )
    {
        // Add enough vertices for the new branch segment
        long VIndex = pMesh->AddVertex( m_Properties.Branch_Resolution );

        // Generate the vertices
        for ( i = 0; i < m_Properties.Branch_Resolution; ++i )
        {
            CVertex * pVertex = &((CVertex*)pMesh->GetVertices())[ VIndex + i ];

            // Calculate angle of rotation ((Branch_Resolution - 1)
            // because we are duplicating one vertex at the seam)
```

```
            float fAngle =
            D3DXToRadian( (360.0f / (float)(m_Properties.Branch_Resolution - 1))
                          * -(float)i );

            // Plot the points for our 'elliptical' branch hull
            float x = pNode->Dimensions.x * cosf( fAngle );
            float y = pNode->Dimensions.y * sinf( fAngle );
```

In the above code, we first tell the mesh that we are about to add a ring of vertices so that it can make room for those vertices at the end of its internal vertex arrays. We do this using the CTriMesh::AddVertex method and pass the number of new vertices we wish to make space for. The number of vertices that will be used to form a ring is stored in the Branch_Resolution member of the growth properties structure (8 by default). The AddVertex method returns the index (VIndex) of the first vertex in the array of vertices we have just added.

We then entered a loop which iterates through each vertex we wish to add and allows us to calculate the position of each new vertex in the ring one at a time. Inside the loop you can see that we retrieve a pointer to the vertex structure whose position and normal we will need to set. Notice how we use the base index of the first new vertex we allocated (VIndex) and add that onto that loop variable 'i' to allow us to step through each of the new vertices.

The next thing we did was calculate a delta angle (fAngle). If we have 8 vertices to place (e.g., Branch_Resolution = 8), then we need to step around the model space position of the node and position vertices in a circle at uniform intervals. As the first and last vertices have duplicated positions for the wrap around, we need to step around a 360 degree circle in increments of (360 / Branch_Resolution - 1). Using the default branch resolution of 8, this means for each iteration of the loop, we will need to step around the circle surrounding the node a further 360/7 = 51.42 degrees and place another vertex.

As 51.42 degrees describes the size of single wedge formed by two adjacent vertices in the ring (with the center point as the apex of the wedge), we can multiply this value with the current loop iteration variable 'i' so we know exactly where we need to place the vertex. For example, in the first three iterations of the loop, fAngle would equal the following:

Iteration 1 : 51.42*0 = 0 (Vertex placed at zero degrees about circle)
Iteration 2 : 51.42*1 = 51.42 (Vertex placed at 51.42 degrees about circle)
Iteration 3 : 51.42*2 = 102.84 (Vertex placed at 102.84 degrees about circle)

Once we have the rotation angle for the current vertex, we can calculate a position on the circumference of the ellipse with the help of the sine and cosine functions. As we know, the sine and cosine functions are 90 degrees apart, so if we wish to place a point on a circle with a radius R at rotation angle A, we calculate the X and Y coordinates of that point as:

X Position = R * cosine (A)
+
Y Position = R * sine (A)
=
(X Position , Y Position , 0)

Notice that we are ignoring the Z coordinate for the moment since we are essentially defining a 2D circle on a plane. At this particular point in time, that plane is actually the XY plane of the model space coordinate system. The circle will also be defined about the origin of the coordinate system at this point.

In our code however, the node's Dimensions.X and Dimenions.Y members define the radii of the ellipse. (If these two members are equal then we define a circle.), Since the X radius may be different from the Y radius, this turns our calculation into:

X Position = pNode->Dimensions.x * cosine (A)
+
Y Position = pNode->Dimensions.y * sine (A)
=
(X Position , Y Position , 0)

Since the cosine and sine are 90 degrees apart, they allow us to apply scaling factors to the X and Y dimensions such that the final result will always lie on the circumference of the ellipse. For example, if the angle is 0 degrees (first iteration) then the cosine will return 0 and the sign will return 1. This will result in a first vertex position of:

(pNode->Dimensions.x , 0 , 0)

The start of the circle is not the top but actually the position of the number 3 in the clock face example (along the X axis). However, at 90 degrees, the cosine returns 0 and the sine returns 1, which results in a final vector at the top of the circle:

(0 , pNode->Dimensions.y , 0)

At 45 degrees the angle is equidistant from both the X and Y axis and the result of both will be ~0.707106. In this instance we are scaling both the X and Y radii of the ellipse to produce a point that is between both axes, but still the correct distance from the circle center point (on the circumference of the circle).

If we imagine that we are calculating the position of a vertex at 45 degrees around the circle of a node that has both an x and y dimension of 1, this will result in the following X and Y coordinates:

X Position = 1 * 0.707106
+
Y Position = 1 * 0.707106
=
(0.707106 , 0.707106 , 0)

As you can see, this is exactly the same vector you would get if you normalized the vector (1, 1, 0), which we know would result in a 45 degree vector describing a position that is halfway between the X and Y axes but still has a length of one.

At the moment we are simply defining the positions of each vertex as if it was being projected onto the XY plane of the model space coordinate system. The center of the circle would be the coordinate system origin. Although we process each vertex one at a time, if we were to imagine the positions of every vertex in the ring at this point in the loop, we would see a result like Figure 12.43.

As Figure 12.43 shows, the dimensions of the current node define the radius of the ring of vertices around its center point. However, at the moment, the vertex positions are not defined relative to the node's plane. That is to say, the center of this circle is currently (0,0,0) and not the node's model space position. Furthermore, the vertices currently lay flat on the XY plane of the coordinate system and not the plane of the current node.

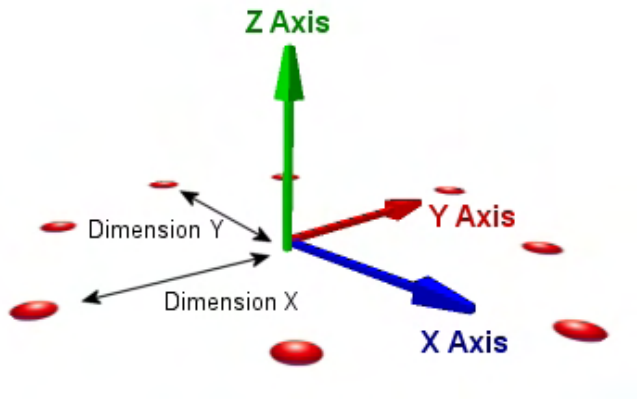

Figure 12.43 : Circle of Vertices in model space

The first thing we must do now that we have our vertex position defined with respect to the center of the ellipse is position that vertex on the node plane. The thing to remember is that the node plane may be oriented quite differently from the XY plane of the model space coordinate system. It will most likely be rotated and/or tilted in some way. So given a vertex position on the XY plane of the model space coordinate system, how do we place it in its corresponding position on another plane with a totally different orientation?

A little while ago, we said that when we specify a coordinate in a Cartesian coordinate system, we are really stating that these components should be multiplied with the X, Y, and Z axes of the coordinate system in which we are trying to plot them. Because we usually mean to plot such points in a coordinate system with the axes (1,0,0), (0,1,0) and (0,0,1), the resulting multiplication with each axis does not alter the input position of the vector. Therefore, while there was no need to perform the calculation explicitly, mathematically speaking, we calculated the position of our vertex as follows:

X Position = pNode->Dimensions.x * cosine (A)) * (1,0,0)
+
Y Position = pNode->Dimensions.y * sine (A)) * (0,1,0)
=
(X Position , Y Position , 0)

Of course, the result is the same, so there was no need to supply the additional model space axis multiplications on the end. However, Figure 12.45 shows how we might want the circle of vertices to look on the actual node plane. Remember it may be tilted or rotated with respect to the XY plane of the coordinate system shown in Figure 12.44.

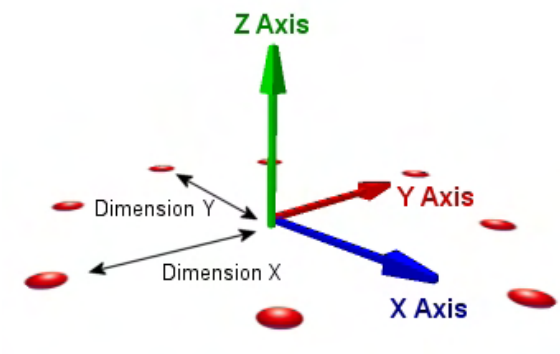

Figure 12.44 : Vertices multiplied by Model Space X and Y axis

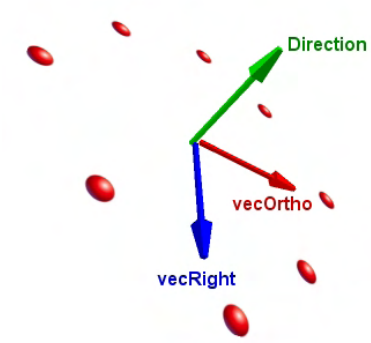

Figure 12.45 : Vertices multiplied by node tangent vectors

So let us piece together some of what we already know. When we positioned the vertices on the XY plane of the coordinate system, we were actually multiplying the X and Y position with the X and Y axes of the coordinate system shown in figure 12.44. We did not have to perform this calculation explicitly and the lack of such a calculation means that it was implied.

In Figure 12.45 we see that our node plane also has its own X and Y axes which are tangent to the plane (vecRight and vecOrtho). Therefore, all we have to do is multiply the vertex position that is currently on the model space XY plane with the node's local axes and we can move each vertex onto the plane.

```
            // Set and scale the vertex position based on the chosen dimension.
            vecVertexPos = (vecRight * x) + (vecOrtho * y);

            // Generate our normal from this position
            D3DXVec3Normalize( &vecNormal, &vecVertexPos );
```

As you can see, we multiply the node's right vector (X axis) with the vertex X position and the node's other tangent vector (the Y axis) with the vertex Y position and then sum the resulting vectors.

At this point, the plane the vertex is on is not really the node plane; it is just has the same orientation as the node plane. It still passes through the origin of the coordinate system (it has a distance of zero). In a moment we can fix this by simply adding the model space position of the node to the vertex position to move it into place on the node plane.

But before we do this, notice that in the above code we calculate a normal for the vertex simply by taking the position of the vertex and normalizing it. Remember, at this point, although we have oriented the plane (and its vertices) the origin of the coordinate system is still the center of the ellipse. Therefore, the vertex position itself represents a vector from the center of that circle out to the vertex.

Figure 12.46 illustrates this concept for a single vertex defined on the oriented plane with the origin of the coordinate system still at the center of the circle.

The black arrow pointing from the center of the circle is the vector that is represented by the vertex position at this time. If we normalize this vector, it actually serves as a fairly good vertex normal for our purposes. After the mesh is complete, if you prefer, you could do an averaging sweep through the mesh such that the vertex normal is actually the average of both the face normals to the left and right of it. Actually, most vertices will belong to four faces as it will form the top row of vertices for one cylinder and the bottom row of vertices for the next cylinder. However, we do not perform this averaging step and simply use this normal 'as is' which seems to give fairly good results when lighting the tree.

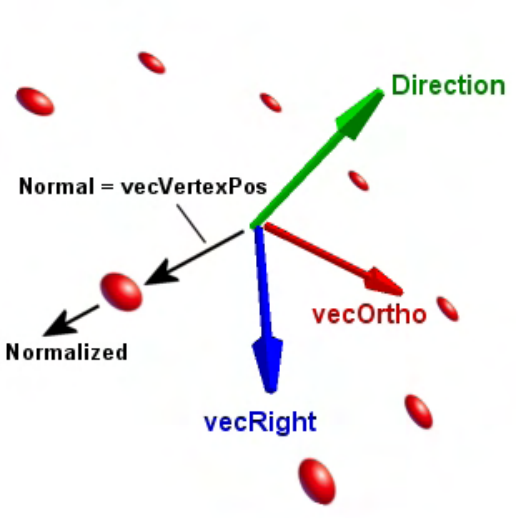

Figure 12.46 :
Normalized Vertex Pos = Vertex Normal

As mentioned, the vertex is oriented on the plane correctly but the center of the circle is still the origin of the coordinate system, not the node position. That is easily fixed by adding our current vertex position and the position of the node and storing the result (along with the normal) in our vertex structure.

```
            // Push out to it's final position, relative to the branch node
            vecVertexPos += vecPos;

            // Store the values in the vertex
            pVertex->x = vecVertexPos.x;
            pVertex->y = vecVertexPos.y;
            pVertex->z = vecVertexPos.z;

            // Store the vertex normal
            pVertex->Normal = vecNormal;
```

Before finishing this vertex we have to assign it a pair of UV texture coordinates. We discussed the technique used for UV calculation earlier in this lesson. The U coordinate is assigned a position across the width of the texture which is a product of the vertex index 'i' within the ring divided by the total number of vertices comprising a ring. This assures that vertex[0] in the ring is mapped to a U coordinate of [0] and vertex [N] is mapped to a U coordinate of 1.0 (where N is the branch resolution). All other vertices between the start and end vertices of the ring will be uniformly mapped across the width of the texture. We also scale the final result by the Texture_Scale_U growth property to allow tiling and/or texture sizing. If left at 1.0, the width of the texture will be wrapped around the cylinder/branch segment once.

Notice that we use Branch_Resolution - 1 because the first and last vertices are in the same position. We want the first vertex to have a U coordinate of 0.0 and the last vertex to have a U coordinate of 1.0 even though they are at the same position in the ring. If we do not, our mapping will be incorrect in the area between the last and first vertex. For example, if we had a ring of 10 vertices where each had its own unique position in the ring (no duplicates), the U coordinates assigned to the last two vertices would be

0.9 and 1.0. We can see that when mapping the face between the last two vertices, the texture would have its final $1/10^{th}$ (the interval 0.9 to 1.0) copied between vertices 9 and 10 in the ring. This is absolutely correct. However, when the texture is mapped to the final face in the ring between vertex 10 and vertex 1 (to wrap around) we would be mapping between a vertex with a texture coordinate of 1.0 and the first vertex with a texture coordinate of 0.0 which gives us a mapping interval of 1.0 - 0.0. In other words, the entire width of the texture (in reverse) would be mapped into the space between the last and first vertex.

By duplicating the first and last vertex positions and assigning them different texture coordinates, we can rest assured that we have two U texture coordinates at that initial vertex position in the ring. For the first two vertices in the ring in our current example the U interval would be 0.0 – 0.1 and for the last the two vertices the interval would be 0.9 - 1.0 (instead of 1.0 - 0.0 which would otherwise be the case if the first vertex was used to complete the last face).

```
            // Generate texture coordinates
            pVertex->tu = ((float)i / (float)(m_Properties.Branch_Resolution - 1))
                            * m_Properties.Texture_Scale_U;

            if ( !pNode->Parent )
                pVertex->tv = 0.0f;
            else
                pVertex->tv = ((float)(pNode->Iteration + 1) /
                               (float)m_Properties.Max_Iteration_Count)
                                    * m_Properties.Texture_Scale_V;

        } // Next Vertex
```

Notice when calculating the V coordinate, if the current node has no parent then it is simply set to 0 (the bottom/top of the texture). Remember from our earlier discussion that unlike the U coordinate, the V coordinate is not local to the ring. In fact, when the Texture_Scale_V growth property is at its default value of 1.0, the height of the texture is mapped to the entire height of the tree. Thus, its level in the virtual tree hierarchy determines the node's V texture coordinate. This is just a simple case of dividing the node's iteration (depth in the hierarchy) by the maximum iteration (maximum depth of the hierarchy) to map its iteration into the 0.0 to 1.0 range. Notice that we actually use Iteration + 1. This is because (as discussed earlier) the first two levels of the branch node hierarchy have the same iteration of zero. As the first iteration will have no parent and will always be assigned a V value of 0 in the above code, we want the second node to be 1 not 0, and the third node to be 2 not 1, and so on.

And there we have it. We have now positioned all the vertices in the ring for this node, assigned them normals and texture coordinates, and added this information to the CTriMesh.

Unfortunately, our work is still not done. We still have to add indices to the mesh also so that we form a band of triangles that join all the vertices in the ring we have just added with the vertices added by the parent node (in a previous AddSegment call). Of course, we only perform this step if the current node is not a BRANCH_BEGIN node, as this would mean we would have only added one ring/row of vertices. We need at least two rings of vertices to create a branch segment, so the following code will only be executed for the second node and beyond in a given branch. Therefore, if the current node is a BRANCH_BEGIN node, we would have nothing left to do in this function.

Let us have a look at the code block that starts to add the indices to the mesh.

```
        // If this is not the start of a new branch, add indices
        if ( pNode->Type != BRANCH_BEGIN )
        {
            ULONG FaceIndex=pMesh->AddFace((m_Properties.Branch_Resolution-1)*2);
```

The first thing we do is call the CTriMesh::AddFace method to reserve space to add indices to the mesh's indices array. Two rings of N vertices allow us to create N-1 quads because there are N-1 pairs of vertices in an N vertex ring with which to form the base of a quad. We also know that if we have two rows of vertices with 8 vertices in each, then by stepping around the ring of vertices a vertex at a time and using two vertices from each ring, we could construct 7 quads to form the hull of the cylinder segment. Furthermore, as each quad would need to be constructed from 2 triangles, we know that with a default branch resolution of 8 we would need to create 7*2=14 triangles to wrap a ring of faces around our rings of vertices and form another branch segment.

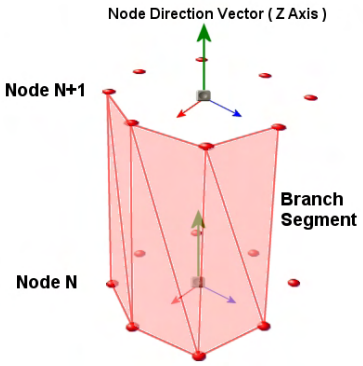

Figure 12.47

In Figure 12.47 we see two rings of vertices with a branch resolution of 8 (which actually creates 8 unique vertex positions that can be seen). While we have not filled in all the faces, you should be able to fill in the blanks yourself and see that in this case we would need to allocate space for 8*2 = 16 triangles. Node N+1 is actually the current node that we are processing and Node N is the ring of vertices that was added to the mesh when the previous/parent node was processed.

Remember that the CTriMesh::AddFace method returns the index of the first face in the array of new triangles that have been added to the mesh. We can use the CTriMesh::GetFaces method to get a pointer to the indices array and offset a pointer to the first new index we just allocated and now must populate. For example, let us assume we have just added 16 faces to the mesh (via the above call) and it returned us a face index of 80. This means that face 80 in the mesh is the first face of the 16 that we just allocated in the face array (80 have been added in previous function calls). Therefore, faces 80 through 95 will be the faces that represent the segment we are about to add.

Although we can use the CTriMesh::GetFaces method to fetch a pointer to the indices array, we only want to alter the indices used by faces 80 through 95. That is no problem since we already know the index of the first new face we added. Since all faces are triangles with three vertices, we just have to make our index pointer offset (80 * 3) into the array in this example. That is exactly why CTriMesh::GetFaces returns that useful 'first new face' index.

```
            // Retrieve the face index array
            USHORT * pIndices = &((USHORT*)pMesh->GetFaces())[FaceIndex * 3];

            USHORT Row1 = (pNode->Parent) ? pNode->Parent->VertexStart : 0;
            USHORT Row2 = (USHORT)VIndex;

            // Store this nodes vertex start
            pNode->VertexStart = Row2
```

What are the Row1 and Row2 locals doing in the above code? We need to access two rings of vertices in order to build this new branch segment. We need to know the indices for the vertices we have just added for the current node's ring as well as the indices of the parent node's ring so that we can stitch them together to make faces. Earlier in the function when we called CTriMesh::AddVertex to make room for our ring of vertices at the current node we were returned VIndex. VIndex describes the start location (first vertex) in our mesh's vertex array for the ring of vertices we have just added. This will be the second row of vertices that will form the top of the branch segment we are about to create. Notice in the above code how the node also stores the index of the first vertex used by this ring. When another branch segment is added to this branch, when we visit the child node, we can simply fetch this value from the parent node to know where its vertices start. You see this happening in the calculation of Row1 in the above code.

If the current node we are processing has no parent, then this is the first segment we have added (second node of the entire tree) and we know that the vertices for the previous node (the branch begin) must start at zero. If it does have a parent node then we fetch the index at which its vertices start in the current mesh (via its VertexStart member). As this code is only executed when we are not processing a branch start node, the VertexStart member for a branch start node will be left at its default value of zero. This is as it should be, because for any individual branch, its first ring of vertices will be created from the branch start node and will be at the very beginning of its vertex buffer.

At this point, we have an index telling us where the parent node's ring of vertices start in the vertex array and an index telling us where the current node's vertices have been added in that same array. All that is left to do now is loop around the ring of vertices and add the indices of the triangle. With each iteration of this loop we will add a quad to the index buffer (i.e., two triangles, 6 indices). Since pIndices currently points to the position in the mesh's index array where we want to start adding this index data, we can simply increment a counter variable (Index) by 6 during each iteration of the loop.

Hopefully, the following code will make sense to you (you may need to review it a few times and work through it on paper). For the first triangle of the quad we index two vertices from the previous node's ring and one vertex from the current node's ring. For the second triangle of the quad we use two vertices from current ring of vertices and one from the previous node's ring.

```
            // For each new face
            for(j=0, Index=0; j<m_Properties.Branch_Resolution-1;++j, Index+= 6 )
            {
                // Add the indices for the first triangle
                pIndices[ Index     ] = Row1 + j;
                pIndices[ Index + 1 ] = Row2 + j;
                pIndices[ Index + 2 ] = Row1 + j + 1;

                // Add the indices for the second triangle
                pIndices[ Index + 3 ] = Row2 + j;
                pIndices[ Index + 4 ] = Row2 + j + 1;
                pIndices[ Index + 5 ] = Row1 + j + 1;

            } // Next Face
        } // End if not beginning of branch
    } // End if not end node
```

As you can see, we are adding six indices (two triangles) with each iteration of the loop and using loop variable ‘j’ to step through the vertices in the top and bottom rows each time.

We have now seen all the code that is executed to add a segment when the current node is not a node of type BRANCH_END. When the current node is an end node things have to be done a little differently. We no longer add a ring of vertices at the current node; instead, we just add one vertex at the model space node position. This vertex is essentially being positioned at the center of the ring of vertices that would have been generated for this node were it not an end node.

```
    else
    {
        // Add just the one tip vertex.
        long VIndex = pMesh->AddVertex( 1 );

        CVertex * pVertex = &((CVertex*)pMesh->GetVertices())[ VIndex ];

        // Same as the node position
        vecVertexPos = vecPos;

        // Store the values in the vertex
        pVertex->x = vecVertexPos.x;
        pVertex->y = vecVertexPos.y;
        pVertex->z = vecVertexPos.z;

        // Store the vertex normal
        pVertex->Normal = vecAxis;
```

The normal calculation is also different for this vertex since we can no longer create a normal using a vector from the center of the circle to the vertex. This is obviously because the vertex is at the center of this circle. Instead, we just use the model space direction vector of the end node as calculated in the virtual tree generation process.

Generating texture coordinates for this vertex is simple also. The U coordinate is always set to 0.5 so that it will be mapped to a point exactly half way across the width of the texture (if no scaling is being used). This seems logical if you consider that this is a tip in the center of where the circle would be, and as such is halfway between both sides of that circle. The V texture coordinate is calculated the same way as before (i.e., a function of node hierarchy depth).

```
        // Generate texture coordinates
        pVertex->tu  = 0.5f;
        pVertex->tv  = ((float)(pNode->Iteration + 1) /
                        (float)m_Properties.Max_Iteration_Count)  *
                         m_Properties.Texture_Scale_V;
```

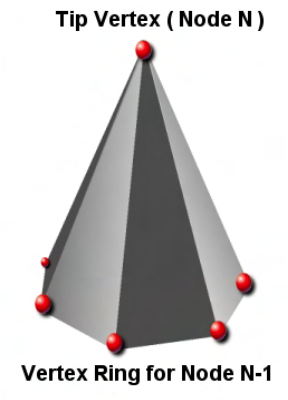

Figure 12.48

Now it is time to add the faces for this end segment. Although we added only one vertex, we still need to form a triangle between this vertex and every vertex in the ring inserted at the previous branch node. This allows us to end the branch using a cone shape (Figure 12.48).

If we have a ring of N vertices at the previous node then we know that these can be used to build the base of N-1 faces. We can see that the number of faces we wish to add to the CTriMesh in order to add this cone would be the branch resolution minus 1. As before, we will use the CTriMesh::AddFace function to allocate this many faces (essentially just multiplies the desired face count by three and allocates that many indices in the mesh's indices array).

```
        // Creating pointed tip
        ULONG FaceIndex = pMesh->AddFace( m_Properties.Branch_Resolution - 1 );

        // Retrieve the face index buffer
        USHORT * pIndices = &((USHORT*)pMesh->GetFaces())[FaceIndex * 3];

        USHORT  Row1 = (pNode->Parent) ? pNode->Parent->VertexStart : 0;
        USHORT Row2 = (USHORT)VIndex;

        // Store the vertex start
        pNode->VertexStart = Row2;
```

Notice that once again, after allocating space for the new indices, we use the CTriMesh::GetFaces function to return a pointer to the start of the index array. We then multiply the index of the first new face we have allocated by 3 to offset the indices pointer so that it points to the first new index position we must fill in.

In the following and final section of code for this function, we loop around each vertex in the ring forming a triangle with the tip vertex (Row2) and each pair of vertices from the previous ring (Row1 and Row1+1).

```
        // For each new face
        for (j=0, Index=0; j<m_Properties.Branch_Resolution - 1; ++j, Index+= 3 )
        {
            // Add the indices for the first triangle
            pIndices[ Index     ] = Row1 + j;
            pIndices[ Index + 1 ] = Row2;
            pIndices[ Index + 2 ] = Row1 + j + 1;

        } // Next Face

    } // End if end node

    // Success!!
    return D3D_OK;
}
```

We have now covered the complete AddBranchSegment function. Remember that it was called with each iteration of the BuildNode function to add a ring of vertices and indices at the current node being processed. Although on first read the function may seem quite intimidating, you should notice after further study that it really is rather intuitive (although admittedly a little long).

There is one more function we must cover before we have essentially covered the entire tree generation process. You will recall from our coverage of the BuildNode method that the BuildSkinInfo method was called whenever we were processing a branch start node (BRANCH_BEGIN). Let us have a look at this function next.

BuildSkinInfo - CTreeActor

The CTreeActor::BuildSkinInfo function is called towards the end of the BuildNode function only if the current node being processed is of type BRANCH_BEGIN. At this point in the BuildNode function, the child nodes of the BRANCH_BEGIN node will have already been visited and all the vertices and indices of each node in this branch added to the new CTriMesh.

Recall that after our CTriMesh has been built, we pass it into the CAllocateHierarchy::CreateMeshContainer function to convert it into a skinned mesh. However, this function requires that we send it an ID3DXSkinInfo object containing the information about each bone in the hierarchy that influences this mesh and the vertices in the mesh that they influence. Traditionally, we have had the ID3DXSkinInfo created for us by D3DX when loading skinned meshes from X files, but because we have hand-crafted this branch mesh ourselves, we are going to be responsible for creating the ID3DXSkinInfo object. Of course, we will also have to populate it with skinning information before passing it along with the mesh into the CreateMeshContainer function.

So what does an ID3DXSkinInfo object contain? Well, when we create a new object of this type using the global D3DX function D3DXCreateSkinInfoFVF, we must pass in the total number of bones that influence the mesh. In our case, this will be the number of bones created for nodes belonging only to this branch. We must also inform the creation function about the number of vertices in the mesh which this object will contain skinning information for.

Once this function returns, we will have an ID3DXSkinInfo object that will have an empty table of bone slots. Each row of this internal table will eventually need to store the information for one bone that influences the mesh. For example, if we have a branch that uses five bones, the empty ID3DXSkinInfo would have a table with five slots. Each element of this table will be used to store a bone name, its bone offset matrix (which we will have to calculate) and an array of vertex indices describing which vertices in the branch mesh are influenced by this bone. It will also contain an array of weights describing the strength at which the bone influences the transformation of each vertex referenced in the bone's vertex index array.

Ultimately, this function will require allocating a new ID3DXSkinInfo for N bones, and then looping N times and setting the bone name, offset matrix, vertex indices and vertex weights for each bone using the following methods of the ID3DXSkinInfo interface:

```
HRESULT SetBoneName( DWORD Bone, LPCSTR pName );

HRESULT SetBoneOffsetMatrix( DWORD Bone,
                             const D3DXMATRIX *pBoneTransform );

HRESULT SetBoneInfluence( DWORD Bone,
                          DWORD numInfluences,
                          CONST DWORD *vertices,
                          CONST FLOAT *weights );
```

The three methods shown above are the only ones we will need to populate the ID3DXSkinInfo with the information about each of the branch bones. Remember, we are only interested in the bones that influence this mesh, which is a single branch. Since the BuildSkinInfo function will only be called for BRANCH_BEGIN nodes (and passed a pointer to that node), we simply have to traverse through the child nodes of the branch, adding bones to the ID3DXSkinInfo object as we encounter them between the start and end nodes of the branch.

The SetBoneName method is used to set the name of the bone we are currently processing. The first parameter describes the zero based index of the bone along the branch and the second parameter is where we pass in a string containing the name we would like to assign to the bone. Obviously this should match the name that we gave to the actual bone/frame in the hierarchy. For example, if this is the bone at the start node of the branch, this will have an index of zero and the name passed will match the name of the frame we created for this node and attached to the hierarchy. Now you know why we stored a frame pointer in the branch node structure when we created the bone hierarchy; it allows us to easily access the bone created from a given branch node here in this function.

As you undoubtedly remember from the previous chapter, the ID3DXSkinInfo object will also store a bone offset matrix for each bone in the hierarchy. We will need to calculate the bone offset matrix ourselves. As discussed in Chapter 11, the offset matrix for a given bone is used to transform its attached vertices into the space of that bone so that local rotation of the vertices about that bone can be achieved when combined with the absolute bone matrix. The bone offset matrix is usually calculated by taking the inverse of the absolute bone matrix in its default pose. This way, when the bone matrix is rotated to some degree and is combined with the bone offset matrix, we are essentially subtracting the reference pose bone matrix from the new absolute bone matrix, leaving us with only the relative rotation to apply.

Normally, when loading a skeletal construct from an X file, the frames of the hierarchy will compose a single skeleton (a character for example). As such, the bone offset matrix for each bone is simply calculated by traversing the hierarchy from the root frame and combining matrices as we step through the levels of the hierarchy, generating the absolute (not parent relative) bone matrix for each frame. We can then invert this matrix and have a matrix that will transform that bone and its vertices into a space where the bone itself is at the origin of the coordinate system during the transformation of the vertex by that bone (i.e., bone local space.)

Things are slightly different in our tree case because our frame hierarchy does not represent the skeleton of a single mesh. Rather, our hierarchy represents multiple mini-skeletons connected together, where each mini-skeleton is the skeleton for a single branch mesh. When calculating bone offset matrices, we are only interested in transforming the bone (and any influential vertices) back to the position of the root

bone of the skeleton for the current mesh. Therefore, we do not wish the bone offset matrix we generate for a bone to be the inverse of the complete concatenation of parent-relative matrices from the root frame of the entire hierarchy right down to that bone. Instead, we wish the bone offset matrix to be only the inverse of the concatenation of matrices from the bone that begins that branch (the root bone of the branch) to the current bone being processed. In short, when calculating the bone offset matrices, we will only be interested in the skeleton of the current branch mesh and not all the bones in the entire tree. Thus, this function will traverse through the child nodes of the branch (starting at the branch start node) and at each bone it visits, concatenate the relative matrices before passing the result down to the child. For any given bone, this matrix will contain the absolute transformation of the bone in the reference pose. All we have to do is invert this matrix and we have the bone offset matrix for the current bone being processed. We can then assign it to the bone using the ID3DXSkinInfo::SetBoneOffsetMatrix method.

The next step is collecting the indices of all vertices that are influenced by the bone we are currently processing so that we can send them into the ID3DXSkinInfo::SetBoneInfluence function. This function accepts as its first parameter the index of the bone we wish to set the vertex influences for. This will be the bone we are currently processing. We also inform this function about the number of vertices it will influence, which we will count when collecting those vertices (more on this in a moment). As the final two parameters to this function we send in pointers to two arrays. The first is the array of vertex indices describing the vertices influenced by this bone. The second is an array of weight values describing how strongly the bone influences the vertices in the previous array. As you will see in a moment, all vertices are influenced by only one bone in our branch mesh, so we will always pass in an array filled with a weight value of 1.0 for each vertex.

Additionally, since no vertex will ever be influenced by more than one bone and the vertices will be added to the ID3DXSkinInfo in the same order that they were added to our CTriMesh when traversing the tree, the indices we pass into this array will always have a 1:1 mapping with the order in which the vertex data was added to the mesh. For example, if the first bone influences the first 3 rings of vertices (starting from the branch start node) and the branch resolution is 8, when setting the first bone we would pass in an array of 8*3=24 indices where the indices in this array range from 0 to 23. Similarly, if the second bone in the branch influences the following 3 rings of vertices, we will be passing another 24 indices into this array when adding the second bone's data, which goes from 24 to 47, and so on. The number of rings of vertices that are influenced by a bone is the same for all bones (except the last). This value is always Bone_Resolution*Branch_Resolution. In other words, if the bone resolution is set to 3 then we know this means that, starting from the beginning of the branch, a bone will be inserted every 3 nodes. A bone is always inserted at the branch start node. Therefore, all rings of vertices inserted from that bone node up to, but *not* including the next bone node, are considered to be influenced by that bone. If the bone resolution was 3 and the branch resolution was 8 this means that every bone would influence 3 rings of vertices (including the vertices inserted at the bone node). If the branch resolution was 8, then each bone would influence 8*3 = 24 vertices. Therefore, we would have to assign 24 vertex indices and 24 weights (all set to 1.0) to each bone we create. The exception is the final bone in the branch which may have ended prematurely by some random calculation during the tree calculation process and because the final node will contain just a single tip vertex.

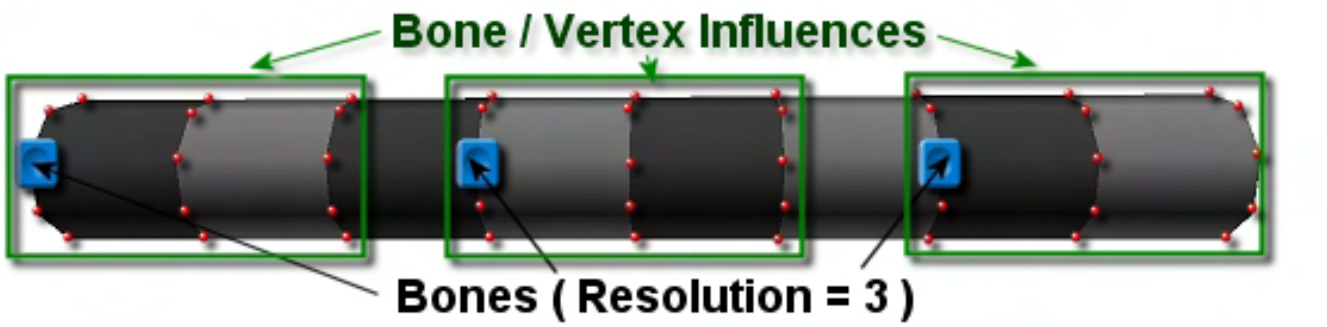

Figure 12.49 : Bone Vertex Influences for : Bone Resolution=3

Figure 12.59 shows the section of a branch where the bone resolution is set to 3. The blue boxes are the bones that are positioned every three ring's of vertices. The green boxes show the vertices which will be mapped to the bone and the bone's influence range over the branch.

Looking at this diagram and remembering that the pNode parameter passed into the BuildSkinInfo function will always be a node of type BRANCH_BEGIN, our strategy becomes clear:

1. Calculate the total number of vertices and bones in the branch.
2. Use the information from step 1 to allocate a new ID3DXSkinInfo of the correct size.
3. Step through each node in the branch starting at the branch start node.
    a. If this node is a bone node then add the name of the bone to the ID3DXSkinInfo and calculate its bone offset matrix. This will be an identity matrix for the start node of the branch.
    b. Add the indices of vertices at this node to a temporary index array.
    c. Step down into child node.
        i. If this node is a bone node, then assign all currently collected vertex indices which reference the previous bone created in step 3a, to the ID3DXSkinInfo object. Empty the temporary vertex index array.
        ii. If this is not a bone node then append the ring of vertex indices at this node to the temporary vertex index array.
4. Repeat steps 3a through 3c until last node is processed

As outlined above, we need to step through the nodes of the branch starting at the root **branch** node. When we find a bone node, we add this bone's information (name and offset matrix) to the ID3DXSkinInfo object. We then continue to traverse until the next bone is reached, collecting vertex indices in a temporary buffer along the way. As soon as we hit a new bone node, we know that the vertex indices currently stored in our temporary array belong to the previous bone, so we call the SetBoneInfluence method to assign them to that bone. We then empty the temporary vertex array so that it can be used to collect indices between the next two bones. We create a new bone at the current node and continue the process.

Let us now look at the code one section at a time. The function accepts three parameters that are passed to it by the BuildNode function. The first is a pointer to the BRANCH_BEGIN node of the branch mesh we are about to calculate the bone influences for. The second is a pointer to the branch mesh, which at this point contains all its vertex and index data. The third parameter is the address of an ID3DXSkinInfo interface pointer which on function return should point to a valid ID3DXSkinInfo interface containing

the bone influences for the mesh. The BuildNode method can then pass this interface into the CreateMeshContainer function for final skinning.

```
HRESULT CTreeActor::BuildSkinInfo( BranchNode *pNode,
                                   CTriMesh * pMeshData,
                                    LPD3DXSKININFO *ppSkinInfo )
{
    HRESULT hRet;
    ULONG  BoneCount   = 0, InfluenceCount=0, Counter=0,IndexCounter = 0, i;
    ULONG  VertexCount = pMeshData->GetNumVertices();

    ULONG      * pIndices    = NULL;
    float      * pWeights    = NULL;
    BranchNode * pSearchNode = NULL;
    BranchNode * pSegmentNode= NULL;
    TCHAR        strName[1024];
    D3DXMATRIX   mtxOffset, mtxInverse;

    // Set offset to identity.
    D3DXMatrixIdentity( &mtxOffset )
```

In the above code we calculate the number of vertices in the mesh and store it in the VertexCount parameter. We will need to know how many vertices our branch mesh contains so that we can feed it into the ID3DXCreateSkinInfoFVF function. We also initialize the local matrix variable (mtxOffset) to an identity matrix. This will be used to store the bone offset matrix for each bone we add to the ID3DXSkinInfo object. However, as the first bone we will add will be the bone at the branch start node, this is the base frame of reference for the entire mesh and the bone offset matrix should be an identity matrix.

In the next section of code we will use the pSearchNode pointer to count all the bones we have added to this branch in the hierarchy. We will need to supply D3DX with this information when it creates the ID3DXSkinInfo object.

Note that the current node may have multiple children if other branch nodes begin at the next node. That is, the next node in the current branch might be in a sibling list with multiple BRANCH_START nodes which we are *not* interesting in processing. Therefore, to locate the next child node we will step down to the first child node of the current node and then search for the one (and only) node in that list that is not a BRANCH_BEGIN node. That is the node in that sibling list that is the continuation of this branch and the next node we must process. Essentially, the next section of code steps through every node in the branch looking for bone nodes (nodes that had bones attached to them) and for each one it finds it increments the BoneCount local variable. This will allow us to count all the bones used by this mesh so that we can allocate the ID3DXSkinInfo to manage that many bones.

```
    // Navigate our way through the branch, setting bone details
    BoneCount   = 1;
    pSearchNode = pNode;

    while ( pSearchNode = pSearchNode->Child )
    {
        // We're not interested in other branches, so shift us through until
```

```
        // we find a node that is our segment, or end node.
        while ( pSearchNode->Type == BRANCH_BEGIN && pSearchNode )
                pSearchNode = pSearchNode->Sibling;

        // If we couldn't find a node, we have an invalid hierarchy
        if ( !pSearchNode ) return D3DERR_INVALIDCALL;

        // Was a frame created here?
        if ( pSearchNode->BoneNode ) BoneCount++;

    } // Next child segment
```

At the start of the above code we initially set the bone count to 1. This is because the first node is a branch start node and will always have a bone. Also, when we enter the while loop that steps through the child branch nodes, we start at the child of the BRANCH_BEGIN node. Therefore, the initial bone at the start of the branch would not be accounted for when keeping the count. Notice that with each iteration of the outer while loop, we step down one level in the hierarchy into the current node's sibling list. The inner while loop searches that sibling list for the only non-BRANCH_BEGIN node, if multiple nodes exist in that list. Essentially, the above code is just stepping down the branch each time, finding the next child node that continues the current branch, and notching the score up for each bone node that is found.

We now have everything we need to allocate a new ID3DXSkinInfo object. We know the number of bones that influence our mesh and the number of vertices in this mesh.

```
    // Create the skin info object ready for building.
    hRet = D3DXCreateSkinInfoFVF(VertexCount, VERTEX_FVF, BoneCount, ppSkinInfo );
    if (FAILED(hRet)) return hRet;

    // Get dereferenced skin info for easy access
    LPD3DXSKININFO pSkinInfo = *ppSkinInfo;
```

When the D3DXCreateSkinInfoFVF function returns, the ID3DXSkinInfo interface pointer (the final parameter) will point to a valid interface. In this case, we pass in the ID3DXSkinInfo interface pointer that was passed into the function by BuildNode so that it will be able to access it on function return. We then assign this interface pointer to a local variable for ease of access so we do not have to de-reference the original pointer each time.

At this point we have our new ID3DXSkinInfo interface but it contains no data. It has empty slots where the bone information should be, so we will spend the remainder of this function setting the information for each bone in the branch mesh.

As mentioned previously, we will need to step through the nodes of this branch and collect the indices of all vertices that are influenced by the bone we are processing. All vertices between two bones will be influenced by the previous bone (see Figure 12.49). Therefore, while stepping between two bones, we will need a temporary vertex indices buffer where we can store the data we have collected at each node as we traversed from one bone to the next. We will also need a temporary array of the same size to store the weights of each of these vertices (one weight for each vertex). We allocate these temporary buffers to be large enough to hold all the vertices in the mesh, just to be safe (e.g., if one bone in the mesh

directly influenced all its vertices, we will still be covered). The next code block allocates the vertex index array and the vertex weights array.

```
    // Allocate enough space to hold all indices and weights
    pIndices = new ULONG[ VertexCount ];
    if ( !pIndices) return E_OUTOFMEMORY;

    pWeights = new float[ VertexCount ];
    if ( !pWeights ) { delete []pIndices; return E_OUTOFMEMORY; }
```

We will step through the nodes of this branch using a while loop, but this loop will start at the child node of the branch start node. Therefore, before we enter the loop we will give the ID3DXSkinInfo object the information (vertices and weights) for the bone stored at the branch start node. We know that the branch start node will always have a bone and that the bone will always by the first bone in the mesh (index 0).

In the next section we setup the first bone in the ID3DXSkinInfo object. We build the name of this bone in the same way we built the name of the bone when we added it to the hierarchy. We must make sure that the name we add here matches the name of the bone in the frame hierarchy it represents. Once we have the name stored in a string, we set it along with the bone offset matrix for this bone (identity for the branch start bone) as shown below.

```
    // Generate root bone name (matches frame)
    _stprintf( strName, _T("Branch_%i"), pNode->UID );

    // Set it to the skin info
    pSkinInfo->SetBoneName( Counter, strName );
    pSkinInfo->SetBoneOffsetMatrix( Counter, &mtxOffset );
    Counter++;
```

The first parameter to both the SetBoneName and SetBoneOffsetMatrix functions is the index of the bone we wish to set. Since the branch start bone is the first bone in the branch it should have an index of 0. This is the initial value of the Counter variable which was initialized at the top of the function. We then increment Counter so that when we add another bone later we know this next bone will be at index 1 in the ID3DXSkinInfo object's internal bone table.

Now we need to add the indices and weights for the vertices that are influences by this bone. We will collect this information in a while loop starting from the child node of the branch start node. This means we must make sure that we add the first ring of vertices that were inserted at the branch start node so that they are not forgotten. The next section of code loops around every vertex in the first ring (Branch_Resolution) adding the index of each vertex to the pIndices temporary array and a value of 1.0 in the corresponding temporary pWeights array.

```
    // Fill in the values so far for the root of the branch
    for ( i = 0; i < m_Properties.Branch_Resolution; ++i )
    {
        pIndices[ InfluenceCount ] = IndexCounter++;
        pWeights[ InfluenceCount ] = 1.0f;
        InfluenceCount ++;
    } // Next index
```

The IndexCounter variable will start off at zero and be incremented for *every* vertex we add; it is not reset when we encounter a new bone. If our mesh has 400 vertices, then we know that the order in which we added them to the mesh is the same order in which they are assigned to their bones. Therefore, we will essentially add vertices 0-399 in exactly that order. Of course, here, we are just adding the first ring of vertices. If the branch resolution was 8 for example, we would add the values 0-7 to the indices array. When we visit the next child node and add that ring of vertices, the index counter will have not been reset, so we will be adding values 8 through 15 to the indices array, and so on.

What is InfluenceCount in the above code? In the pIndices array we are collecting the influenced vertex indices for one bone. Therefore, influence count will be reset to zero each time we start collecting vertices for a new bone. It is simply used to place the vertex index in the correct zero based location in the indices array for the current bone. For example, if a bone is influenced by 40 vertices, while collecting those vertices, influence count will count from 0 to 39. When a new bone is encountered, we will add all currently collected vertices to the ID3DXSkinInfo for the previous bone, reset the InfluenceCount back to zero, and start collecting vertex indices all over again using the same buffer for the next bone (overwriting any previous data).

At this point we have added the first bone's name and offset matrix and have collected the first ring of vertices from the BRANCH_BEGIN node and stored them in the indices buffer. We will now enter a while loop that will start at the child node and continue to make its way down to the end of the branch. It will collect the vertices from each node exactly as we did above and add them to the indices buffer. When we finally hit another bone node, we know that the indices buffer will contain all the vertex indices influenced by the previous bone, so we can add them to the ID3DXSkinInfo and attach them to the previous bone. We then flush the indices buffer, reset the influence count and start collecting vertices for this new bone, and so on.

Let us now examine the while loop which comprises the rest of the function and adds the remaining bone information for the branch.

As before, we start by stepping down into the child node of the BRANCH_BEGIN node. This is the first node we process in this loop. We then use the same inner while loop mechanism we used before to make sure that if the child node is in a sibling list with other nodes, we locate the correct node that is the continuation of the branch (not a BRANCH_START that spawns from that node).

```
    // Now we make our way through and build the skin info
    pSearchNode = pNode;
    while ( pSearchNode = pSearchNode->Child )
    {
      // Reset the segment node (we must find one at each level)
       pSegmentNode = NULL;

       // Loop through all siblings of this node
       for ( ; pSearchNode; pSearchNode = pSearchNode->Sibling )
       {
           // If this is a begin node, skip it. We aren't interested in other branches
           if ( pSearchNode->Type == BRANCH_BEGIN ) continue;

           // If this is the segment node, store it, we want to continue down from here
           if ( pSearchNode->Type == BRANCH_SEGMENT ) pSegmentNode = pSearchNode;
```

If we find any node in the sibling list that is a BRANCH_BEGIN node, we skip it and advance to its sibling. We are searching for the node that is a continuation of the current branch; the only node in the sibling list which is of type BRANCH_SEGMENT.

If we get this far then pSearchNode points at the child node (i.e., the next node we will process). We also store a copy of this node's pointer in the pSegmentNode local variable for later use.

The first thing we will do is test to see if this is a bone node. If it is, then it is time to calculate the bone offset matrix for this new bone, build its name, and set the name and bone offset matrix in the next row of the ID3DXSkinInfo bone table.

```
        // Was a frame created here?
        if ( pSearchNode->BoneNode )
        {
            // Combine the bone matrix, and inverse for the reference pose offset
            D3DXMatrixMultiply( &mtxOffset,
                                &pSearchNode->pBone->TransformationMatrix,
                                &mtxOffset );

            D3DXMatrixInverse( &mtxInverse, NULL, &mtxOffset );

            // Generate bone name (matches frame)
            _stprintf( strName, _T("Branch_%i"), pSearchNode->UID );

            // Set it to the skin info
            pSkinInfo->SetBoneName( Counter, strName );
            pSkinInfo->SetBoneOffsetMatrix( Counter, &mtxInverse );

        } // End if bone created
```

Notice that every time we encounter a bone we combine its parent relative matrix (the frame matrix) with the current contents of the mtxOffset matrix (which will be set to identity at the start node of the branch). This means that whenever we reach a bone, it will always contains the absolute transformation of that bone in its reference pose relative to the start node of the branch. As discussed earlier, inverting this matrix gives us our bone offset matrix. Also remember that when we added the first bone we incremented the Counter variable, so if this was the first bone we encountered after the branch start node, Counter would be set to 1 and we would be setting the properties of the second bone in the ID3DXSkinInfo bone table.

As discussed, when a new bone is encountered, we need to take the current vertex indices we have collected between the previous bone and this new bone and assign them as influences for the previous bone. We also have to perform this same step if the current node is a BRANCH_END node as we have reached the end of the line. In the case when the node is an end node, we also add the final tip vertex index to the index array before we assign the influences.

```
        // If we're about to switch to a new bone, or we have completed
        // this branch, fill in the PREVIOUSLY started bone's influence details
        if ( pSearchNode->BoneNode || pSearchNode->Type == BRANCH_END )
        {
            // If this is the end of the branch, just add the last influence
```

```
            if ( pSearchNode->Type == BRANCH_END )
            {
                // There is only one tip vertex on branch ends
                pIndices[ InfluenceCount ] = IndexCounter++;
                pWeights[ InfluenceCount ] = 1.0f;
                InfluenceCount++;

            } // End if end

          // Set the bone influence details
          pSkinInfo->SetBoneInfluence(Counter-1,InfluenceCount,pIndices,pWeights );

            // Reset to start again
            InfluenceCount = 0;

            // Move on to next bone
            Counter++;

        } // End if switching
```

Notice that when we call SetBoneInfluence function we use the index Counter - 1 to assign everything accumulated to the previous bone. Because Counter always contains the index of the next bone we hope to encounter, subtracting 1 from it gives us the index of the previous bone we processed. This is the bone which the vertices we have accumulated in the pIndices buffer should be assigned to. When we add the new bone and assign the collected indices to the previous bone, we reset InfluenceCount to zero to start collecting indices at the beginning of the array again for the next bone. We also increment the Counter variable so that we know the index of the next bone we encounter and which slot it should occupy in the ID3DXSkinInfo object's bone table.

The final section of code shows what happens when the node is not a bone node or branch end node. If for example, your branch had a bone resolution of 5, the code in the above code block would only be executed every 5 nodes of the branch. For all nodes in between bone nodes, the following code would be executed. It simply adds the vertex indices for the next ring of vertices to the pIndices buffer.

```
        // Add influences to the previous bone
        if ( pSearchNode->Type == BRANCH_SEGMENT )
        {
            for ( i = 0; i < m_Properties.Branch_Resolution; ++i )
            {
                pIndices[ InfluenceCount ] = IndexCounter++;
                pWeights[ InfluenceCount ] = 1.0f;
                InfluenceCount ++;

            } // Next index

        } // End if segment

       } // Next Node Sibling

       // If we couldn't find a segment node in the sibling list
       // we've reached the end of the branch
       if ( !pSegmentNode ) break;
```

```
    } // Next child segment

    // Clean up
    delete []pIndices;
    delete []pWeights;

    // Success!!
    return D3D_OK;
}
```

At the end of the function you can see that we release the temporary index and weight arrays and return.

We have now covered the entire tree generation process and program flow returns to CTreeActor::GenerateTree. If we look at the code for that function again we can see that there is only one more task that must be performed before program flow goes back to the caller (the application in our case) and the tree is considered complete.

```
HRESULT CTreeActor::GenerateTree( ULONG Options, LPDIRECT3DDEVICE9 pD3DDevice,
                                  const D3DXVECTOR3 &vecDimensions,
                                  const D3DXVECTOR3 &vecInitialDir,
                                  ULONG BranchSeed )
{
    HRESULT            hRet;
    CAllocateHierarchy Allocator( this );

    // Validate parameters
    if ( !pD3DDevice ) return D3DERR_INVALIDCALL;

    // Release previous data.
    Release();

    // Store the D3D Device here
    m_pD3DDevice = pD3DDevice;
    m_pD3DDevice->AddRef();

    // Store options
    m_nOptions = Options;

    // Generate the branches
    hRet = GenerateBranches( vecDimensions, vecInitialDir, BranchSeed );
    if (FAILED(hRet)) return hRet;

    // Build the frame hierarchy
    hRet = BuildFrameHierarchy( &Allocator );
    if (FAILED(hRet)) return hRet;

    // Build the bone matrix tables for all skinned meshes stored here
    if ( m_pFrameRoot )
    {
        hRet = BuildBoneMatrixPointers( m_pFrameRoot );
        if ( FAILED(hRet) ) return hRet;

    } // End if no hierarchy
```

```
    // All is well.
    return D3D_OK;
}
```

Just as we did in CActor::LoadActorFromX, as soon as the mesh hierarchy has been constructed we must call the base class BuildBoneMatrixPointers function. Hopefully you will recall from Lab Project 11.1 that this function traverses the entire hierarchy searching for mesh containers. For each mesh container found that stores an ID3DXSkinInfo object, it extracts each of the bone names, searches for the matching frame in the hierarchy, and adds the pointer to each frame's absolute matrix to the mesh container's bone matrix pointer array. When this function returns, each mesh container will contain an array of bone matrix pointers and an array of matching bone offset matrices that can be easily accessed and combined when rendering the mesh.

12.5 Animating CTreeActor

The CTreeActor class includes a function that creates animation data for the frame hierarchy. The GenerateAnimation function should be called by the application after the call to the GenerateTree function. This function is not automatically called by GenerateTree since you might want to generate a tree that does not animate, or perhaps you want to animate the tree using your own algorithms. Furthermore, if you intend to simply save the tree data out to disk and import it into GILES™ for placement purposes, the animation data will be lost anyway.

However, we felt that it would be helpful to go through the process of creating some simple animations. It should provide you with some additional insight into the animation system as a whole and hopefully spark some of your own creative ideas regarding animation. If you wish to use the feature, the GenerateAnimation function can be called to build keyframes for each bone in the tree. The animation we will create will simulate wind and the tree branches will sway back and forth.

To get an idea of the overall process, below we see how some code may look in an application that has created a CTreeActor and would like it to animate.

```
// Allocate new Tree Actor
CTreeActor *pTree = new CTreeActor;

// Set actor skinning mode
pTree->SetSkinningMethod( CActor::SKINMETHOD_AUTODETECT );

// Register global texture/material callback for non-managed mode
pTree->RegisterCallback( CActor::CALLBACK_ATTRIBUTEID, CollectAttributeID, this );

// Set the texture and material to use for the branches
pTree->SetBranchMaterial( _T("LondonPlaneBark.dds"), NULL );

// Generate skinned tree
pTree->GenerateTree( D3DXMESH_MANAGED,
                     m_pD3DDevice,
                     D3DXVECTOR3( 2.0f, 2.0f, 2.5f ),
```

```
                        D3DXVECTOR3( 0.0f, 1.0f, 0.0f ));

// We wish to animate so generate animation data and controller for actor
pTree->GenerateAnimation( D3DXVECTOR3( 0.0f, 0.0f, 1.0f ), 30.0f, true );
```

For completeness, we see the actor being allocated and its skinning method being set to auto-detection mode. We then see the scene registering a callback function that will be used by the actor to process the textures and materials needed by the actor. The application then calls the SetBranchMaterial method to supply the actor with the filename of the texture it would like mapped to its branches. Notice that the second material parameter, which can be used to pass a pointer to a D3DMATERIAL9 structure, is set to NULL in this example. We have elected to let the tree use the default material it creates in its constructor.

The call to the GenerateTree method is then made with the final two vectors describing the dimensions of the root node and the direction vector for that node. When this function returns, the actor will have a final frame hierarchy and every branch will be represented by a skinned mesh.

On the final line we call the CTreeActor::GenerateAnimation method, which will create the actor's animation controller and populate it with animation data. The function takes three parameters. The first is the wind direction vector which will be used to calculate how the bones of the tree will animate. This vector describes the direction that the wind is blowing and is used to calculate a rotation axis for the bones. The second vector is the strength of the wind, which is used to scale the rotation of each branch with respect to the rotation axis. The third parameter is a boolean which specifies whether the CActor::ApplyCustomSets function of the base class will be called after the sets have been created. As you will recall, this function converts each ID3DXKeyframedAnimationSet into one of our custom CAnimationSets to overcome the GetSRT bug. Since the GenerateAnimation function will only create one animation set for the entire tree, only this one animation set will have to be converted in the ApplyCustomSets method. However, we have left this parameter as a Boolean so that should this bug be fixed in the future, you can pass false and use the ID3DXKeyframedAnimationSets that are initially created. Lets us now examine the code to this function and discuss the animation it is trying to implement.

GenerateAnimation - CTreeActor

The animation we will create will be very simple. Given a wind direction vector, we will perform the cross product between that vector and the world up vector <0, 1, 0> to get a vector that is perpendicular to the wind direction vector. We can think of this new vector as being a rotation axis which the direction vector is blowing directly against. If we create a scenario where the axis exists at each bone in the tree, we can rotate the branches about this axis by a small amount determined by the fWindStrength parameter passed into the function.

By default, we will create 20 keyframes for each bone in the hierarchy. For each of those keyframes (for a given frame) we will rotate the frame by some amount. Each keyframe for every frame will contain a rotation around the same axis, but at varying degrees. The pattern we want to simulate is not simply for the branches to always be blowing away from the wind, as this would simply bend the tree away from

the wind direction vector. Rather, we wish to rotate the bones away from the wind vector but also let them move back again so that the branches sway back and forth. Admittedly, this is not particularly realistic, nor is it going to be physically correct, but the end result will be close enough to what we want to work for our purposes in this lesson.

As an example of how things will work, the animation stored in each keyframe for a given frame might slowly rotate the bone an angle of 30 degrees away from the wind vector around the rotation axis in keyframes 1 – 10. It might then spend the next 10 keyframes rotating it back again to its initial position. Our animation will not be quite that simplistic, but hopefully you understand that each frame will have an array of 20 keyframes and that at each keyframe, we store the rotation angle of the bone around the rotation axis at that particular time. To make things more realistic, we will also introduce the concept of a height delay, so that the further up the tree we move, the bones rotate slightly behind the bones beneath them in the tree. This will generate a whip-like effect, where the bottom of branches will start to move first and the end of the branch will be dragged along with it a short time later. At the midway point, the bottom section of a branch may be rotating back to its initial pose while it top part is still on its way out to full extension (the position at which the bottom section starts to pull the top section of the branch back with it).

The actual creation of the keyframe data is done using a recursive function called BuildNodeAnimation. It is called from the GenerateAnimation function to traverse all the nodes in the tree and build the keyframes for each one. We will discuss this all shortly. First though, let us have a look at the parent function and the doorway to this recursive process.

One of the first things this function must do is create the actor's ID3DXAnimationController. Because we did not load our actor's data using the D3DXLoadMeshHierarchyFromX function, our actor will currently have no animation controller assigned. However, before allocating this new controller, the function will release the previous controller interface if one exists. This is done for safety as it lets the application call this function even if the actor has previously had animation defined for it. It is possible that the application may wish to call this function again to generate animation data with a different wind direction vector or wind strength than that specified the first time the function was called.

Once we have released the controller interface we must create a new one. Recall that when we use the D3DXCreateAnimationController function to create a new controller we must pass in the limits. We only need one animation set and we may as well specify the default number of tracks (2) and the default number of key-events (30) even though we do not need them.

However, you will recall from our discussion of the animation controller in Chapter 10, that when creating one, we must know how many animation outputs (i.e., frame matrices) to make room for inside the controller. Luckily, we can use the D3DXFrameNumNamedMatrices helper function to traverse the actor's frame hierarchy and count the number of named frames. We will then reserve this many animation outputs so that we reserve enough room for every frame in the hierarchy to be manipulated by the animation controller. Furthermore, once we have created the animation controller, we still have to register each frame matrix in our hierarchy with the controller so that the controller can cache a pointer to it for animation updates. We can use the other D3DX global function D3DXFrameRegisterNamedMatrices function to automate that process too. We simply pass this function the root frame of our hierarchy and it will traverse it and register the parent-relative matrix for

each named frame as an animation output in the controller. The first section of the function that performs these tasks is shown next.

```
HRESULT CTreeActor::GenerateAnimation( D3DXVECTOR3 vecWindDir,
                                       float fWindStrength,
                                       bool bApplyCustomSets /* = true */ )
{
    HRESULT                     hRet;
    D3DXTRACK_DESC              Desc;
    ULONG                       FrameCount;
    D3DXVECTOR3                 vecWindAxis;
    LPD3DXKEYFRAMEDANIMATIONSET pAnimSet = NULL;

    // If there is already an animation controller, release it. This allows
    // the application to call this function again, specifying different
    // properties without having to rebuild the tree itself.
    if ( m_pAnimController ) m_pAnimController->Release();
    m_pAnimController = NULL;

    // Count the number of frames in our hierarchy
    FrameCount = D3DXFrameNumNamedMatrices( m_pFrameRoot );

    // Create a new animation controller
    hRet = D3DXCreateAnimationController(FrameCount,1,2,30,&m_pAnimController );
    if ( FAILED(hRet) ) return hRet;

    // Register all of our frame matrices with the animation controller
    hRet = D3DXFrameRegisterNamedMatrices( m_pFrameRoot, m_pAnimController );
    if ( FAILED(hRet) ) return hRet;
```

We now have an empty animation controller that has room for one animation set. Let us now create that animation set and call it ‘SwaySet’ (it is the only set we will use). We will work using a ticks-per-second ratio (timing resolution) of 60 for our keyframe timestamps and set the animation to loop.

```
    // Create a new animation set
    hRet = D3DXCreateKeyframedAnimationSet( _T("SwaySet"),
                                            60.0f,
                                            D3DXPLAY_LOOP,
                                            FrameCount,
                                            0,
                                            NULL,
                                            &pAnimSet );
    if ( FAILED(hRet) ) return hRet;
```

The fourth parameter in the above code is where we specify the number of animations we would like to store in this animation set. Remembering that an Animation is a collection of keyframes for a single frame in the hierarchy, we know that we wish to have an animation for every hierarchy frame. Therefore we pass in the value FrameCount, which is the total number of frames in our hierarchy as calculated earlier in the function. The fifth and sixth parameters are set to zero and null as we have no need to register callback keys. As the final parameter, we pass the address of an ID3DXKeyframedAnimationSet interface pointer which, on function return, will point to our new and empty animation set. The animation set is still not registered with the controller at this point.

We now have an animation set that we will use to store the keyframes for each frame in the hierarchy. Before we calculate those keyframes however, we need to know the axis of rotation we will use for the bones of our tree. The wind direction vector was passed into the function and describes the exact direction the wind is blowing in tree space. As such, we know that this vector is perpendicular to the axis we actually wish to rotate about. For example, imagine a player mounted on a pole in a table football game (also called Foosball in some places). The wind direction can be thought of as the vector hitting the player head on, while the pole on which the player is mounted is actually the rotation axis the player will rotate around in response to that wind. Therefore, provided our wind direction vector is not equal to the world up vector <0,1,0>, which should never realistically be the case, we can cross these two vectors to get the rotation axis by which we will rotate each bone.

```
    // To make things a little more user friendly we accept a wind direction to
    // this function, however BuildNodeAnimation requires an axis about which
    // the branches will rotate. We convert this here.
    D3DXVECTOR3 vecCross = D3DXVECTOR3( 0.0f, 1.0f, 0.0f );
    D3DXVec3Cross( &vecWindAxis, &vecCross, &vecWindDir );
```

We now have the rotation axis stored in the vecWindAxis member, so it is time to walk through the nodes of the tree and generate the keyframe data. This step is handled with a single call to the recursive function BuildNodeAnimation, whose code we will discuss next. This function is passed the root node of the branch node hierarchy, the rotation axis we just calculated, the wind strength, and the interface of our new animation set, which will be the recipient of the keyframe information calculated by this function.

```
    // Build the animations
    hRet = BuildNodeAnimation( m_pHeadNode, vecWindAxis, fWindStrength, pAnimSet);
    if ( FAILED(hRet) ) { pAnimSet->Release(); return hRet; }
```

When this function returns, every frame in the actor's hierarchy will have had its animation generated and added to the animation set. Next we must register this animation set with our animation controller and assign it to the first track on the mixer.

```
    // Register the animation set with the controller
    hRet = m_pAnimController->RegisterAnimationSet( pAnimSet );
    if ( FAILED(hRet) ) { pAnimSet->Release(); return hRet; }

    // Set this in track 0 to ensure it plays
    SetTrackAnimationSet( 0, pAnimSet );
```

We must be careful to initialize the properties of any track we use, especially when creating the animation controller manually. D3DX will not perform any track property initialization (we learned the hard way in our tests that the initial properties of a track are all zero -- which generates no visual output). In the following section of code we set the properties of the first and only mixer track we will use such that it is enabled, has a speed of 1.0 (the default), a weight of 1.0 (the default) and has a track position of 0.0 (the start).

```
    // Setup the track description (defaults to disabled)
    ZeroMemory( &Desc, sizeof(D3DXTRACK_DESC) );
```

```
    Desc.Enable   = true;
    Desc.Weight   = 1.0f;
    Desc.Speed    = 1.0f;
    Desc.Position = 0.0f;

    // Set the track description
    m_pAnimController->SetTrackDesc( 0, &Desc );
```

At this point we can release the pAnimSet set interface since it has been registered with the controller and had its reference count increased.

```
    // We can release the animation set now (controller owns it)
    pAnimSet->Release();
```

As a final step we see whether the application would like the ID3DXKeyframedAnimationSet we have just created replaced with our custom CAnimationSet object. If true is passed as this parameter, we call the base class method ApplyCustomSets, which we know from the previous lesson performs this task.

```
    // Apply custom animation sets if requested
    if ( bApplyCustomSets ) ApplyCustomSets();

    // Success!!
    return D3D_OK;

}
```

The function then returns to the application with a completely valid animation controller that can be used by the application to update the animation (via AdvanceTime).

There was nothing too challenging happening in that function, but then again, the real work is performed in the BuildNodeAnimation call. This function recursively visits every frame in the hierarchy, generating animation data for it. Let us have a look at that final function now.

BuildNodeAnimation - CTreeActor

When this function is first called, it is passed the root node of the branch node hierarchy. The function will recursively call itself visiting all child and sibling nodes in the tree. However, only significant action is taken when the node we are visiting is a bone node. If it is a bone node then we know this node has a corresponding frame in the hierarchy and it must have an animation built for it and registered with the passed animation set.

Virtually all the code in this function is placed within the “if(pNode->BoneNode)” code block. The only code that is not in that block comes at the end of the function when the function calls itself recursively if child and/or sibling nodes exist. Let us take a look at the first section of this function.

```
HRESULT CTreeActor::BuildNodeAnimation( BranchNode * pNode,
                                        const D3DXVECTOR3 & vecWindAxis,
```

```
                                        float fWindStrength,
                                        LPD3DXKEYFRAMEDANIMATIONSET pAnimSet )
{
    ULONG       i;
    HRESULT     hRet;
    D3DXVECTOR3 vecChildWindAxis = vecWindAxis;

    // If this is a bone node, build animation for us.
    if ( pNode->BoneNode )
    {
        D3DXKEY_VECTOR3    pTranslation[2];
        D3DXKEY_QUATERNION pRotation[20];
        D3DXQUATERNION     quatRotate, quatValue;

        // Transform the wind axis by this frame
        D3DXMATRIX  mtxInverse;
        D3DXMatrixInverse(  &mtxInverse,
                            NULL,
                            &pNode->pBone->TransformationMatrix );

        D3DXVec3TransformNormal(&vecChildWindAxis,&vecChildWindAxis,&mtxInverse );
```

The above code block is only executed for bone nodes. First it allocates space for two translation keyframes and 20 rotation keyframes. We have decided that each node will need 20 rotational keyframes to get good looking rotation results on screen. Although we never wish to actually translate any bone directly, unfortunately, we must always include two translation keyframes; one at the start one at the end. We do this is because the SRT data stored in the keyframes overwrites the data in the frame's transformation matrix when we call AdvanceTime. If no translation vectors are specified at all, then a translation vector of <0,0,0> will be assumed and will overwrite the actual parent-relative positional offset of the frame stored in its matrix.

For example, if we have a frame with a parent-relative matrix translation vector of <10,10,10>, we know that this offsets it from the position of the parent frame <10,10,10> units in parent space. However, when the animation has no translation or scale keyframes, <0,0,0> is used. In the case of our matrix, the <10,10,10> translation vector in the frame matrix would be overwritten each time with a translation value of <0,0,0>. This would essentially translate the child frame back to the position of the parent bone and cause a huge mess. As long as we supply at least two translation keyframes, the animation system will happily interpolate between them. The result of the interpolation will be used to replace the translation vector in the frame matrix.

Therefore, we extract the position vector stored in the frame matrix (<10,10,10> for example) and store that same position vector in a translation keyframe at the start of the animation (time 0) and a keyframe at the end of the animation (time = max time). Every time AdvanceTime is called by the application, the GetSRT function will interpolate between <10,10,10> and <10,10,10> and of course, generate the parent-relative position of <10,10,10>. Simply put, by inserting two translation keyframes at the start and end of the periodic position of the animation set, we retain the position vector of the frame in its default pose throughout the interpolation process. You will see us setting up these two translation frames in a moment.

Notice in the above code that we multiply the rotation axis (ChildWindAxis) by the inverse parent relative matrix of the current frame. This is because the rotation axis was originally defined in tree space and we need to perform the rotation in bone space. This is the same as multiplying the vector with the frame's bone offset matrix, although done slightly differently. In this case, we are multiplying it by the inverse of the parent relative matrix instead of using the inverse of the absolute matrix of the frame. However, notice the transformed rotation vector is passed by reference to its child node; therefore, instead of accumulating relative matrices and using the inverse as the bone offset matrix, we are instead accumulating the transformations applied to the wind vector from inverse parent relative matrices, which equates to the same thing. Suffice to say, at this point, we have the tree space wind vector transformed into the space of the bone's local coordinate system.

We do not want all nodes in our tree to rotate back and forth at the same time since this would look a little unnatural (like rotating a cardboard cut-out of a tree on a pivot). Instead, we would like the base of the tree to start rotating first. Then, the higher nodes in the tree will have a slight delay on them as if trying to catch up, but never quite doing so. Rather than a straight pivot motion, it causes a sweeping motion and the rotation applied to the lower branches is filtered slowly up to the branch end segments.

In order to accomplish this, we calculate a delay value that is a function of the current node's depth in the tree. By dividing the node's iteration value by the maximum iteration count of the virtual tree, we are essentially mapping the iterations of all nodes into the 0.0 to 1.0 range (much like when calculate the V texture coordinates of each vertex). So a node at the deepest level of the hierarchy (branch end nodes) is assigned a delay value of 1.0, and a node at the lowest level of the hierarchy is assigned a delay value of 0.0. Any nodes in between these hierarchy levels are mapped a value in the 0.0 to 1.0 range. Notice however, that we negate the calculation such that the branch end nodes will have a delay of –1 and the root would have a delay value of zero. Do not worry about how this is used at the moment, just be aware that the delay value describes the position of the node in the tree as a number from 0 (base of tree) to –1 (tips of branches).

```
        // Higher Up bigger animation delay causes a sweep motion
        float fDelay = -((float)pNode->Iteration /
                         (float)m_Properties.Max_Iteration_Count);
```

Not only do we need a delay such that bones positioned higher up the tree rotate slightly after bones placed towards the bottom of the tree, we also need another scalar that will be used to scale the amount of rotation we apply to a bone. If we think about a tree swaying in the wind, we know that thinner lighter branches experience much more motion than thicker heavier branches. So we can see that even if the base of the tree was swaying slightly from side to side by let us say –4 to +4 degrees, this same movement filtered up to the branch ends would result in much more movement. We might imagine the upper branches rotating between –15 and +15 degrees.

Thus, we will create a scalar in the 0.0 to 1.0 range that acts as a way to dampen the amount of rotation applied to each bone. Dampening will be a function of that node's depth in the branch node hierarchy. Once we calculate a rotation angle, it will be scaled by this value. A bone at the top of the tree would have no dampening (1.0) and the full angle value will be used in its rotation (Angle * 1.0). Bones at the base of the tree would have full dampening (Angle * 0.0). Bones in between these two extremes would be scaled appropriately. The nearer to the end of a branch a bone is located, the less dampening will

occur. We calculate this dampening value for the current node by dividing the position of the node in the hierarchy by the total depth of the hierarchy (much like above, only this time the value is not negated).

```
        // The amount of motion applied at this node. Simple calculation which
        //  increases the overall movement of the branch the higher up we get.
        float fMovement = ((float)pNode->Iteration /
                           (float)m_Properties.Max_Iteration_Count);
```

This is a simple way to calculate the dampening factor, but not necessarily the most realistic. You might decide to include other factors in your implementation (actual branch thickness for example).

It is now time to loop around and build the 20 keyframes for this node. We will set the maximum time of the animation to run for 600 ticks. In this loop, each keyframe we add will be for a time between 0 and 600 ticks (evenly spaced) and will be a rotation keyframe.

```
        // Retrieve the frame for the bone
        D3DXFRAME_MATRIX * pFrame = (D3DXFRAME_MATRIX*)pNode->pBone;

        // Generate rotation over n keys
        ULONG KeyCount = 20;
        float MaxTime  = 600.0f;

        for ( i = 0; i < KeyCount; ++i )
        {
            // Set the key time
            pRotation[i].Time = (MaxTime / (float)(KeyCount - 1)) * (float)i;

            // Retrieve initial rotation from transform matrix
            D3DXQuaternionRotationMatrix( &quatValue,
                                          &pFrame->TransformationMatrix );
```

At the start of the loop we calculate the time for the current keyframe we are adding for this node. To evenly space out our keyframes we divide the maximum time (600) by the total keycount - 1 (remember that keys are zero index based) to get a value of 31.57. This tells us we need a space of 31.57 ticks between each keyframe we add. As you can see, we then multiply this value by the current value of loop iteration variable ‘i’ (the current key we are processing) to generate the value for the current keyframe’s timestamp. For example, if we are adding the second keyframe, the timestamp is 1*31.57 = 31.57. Remember, the first keyframe would have been at position 0.0.

In the next step, we fetch the initial orientation of the frame’s parent-relative matrix as a quaternion representation using the D3DXQuaternionRotationMatrix function. Since rotation keyframes are stored as quaternions we can get the orientation of the frame in its reference pose as a quaternion and apply the rotation to that. We can then store the rotated quaternion in the keyframe to represent the orientation of the frame at this time. We know that later, the animation controller will fetch the quaternion and translation vectors for each keyframe and use them to rebuild the matrix for the frame. At this point, we need to do it the other way around. That is, we need to disassemble the matrix and store its orientation as a quaternion keyframe. In a moment, we will also apply a rotation to this quaternion so that it correctly represents the bone at the current time.

In the next three lines we will calculate how much rotation we wish to apply to the bone. It may look a little obfuscated, but just remember that all we are trying to do is find the correct rotation angle for this keyframe for the current node.

Although the next three lines of code are quite small, we will discuss each line one at a time so as we do not lose anybody along the way.

The first part of the calculation looks like this.

```
            // Calculate the angle of rotation
            float fInput = (((float)i / (float)(KeyCount - 1))
                           + fDelay) * (D3DX_PI * 2.0f);
```

When looking at the line above remember that 'i/(keycount-1)' is calculating the time of the current keyframe for this node in the 0.0 to 1.0 range. For example, we know there are 20 keyframes in total for this node, so if 'i' was currently 9, this would generate a parametric time value of 9/19 = 0.47 (approximate halfway through the 600 tick cycle). If we imagine this part in isolation, when calculated for every keyframe for this node, we are generating 20 parametric time values for each of the keyframes for the current bone. Obviously we will want each keyframe for this node to have a different rotation angle so that our branch sways backwards and forwards over time. It is intuitive then that the parametric time of the keyframe will need to play some part in its rotation angle.

We then add a Delay factor to this value. The Delay is in the range of –1.0 to 0.0 and will be closer to –1.0 the nearer to the ends of the branches the current bone we are processing is situated. Essentially, before the delay is added, we are calculating the actual time value parametrically for the current keyframe in the sequence for this bone. By adding the delay, we are effectively setting back the time (delaying) based on the position of the bone in the tree. While perhaps still not clear at this point, we have discussed how we wish the movement of bones nearer the top of the tree to seem more delayed than those near the bottom. So we are offsetting the parametric value by 0.0 to –1.0 based on the bone's position up the tree.

At this point that we have a possible range of values between –1.0 and 1.0 depending on the value of 'i' (the current keyframe being calculated for the node) and the delay (the iteration of the node in the tree). We will now map this –1 to +1 possible range of values into the –360 to +360 range by multiplying by 360 degrees ($\pi * 2$). Of course, we will work in radians, so the range of fInput after the above line will be [–6.28, +6.28].

Why would we want the position of the keyframe (with the appropriate delay added) mapped over the range of two circles (-360 to +360)? The reason is that we are going to use the shape of the cosine waveform to generate a scalar value which will be used to scale the wind strength value and the fMovement value we calculated earlier. At the top of the function, the fMovement value was calculated as a value between 0.0 and 1.0, based on the distance of the node from the base of the tree.

How does the cosine help us? To understand that, let us have a look at a graph of what the cosine function looks like if we plot its values over a large range of degrees (Figure 12.50).

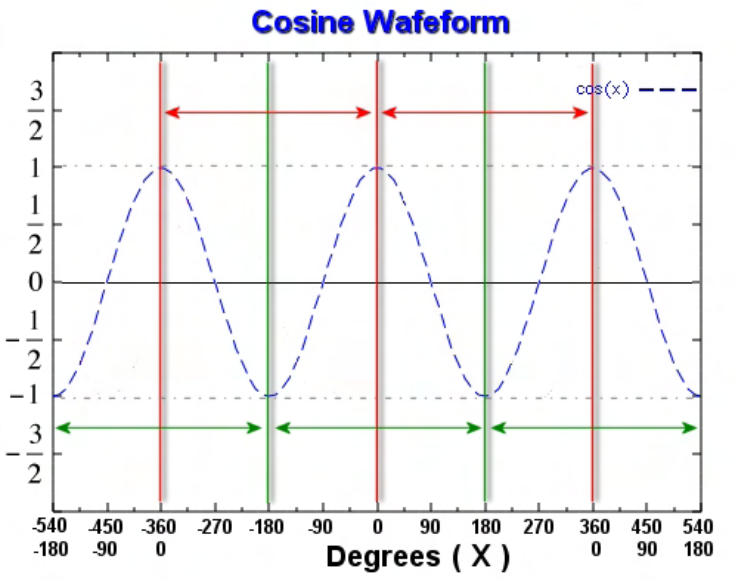

Figure 12.50

The output from the cosine function is between –1 and +1 over the range of a 360 degree circle. Furthermore, we can feed it values outside of this range and it will automatically wrap around to continue the shape of the waveform.

We can see for example that if we were to feed it values between 0 degrees (where the cosine is 1.0) to 180 degrees (where the cosine is –1) and then continue up to 360 degrees, the curve climbs back up again to a value of 1.0. This pattern is repeated as we increase or decrease values.

We can use the shape of this waveform to influence the angle by which we rotate a bone, such that the rotation pattern for the tree follows the cosine shape. For example, let us imagine that we are currently processing the first node in the tree, which would have a delay of zero. Also assume that there is a maximum of five keyframes for this frame. We know that in this case the value of fInput in the above calculation (for each keyframe) would be in the range [0, 360] degrees or [0, 6.28] radians. If we send each of these five values into the cosine function, we essentially plot five positions on the cosine waveform as shown in Figure 12.51.

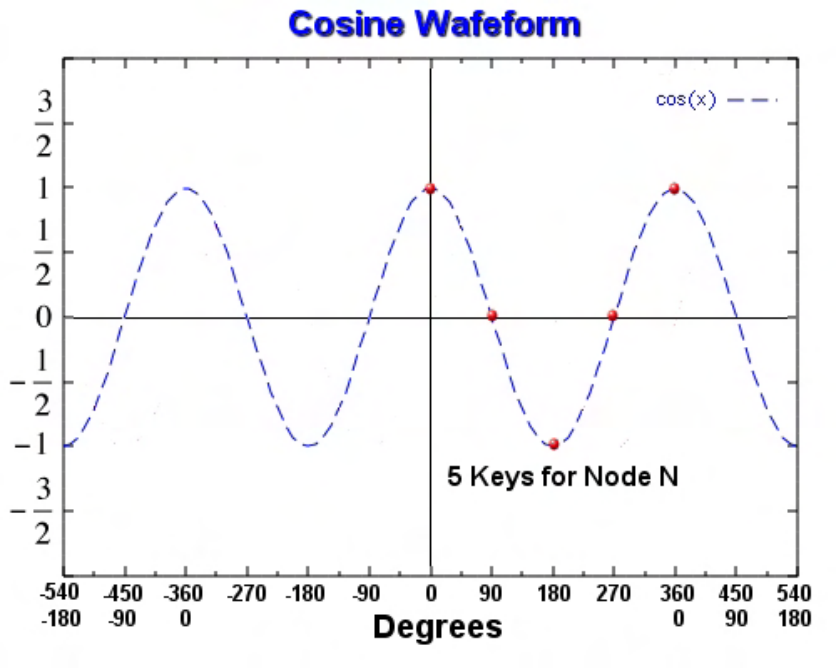

Figure 12.51

As you can see, the value assigned to each of the five nodes would be plotted on the graph and would return a value in the –1 to +1 range. This is not quite what we want at the moment, we want a value in the 0 to 1 range to act as our rotation scaling factor, but we will perform that mapping in a moment.

We see that the first node would have an input value of 0 and would therefore be assigned a height of 1 on the cosine graph. The next node would have an input of 90 degrees and would be assigned a height of 0. The third would have an input value of 180 and would be assigned a height of –180, and so on. By the time we get to the fifth node, the values start to repeat themselves.

If we imagine these values in the range of 0.0 to 1.0 (instead of –1 to +1) we can see that the result of the cosine function would return a scaling value, such that the first node would have full rotation applied, the second node half rotation, the third node no rotation, the fourth half rotation and the fifth full rotation, and the pattern continues. In other words, if we imagine these values being used to scale a rotation angle, we can see that the node would start at time zero in its fully rotated position, and over the five nodes, would rotate back to a rotation of zero and back out to a position of full rotation at the final node. Thus it is obvious why we are not happy with using the direct result from the cosine function -- it would be in the –1 to +1 range and we never want to invert the rotation angle, only scale it from zero to full rotation. The following code feeds in the input value into the cosine function and maps the result into the 0.0 to 1.0 range.

```
            float fCycle = (cosf( fInput ) + 1.0f) / 2.0f;
```

So using the above technique we essentially generate unique rotation values for each keyframe for a node. The pattern follows the shape of the cosine waveform to create a cyclical template for us to use (perfect for swaying our branches back and forth). But how did the initial fDelay value play a part? While the keyframes of the root node will always generate an fInput parameter in the range of 0-360

degrees (when fDelay=0), we must remember that the delay member can be in the range of 0.0 to –1.0. For the final node this would generate keyframes in the range of –360 to 0 degrees, which comes a whole cycle earlier on the cosine waveform. Therefore, what we are doing with this delay is moving all the nodes back from zero into the previous cosine cycle based on distance from the root node of the tree. For example, in Figure 12.52 we see how a node that is not the root node has had its cosine input value offset by the negative delay value. Note that the plotted points on the cosine graph lag behind the root node's plotted points.

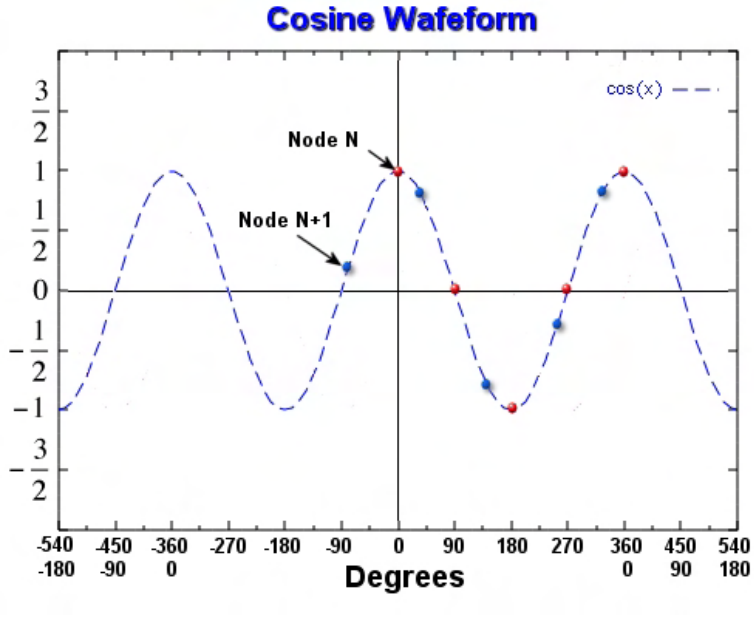

Figure 12.52

Hopefully you get the idea. The second node will have a different scaling value for each of its keyframes, but the pattern by which those angle scaling values transition from 0.0 to 1.0 will be the same. It will just be offset to some degree and mapped to a different interval of the waveform. Each node in the tree will still have the angle scaled by a complete 360 degree interval of the cosine waveform; it is just that for nodes further from the root, their initial start position on the waveform is shifted back to some position between 0 to –360.

We now have a local variable called fCycle which contains a value in the [0.0, 1.0] range. It describes how the rotation angle that we apply to this bone should be scaled based on the position of the node in the tree and the position of the keyframe we are currently processing in the keyframe list. What happens next?

Well, we know that the fWindStrength variable describes the strength of rotation in some way. Actually, we can think of this value as being the base rotation angle. For example, if a value of 30.0 was passed as the wind strength, this essentially describes a maximum rotation of 30 degrees at the branch end nodes (since the fCycle value we just calculated ranges from 0.0 to 1.0). So, we could just do fCycle * fWindStrength to get a rotation angle in the range of 0 to 30 degrees (in this example) that describes the rotation of the current keyframe. However, let us not forget that we calculated the fMovement value earlier (range = [0.0, 1.0]) which parametrically describes the distance from the

current node to the root node (0.0 = root node). As discussed, we definitely do not want the root nodes of the tree blowing back and forth nearly as much as the branch end nodes.

The fMovement value can be used to scale the wind strength angle (fMovement * fWindStrength) such that at the end nodes the rotation angle will be (1.0 * fWindStrength = Full Rotation) and at the root node it will be (0.0 * fWindStrength = No Rotation). So, we have the rotation angle for each node based on its position in the tree. This describes the maximum amount it will rotate through the sequence. We then must scale this by the fCycle value to account for the position of the current keyframe on the cosine waveform.

Angle = fCycle * (fMovement * fWindStrength)

If fWindStrength was 30 degrees and the node currently being processed was halfway up the tree from the root node, the fMovement value would be 0.5 and the maximum rotation angle for this node would be 15 degrees. Then, for each keyframe, fCycle would be a value in the range of 0.0 to 1.0, scaling the 15 degree rotation angle based on the position of the keyframe in the sequence and the delay for that node. Essentially, we generate a sequence where the bone will rotate between 0.0 and 15 degrees over its initial animation cycle and then rotate back to zero.

We are almost done, but not quite just yet. It will look unnatural if the wind is blowing our branches only to and from their default orientations. In real life, if we were to bend a branch and let it go, it would not neatly snap back to zero deviation, but likely overshoot the original center point (because of inertia) by some amount and oscillate. Perhaps it would bend 5 degrees in the negative direction before resetting itself. We will want to simulate the same thing at a simplistic level. Therefore, we will subtract 0.25 from the fCycle value to map it from [0.0, 1.0] to [–0.25, +0.75]. If a bone has a maximum rotation of 80 degrees, instead of rotating 80 degrees in one direction and then 80 degrees back to its starting position, it will actually rotate between –20 and +60 degrees. This means it will sway either side of its original starting position but with a ¾ bias in the wind direction. The final line that calculates the rotation angle is shown below.

```
  float fAngle = (fCycle - 0.25f) * (fMovement * fWindStrength);
```

We now have the angle, so our next task is to generate a rotation quaternion that represents a rotation angle equal the one we have just calculated for the wind rotation axis. To do this we will use the D3DXQuaternionRotationAxis function. We pass it an angle in radians and a rotation axis vector, and it will return a quaternion that represents the angle/axis rotation.

```
            // Rotate quaternion
            D3DXQuaternionRotationAxis( &quatRotate,
                                        &vecChildWindAxis,
                                        D3DXToRadian( fAngle ) );
```

Now all we have to do is multiply this rotation quaternion with the original quaternion we extracted from the frame matrix. This results in a quaternion that describes the orientation of the bone at this keyframe. Notice how we use the D3DXQuaternionMultiply function to rotate the original quaternion and then perform a quaternion conjugate on this quaternion to make it right handed. For some reason (as we discussed in Chapter 10), the D3DX animation system expects right handed quaternions even though

the D3DX quaternion functions generate left handed ones. The Conjugate function simply negates the axis of the quaternion so that it is pointing positive in the opposite direction (-x , -y , -z). We store the result of the conjugate directly in the keyframe's value. That completes the inner loop code and the process used to generate each of the 20 rotation keyframes for the current node.

```
            D3DXQuaternionMultiply( &quatValue, &quatValue, &quatRotate );

            // Conjugate quat into storage.
            D3DXQuaternionConjugate( &pRotation[i].Value, &quatValue );

        } // Next Key
```

As discussed earlier, we need to store at least two translation keyframes or GetSRT will interpolate between <0,0,0> and <0,0,0> (which will always return a result of <0,0,0>) and overwrite the true position of the frame when we call AdvanceTime. Therefore, for each node, we create two translation keyframes, one at the start of the timeline and one at the end, that both store the same frame position. This position is extracted from the translation vector of the frame matrix. The animation system will simply interpolate the translation value between the start position and the end position, which are the same, leaving the position of the frame constant.

```
        // Generate two bounding translation keys from original matrix
        pTranslation[0].Time  = 0.0f;
        pTranslation[0].Value = D3DXVECTOR3( pFrame->TransformationMatrix._41,
                                             pFrame->TransformationMatrix._42,
                                             pFrame->TransformationMatrix._43 );

        pTranslation[1].Time  = MaxTime;
        pTranslation[1].Value = D3DXVECTOR3( pFrame->TransformationMatrix._41,
                                             pFrame->TransformationMatrix._42,
                                             pFrame->TransformationMatrix._43 );

        // Register the animation keys
        hRet = pAnimSet->RegisterAnimationSRTKeys( pFrame->Name,
                                                   0,
                                                   KeyCount,
                                                   2,
                                                   NULL,
                                                   pRotation,
                                                   pTranslation, NULL );

    } // End if this is a bone node
```

In the above code, you can then see that after we have built the two translation vectors, we have all the information we need to build the animation for this frame in the hierarchy. We have an array of 20 rotation keyframes and 2 positional keyframes. We then register those keyframes with the animation set. Notice how we are careful to assign the name of the animation the same as the frame it is intended to animate. Remember, the animation controller uses this as its means for linking frames to animations. That ends the entire code block that is executed if the current node we are processing is a bone node. If not, all of the above code will be skipped and no animation will be created.

Finally, at the bottom of the function we see the common code that is executed for all nodes and not just bone nodes. It recurses along the sibling list if it exists and then down into the child list.

```
    // Build the nodes for child & sibling
    if ( pNode->Sibling )
    {
        hRet = BuildNodeAnimation( pNode->Sibling,
                                   vecWindAxis,
                                   fWindStrength,
                                   pAnimSet );

        if (FAILED(hRet)) return hRet;

    } // End if has sibling

    if ( pNode->Child )
    {
        hRet = BuildNodeAnimation(  pNode->Child,
                                    vecChildWindAxis,
                                    fWindStrength,
                                    pAnimSet );

        if (FAILED(hRet)) return hRet;

    } // End if has child

    // Success!!
    return D3D_OK;
}
```

When the root iteration of this function (called from GenerateAnimation) returns, the animations for every bone in the hierarchy will have been constructed and added to the animation set. We saw earlier that when program flow returns, the GenerateAnimation function then registers the animation set with the controller and assigns it to an active mixer track.

That brings us to the end of our first tree discussion. Granted, there was quite a lot to take in, but it really did provide some very good insight into how skeletons and skins and animation all tie together.

12.6 Results

Lab Project 12.1 implements everything we have discussed so far in this chapter. Our tree class does not yet support adding leaves to the branches, but that is what the second part of this chapter will discuss. An example of a tree generated by Lab Project 12.1 is shown in Figure 12.53.

Admittedly, this does not look very impressive at the moment, but when we add leaves to this tree there will be a vast improvement. Since we will essentially just be adding new code to what we have already developed, it is recommended that, before reading any further, you examine the source code to Lab Project 12.1 and make sure that you understand the previous section of this textbook.

Figure 12.53

12.7 Adding Leaves to our Trees

Figure 12.54

For the remainder of this textbook we will discuss an upgrade to our tree system that allows us to significantly increase both detail and realism. Figure 12.54 shows a screenshot of a CTreeActor generated using the techniques we will discuss in this section. Looking at the image in Figure 12.54 it would seem as if our current code is a long way from creating trees of such detail. But as it happens, all that will be needed are a few (small) extra functions and a few minor tweaks to some existing code. After that, our CTreeActor class will be generating lush green trees as illustrated here.

The process of adding leaves to our tree will be one of adding a new branch node type to the virtual tree building process. Currently, a branch node can either be a BRANCH_BEGIN node which means it starts a new branch, a BRANCH_SEGMENT node which means it is just another segment in the branch, or a BRANCH_END node which means it ends the branch and represents the insertion of the tip vertex. We also know that any node in our virtual tree can have any of these nodes as its children. For example, we know that a given branch node might have three child nodes: a segment node that continues the branch and two branch start nodes that spawn new branches from that point. We will now introduce a new node type into our virtual tree referred to as a *frond node*.

Whenever a frond node is generated, we will insert special geometry into its parent branch mesh that will create leaves and the tiny little stalks that connect those leaves to their parent branch. You will see in a moment that while this might sound complicated, we represent a frond as two, two-sided quads criss-crossed and textured with a frond texture (see Figure 12.55).

> **Note:** The botanical meaning of the word “frond” is literally a leaf and its supporting structure (its stalk). So we will be adding not just leaves, but full fronds. That is, the leaves and the tiny twigs which connect them to their parent branch.

Figure 12.55

In Figure 12.55 we see the geometry that will be added to the branch mesh for a single frond node. The texture we apply to the intersecting quads is obviously going to be very important. In our application, we use a texture that contains not both the leaves and the stalk that will attach to the parent branch. This is important because when a frond node is randomly generated along a branch during the virtual tree building process, the position assigned to the frond node will be the same as the parent node that spawned it. That is, the base of the criss-crossed polygons shown in Figure 12.55 will actually begin

inside the branch mesh (at the center of the parent branch segment). As such, the stalk of the frond will be seen sticking out of the parent branch (like little branches flourishing into leafy tips).

With regards to the virtual tree building process, frond nodes are like normal branch nodes. They have a position and a direction vector which is deviated from the parent just like normal branch nodes. There is only one real difference between a frond node and a normal branch node; a frond node will never have any child nodes of its own. We can think of them as being child branches that are always one node in length. In this way, we can think of a frond node as being a little like a child branch being spawned in the traditional sense, where its first branch node is a branch end node. Frond nodes can be spawned from any other branch node, and although it is possible to have any given branch node spawn multiple frond nodes, in our implementation we found that this was not necessary. By giving each node a chance to create a single child front node we get trees with plenty of foliage. When the frond geometry created at one branch node overlaps the frond geometry created at its neighboring branch node we get a jumbled mix of leaves that can look very full and bushy.

In Figure 12.55 we can see that by adding four quads for a given frond node (remember that both the intersecting quads must be two-faced, which equates to four quads in total) we are able to simulate a lot of detail with a very low polygon count. Of course, much depends on how detailed the frond texture is. If the texture contained a single leaf, many more frond nodes would have to be created to build up a busy looking tree (and probably would not look very good anyway). The texture image we used in our demonstration actually contains multiple leaves and their stalks, connected by a central thin branch. The frond geometry created in Figure 12.55, if added to our tree and rendered in the way illustrated, would look quite terrible because we can clearly see the black background of the texture. This makes it a little too obvious that we are just mapping textures to quads and randomly scattering them through the tree.

Figure 12.56

Not surprisingly, our frond texture has an alpha channel so that we can enable alpha testing in the pipeline and filter out the black background pixels. Only the branch and leaf pixels will be rendered to the frame buffer. This allows other branches and frond constructs to be seen through the gaps in those leaves. We will set the pipeline alpha testing mechanism to reject any pixels from the texture that are below a certain alpha value. This will stop nearly all the background pixels being rendered.

The problem with just performing this test however is that if you study the alpha channels for such textures, they usually blend from transparent to opaque around the outside of the leaves. Therefore, even with alpha testing enabled, we can still see a dark silhouette around the leaf boundaries where the pixels are slightly darker and have alpha values that are just above the rejection value set as the alpha testing reference. If we enable alpha blending, we can remedy this using the SRC_ALPHA and INV_SRCALPH blend modes from the source and destination blend modes respectively. This will cause what was once a dark silhouette around the main image to blend with the contents of the frame buffer. With alpha blending and alpha testing enabled, the boxes around the frond texture image are removed, the quads are no longer visible, and we

end up with quite organic looking foliage (see Figure 12.56). This is a very common technique in real-time games and it is used to produce all manner of foliage, not just fronds.

12.7.1 The Frond Node

Our virtual tree building function (BuildBranchNodes) will have to be modified so that at any given branch node, it also has the ability to spawn child frond nodes. It is important to realize at this point that the frond node is not really any different from a normal branch node. The node's direction and right vector will still be deviated from its parent and the direction vector of the frond node will be used in the mesh building process to construct the direction of the frond construct. Just as in the normal branch building process, where the branch node position and direction vector describe a plane on which a ring of vertices will be placed, the frond node normal and position describe the orientation of a plane on which the base of the frond quads will be mounted (Figure 12.57).

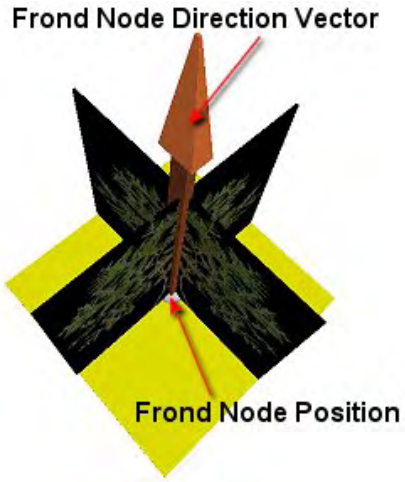

Figure 12.57

In Figure 12.57 the large brown arrow describes the direction of the node which was randomly deviated during node creation. The yellow slab represents the plane described by the node position and the direction vector. If this was a normal branch node, this the plane on which the ring of vertices would be placed. However, because this is a frond node, during the mesh building process we will build the two intersecting two-sided quads where the bottom vertices of each quad lay on the plane and the top vertices of each quad are offset from the plane in the direction of the node plane normal. That way, whichever way the plane is facing, the quads will always have their bottom vertices attached to the plane and the fronds will always point in the direction described by the node direction vector. As you have no doubt gathered by now, the only real difference between a normal branch node and a frond branch node is how each is treated during the mesh creation phase. The building of the virtual tree of branch node structures will require very few modifications. All it needs is the ability to randomly create frond nodes, just like it creates any other child node.

So that we are clear on how these nodes will be placed and how the geometry for these frond nodes will be generated, before we discuss the code let us just look at an example of how multiple frond nodes may be created to provide a nice combined visual effect.

In Figure 12.58 we see a tree that has a branch that contains a single frond node between its second and third branch segment. The position of the frond node will be inherited from its parent. Therefore, we can see that the frond node is the child of the branch node that forms the end of segment two and the beginning of segment three in the parent branch. We can also see that at the exact same spot the frond node is spawned, a new child branch is also spawned.

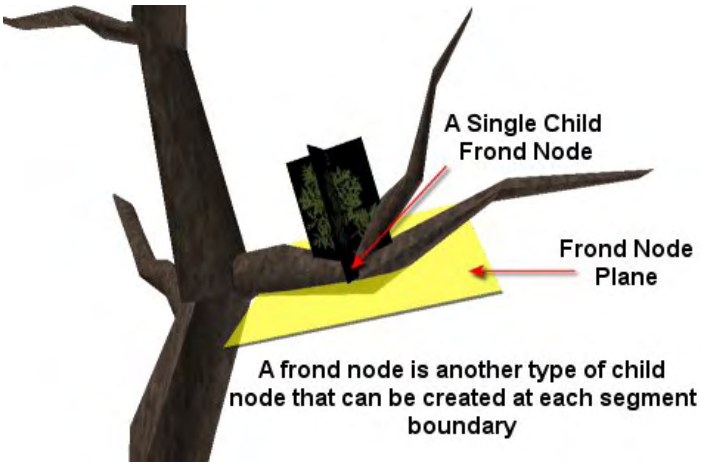

Figure 12.58

As discussed, the frond node is assigned an arbitrary direction just like any other node. The direction vector of this particular frond node, along with its position, would describe the orientation of the yellow plane in the diagram. Notice how the orientation of the frond quads is such that they are aligned to this plane. It is like the plane forms the base on which the quads are mounted and as such, the orientation of this plane determines the orientation of the frond construct. Therefore, we can think of the direction vector of the frond node as not just describing the normal to this plane, but also describing the orientation of the central spine of the frond construct where the quads intersect one another. So generating a frond node is identical to generating any other node during the virtual tree building process. We just generate a new node of type frond and assign it the direction and right vectors as normal.

The position and frequency at which frond nodes are generated will be controlled by some additional members in our TreeGrowthProperties structure. Of course, we will generally want to spawn frond nodes much more frequently than branch nodes so that we get satisfactorily dense foliage. We will often wish to spawn many child frond nodes from each parent. For example, Figure 12.59 shows the same parent node in the branch now spawning multiple frond nodes. Notice how each frond node (just like a branch start node) is randomly deviated so that we have multiple frond constructs originating from the same position in the branch but having arbitrary directions. In this example, the branch node has spawned four frond nodes as children, and also exists in a sibling list with a branch start node.

Figure 12.59

When we couple the fact that every node that meets the frond growth requirements (specified in the TreeGrowthProperties structure) can spawn multiple child frond nodes with the fact that most branch nodes will spawn child frond nodes, we have a situation where neighboring branch nodes spawn multiple fronds which all collide and overlap with each other making for a very busy looking tree. Figure 12.60 demonstrates this concept by showing just two branch nodes in close proximity that have each spawned multiple frond nodes. Even in this example, the tree is starting to look pretty busy. Imagine the same number of frond nodes being generated at most branch nodes and we can image how full our foliage will look. Because fronds from neighboring branch nodes collide and overlap it actually adds to the chaotic realism of the tree.

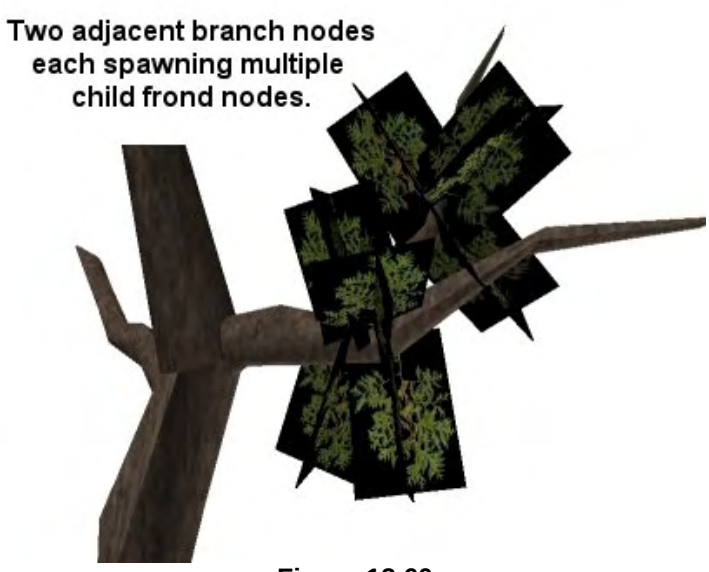

Figure 12.60

If we take the example shown in Figure 12.60 and add alpha testing and alpha blending, we can see that the results are starting to look quite pleasing even in this example where only two branch nodes are spawning fronds. The alpha tested/blended result is shown in Figure 12.61.

Figure 12.61

> **Note:** In our demo implementation we only generate one child frond node for any given parent. That is, a branch node will either have zero or one child frond nodes and never any more. However, this is certainly a behavior you can change to generate trees with more dense foliage. At the moment we are talking generically about the technique.

Now that we know exactly where frond nodes should exist and we understand the geometry they use, we can discuss the additions to the CTreeActor class that will need to be made to add frond support to the code developed in Lab Project 12.1. As we will, for the most part, simply be discussing additions to pre-existing functions, it is highly recommended that while reading this next section you open up the source

code to lab project 12.2 so that you can follow along with the code changes made in this section of the textbook. In most cases, we will not be showing all of the function code again, but only discussing the changes that have been made.

12.7.2 Updating the Virtual Tree Generation Process

As we know from the coverage of Lab Project 12.1, the first phase of the tree generation process is the construction of the virtual tree (the tree of BranchNode structures). Phase one is activated from the GenerateTree method (called by the application) via a call to the function GenerateBranches. You will recall that this function simply created the root branch node (or multiple root nodes if applicable) and then called the BuildBranchNodes function to kick off the recursive process for each root. The BuildBranchNodes function recursively called itself, adding branch nodes to the virtual tree hierarchy until it had been completely built.

For any given instance of the BuildBranchNodes method there was a simple task. The underlying question was, using the probabilities specified in the TreeGrowthProperties structure, should the current node being processed spawn a child node that continues the branch or an end node that ends it? Apart from this, it also decided how many BRANCH_BEGIN nodes should be generated as children of the current node. Recall that a BRANCH_BEGIN node signifies the beginning of a new child branch spawning from the parent.

This function will have to be modified so that it now has the option to randomly generate child frond nodes. Previously the strategy was simply:

1. Does this branch continue?
   Yes: Create child BRANCH_SEGMENT node and recur into Child Node
   No : Create child BRANCH_END node and recur into Child Node

2. Do we wish to create any child branches?
   Yes: Decide how many and create each child BRANCH_BEGIN node and recur into each
   No : Do nothing and just return

Of course, any given instance of the function returned if it had stepped into an end node. This logic will not change, but it will be supplemented. As you can see, the first step was to determine what type of node the next node in the current branch will be and to process it. The second step was to determine if child branches should also be started at this node and have the relevant child nodes created.

Now, after recursively processing the node that continues the branch and any child branch start nodes, we will add a third section that decides whether we would like to add a child frond node. Currently, each branch node can be one of three types: BRANCH_BEGIN, BRANCH_SEGMENT, or BRANCH_END. Now we will add a fourth type to the BranchNodeType enumeration called BRANCH_FROND. The updated enumeration, which is part of the CTreeActor namespace, is shown below.

Excerpt from CTreeActor.h

```
enum BranchNodeType {   BRANCH_BEGIN      = 1,
                        BRANCH_SEGMENT    = 2,
                        BRANCH_END        = 3,
                        BRANCH_FROND      = 4 };
```

Whether we create a frond node at any given parent node will once again be a random decision within limits given by the probabilities set in the TreeGrowthProperties structure. We will add five members to this structure which will be used by the virtual tree generation process to decide if a frond node should be created at a given node in the tree. Below we see the five new members of the TreeGrowthProperties structure (as defined in CTreeActor.h) followed by a description of each member and how it is used by the BuildBranchNodes method.

TreeGrowthProperties Structure (additions)

```
bool        Include_Fronds;             // Include fronds in the build
USHORT      Min_Frond_Create_Iteration; // Min iteration fronds can be created.
float       Frond_Create_Chance;        // Chance frond will be created at a node
D3DXVECTOR3 Frond_Min_Size;             // The smallest size a frond can be
D3DXVECTOR3 Frond_Max_Size;             // The largest size a frond can be
```

bool Include_Fronds

This boolean is used as a frond switch. Setting it to false will disable the generation of frond nodes and we will get trees identical to the ones from Lab Project 12.1. Setting this to true (default) will enable frond generation.

USHORT Min_Frond_Create_Iteration

We want to be able to control the node iteration at which frond nodes are created. The concept of a node's iteration is not new to us; it describes depth in the hierarchy (the number of branch segments that would need to be traversed from the root of the tree to reach that node). This value describes how many nodes deep in the hierarchy we must be before frond nodes are created. We do not usually want this to be set to a low number (or zero) or we will see frond nodes at the root of the tree. Usually, we want the fronds to start only when we get a certain way up the tree and out along the branches. The default value is 6. So fronds will not be generated at a given node while its depth in the hierarchy is smaller than 6 levels below than the root.

float Frond_Create_Chance

This property which (range = [0.0, 100.0] describes the probability that a frond node will be created as a child of the current node being processed (assuming the hierarchy depth test passes). For any given non-frond node that we are processing we will generate a random value between zero and one hundred. If the value is less than this probability, a new child frond node will be generated. Higher values for this property create more fronds and bushier trees.

D3DXVECTOR3 Frond_Min_Size
D3DXVECTOR3 Frond_Max_Size

We will usually want our fronds to become smaller in size as they progress up the tree. These two vectors describe the minimum and maximum sizes that a frond can fall between. These vectors actually describe the half-lengths of the intersecting quads (x,y) that will be generated. The z components of these vectors describe the height range for the quads (i.e., the height with respect to the node plane they

are mounted on). Larger z values will essentially create longer fronds. We will see how these values are used in the branch mesh creation phase (phase 2).

Although these properties (along with all the other tree growth properties) can be set by the application using the CTreeActor::SetGrowthProperties method, default values are specified in the constructor, as shown below.

Excerpt from CTreeActor.cpp : CTreeActor::constructor

```
// Setup frond defaults
m_Properties.Include_Fronds             = true;
m_Properties.Min_Frond_Create_Iteration = 6;
m_Properties.Frond_Create_Chance        = 25.0;
m_Properties.Frond_Min_Size             = D3DXVECTOR3( 7.5f, 7.5f, 11.25f );
m_Properties.Frond_Max_Size             = D3DXVECTOR3( 10.5f, 10.5f, 15.75f );
```

Let us now take a look at the code that has been added to the end of the BuildBranchNodes function to allow for the random generation of a child frond node.

CTreeActor::BuildBranchNodes - Updated

It is advisable to load up the source code to the BuildBranchNodes function in Lab Project 12.2. This function was covered in a lot of detail in the first section of this chapter and should be fully understood. We are now going to add a new conditional code block to the bottom of this function to create a new child BRANCH_FROND node. We will show only the new code.

```
…
…
…
} // End create child branch nodes

// Should a frond be created as a child of this node?
if ( m_Properties.Include_Fronds &&
     Iteration >= m_Properties.Min_Frond_Create_Iteration
     && (bEnd || ChanceResult( m_Properties.Frond_Create_Chance )) )
    {
```

In the above code we see that we only enter this new code block if the iteration value of the current node being processed is larger or equal to the Min_Frond_Create_Iteration growth property and if the boolean growth property bInclude_Fronds has been set to true. If these conditions are true and the ChanceResult function returns true (notice we feed in the Frond_Create_Chance growth property as the parameter) or if we have just created a child BRANCH_END node, we will create a child frond node. (We will always generate a frond node at a branch end node provided its iteration value is larger than Min_Frond_Create_Iteration).

If we get into this code block then we wish to create a new frond node. We allocate a new branch node and set its properties much like we do any other node.

```
        // If this node was the end of a branch, insert a frond node
        BranchNode * pFrondNode = new BranchNode;
        if ( !pFrondNode ) return;

        // Store node details
        pFrondNode->UID          = BranchUID++;
        pFrondNode->Parent       = pNode;
        pFrondNode->Dimensions   = pNode->Dimensions;
        pFrondNode->Position     = pNode->Position;
        pFrondNode->Direction    = pNode->Direction;
        pFrondNode->Right        = pNode->Right;
        pFrondNode->BranchSegment= 0;
        pFrondNode->Iteration    = (USHORT)Iteration + 1;
        pFrondNode->Type         = BRANCH_FROND;
```

Notice how the position and dimensions are inherited from the parent node and it is assigned its own unique ID like all other branch nodes. This time however, the Type member of the BranchNode structure is set to BRANCH_FROND. We inherit the direction and right vectors from the parent and these will be deviated in the next line of code using the same deviation angle ranges as a normal BRANCH_BEGIN node.

```
        // Deviate the node
        DeviateNode( pFrondNode,
                     m_Properties.Split_Deviation_Min_Cone,
                     m_Properties.Split_Deviation_Max_Cone,
                     m_Properties.Split_Deviation_Rotate );
```

At this point we have created a new frond node and have it located at the position of the parent node, pointing in an arbitrary direction (just like the start of a new branch). However, the frond node is not yet attached to the parent node's child list.

We need to make sure we add it to the right place in the child list if the parent node already has child nodes. It is important when building the skinning information that if the parent node contains a branch end node child, that the frond node be placed before it in the list. The vertices of the frond will be added as influences of the previous bone that was created back from it along the branch, so we wish to add these vertices before hitting the branch end node, where we add the single tip vertex and abort any further processing of the branch. The next section of code makes sure it is added to the child list prior to any BRANCH_END node that may exist there.

```
        // Link the node
        if ( !pNode->Child )
        {
            // No child already exists, just store
            pNode->Child = pFrondNode;

        } // End if no child node
```

As the above code shows, if the parent node has no other children, then we just assign its child pointer to point at the new frond node. Our new frond node will be the only node in the child list. Otherwise, the next code block is executed.

The following code sets up a while loop to traverse the child list and breaks from the loop as soon as a BRANCH_END node is found. Because with every iteration of the loop it stores the current child in its pPrev pointer before stepping into the next sibling, if the loop breaks because a BRANCH_END node is found, the pPrev pointer will point at the sibling node that exists prior to the end node in the list (the node to which we wish to add our new frond node as a sibling). That is, we will sandwich our new frond node between the branch end node and the node that existed prior to it in the sibling list.

```
        else
        {
            BranchNode * pTemp = pNode->Child, *pPrev = NULL;
            while ( pTemp )
            {
                // Have we found the end of the branch?
                if ( pTemp->Type == BRANCH_END ) break;
                pPrev = pTemp;
                pTemp = pTemp->Sibling;

            } // Next sibling

            if ( !pPrev )
            {
                // The BRANCH_END is right at the start.
                pFrondNode->Sibling = pNode->Child;
                pNode->Child = pFrondNode;

            } // End if no previous item
            else
            {
                // Attach to the 'previous' item.
                pFrondNode->Sibling = pPrev->Sibling;
                pPrev->Sibling = pFrondNode;

            } // End if previous item exists

        } // End if child node

    } // End if create frond

} // End function
```

And that represents all the code changes that had to be made in BuildBranchNode.

What is important to notice in the above code is that unlike normal branch node creation, where after it is created we recur into that node, for frond nodes we do not do this. We can think of a frond node as being a single node branch. We never recur into a frond node or add other child nodes to it.

12.7.3 Setting the Frond Texture and Material

In our previous incarnation of CTreeActor we had the ability to store the texture and material that would be used to render the branches of the tree. We exposed a method to allow the application to set these properties prior to the call to the GenerateTree function. We will now need to add two new members to CTreeActor that will contain the texture filename and material that will be used for the fronds. An accompanying member function will allow the application to set these properties prior to tree generation.

Excerpt from CTreeActor (Additional Member Variables)

```
D3DMATERIAL9 m_FrondMaterial;    // The material to apply to the fronds.
LPTSTR       m_strFrondTexture;  // The texture to apply to the fronds.
```

CTreeActor – SetFrondMaterial

This function accepts two parameters: a string containing the name of the image file we would like to use as the texture for the fronds and a pointer to a D3DMATERIAL9 structure. The texture and material are copied into the class member variables.

```
void CTreeActor::SetFrondMaterial( LPCTSTR strTexture, D3DMATERIAL9 * pMaterial )
{
    // Free any previous texture name
    if ( m_strFrondTexture ) free( m_strFrondTexture );
    m_strFrondTexture = NULL;

    // Store the material
    if ( pMaterial ) m_FrondMaterial = *pMaterial;

    // Duplicate the texture filename if any
    if ( strTexture ) m_strFrondTexture = _tcsdup( strTexture );
}
```

In the next section we will discuss the upgrades to the CTreeActor::BuildNode method. We discovered in the first section of this textbook that this method implements the second phase where the actor's hierarchy and branch skins are constructed. We will only examine the portions containing the updated code, so it is recommended that you open Lab Project 12.2 and follow along in the next section using the actual source code.

Updating CTreeActor::BuildNode

This function is called once by the BuildFrameHierarchy function and is passed the root node of the virtual tree. It steps through the hierarchy recursively from the root node visiting each branch node in the tree. For a given node, this function would add a frame to the actor's hierarchy if it was determined that

the current node should generate a bone. If the node is a BRANCH_BEGIN node, a new CTriMesh would be created and the branch would be traversed to add the vertex and index data. For any non-branch node that is not a BRANCH_BEGIN node the passed mesh is the mesh that is currently being built for the current branch being processed (i.e., the mesh that the vertices generated at this node should be added to).

In the first section of the code shown below you can see that we have snipped out nearly all the logic that generates the new frame if this is a bone node. A bone is never generated for a BRANCH_END node and likewise, if it is a BRANCH_FROND node, a bone will also *not* be created. Therefore, the code inside this conditional is completely unchanged (the conditional code never gets executed if the current node is a frond node).

We have removed all the code that generates the new frame and attaches it to the hierarchy as well as the code that creates the new CTriMesh if the current node is a BRANCH_BEGIN (bones are always added to the start of a branch). What we have left in place as a reminder at the bottom of the code block is the call to the AddBranchSegment method which was responsible for adding the ring of vertices and their indices to the mesh.

```
HRESULT CTreeActor::BuildNode( BranchNode * pNode,
                               D3DXFRAME * pParent,
                               CTriMesh * pMesh,
                               const D3DXMATRIX & mtxCombined,
                               ID3DXAllocateHierarchy * pAllocate )
{
    HRESULT     hRet;
    CTriMesh   *pNewMesh  = NULL, *pChildMesh  = NULL;
    LPD3DXFRAME pNewFrame = NULL,  pChildFrame = NULL;
    D3DXMATRIX  mtxBranch, mtxInverse, mtxChild;
    D3DXVECTOR3 vecX, vecY, vecZ;
    TCHAR       strName[1024];

    // What type of node is this
    bool bIgnoreNodeForBone = (pNode->Type == BRANCH_END ||
                               pNode->Type == BRANCH_FROND);

    if ( pNode->Type == BRANCH_BEGIN ||
        ((pNode->BranchSegment % m_Properties.Bone_Resolution) == 0 &&
         !bIgnoreNodeForBone) )
    {
        …
        …
        …
        …  --- snip ---   ( Create Frame and Setup Parameters to pass to child)
        …
        …
        …

        // Add the ring for this segment in this frame's combined space
        hRet = AddBranchSegment( pNode, pChildMesh );
        if ( FAILED(hRet) ) { if (pNewMesh) delete pNewMesh; return hRet; }

    } // End if adding a new frame
```

The next section of code was executed if the current node is not a BRANCH_BEGIN node and is not a node that should have a bone created for it. You will recall that originally this just meant calling the AddBranchSegment function to add a ring of vertices to the current mesh being built (the one passed into the function from the parent). Now we have some conditional logic. If the current node is a BRANCH_FROND node then we do not call the AddBranchSegment function since we do not wish a ring of vertices to be inserted on the frond node plane. Instead, we wish to insert vertices into the mesh that will build the intersecting quads for the frond. Therefore, we call a new method called AddBranchFrond to add the frond geometry to the current mesh. This function will be discussed in a moment.

```
    else
    {
        // Store which bone we're assigned to in the node
        pNode->pBone = pParent;

         // Is this a frond?
        if ( pNode->Type != BRANCH_FROND )
        {
            // Add the ring for this segment in this frame's combined space
            hRet = AddBranchSegment( pNode, pMesh );
            if ( FAILED(hRet) ) { return hRet; }

        } // End if not frond
        else
        {
            // Add the frond data in this frame's combined space
            hRet = AddBranchFrond( pNode, pMesh );
            if ( FAILED(hRet) ) { return hRet; }

        } // End if frond

        // Since no new frame is generated here, the child will receive
        // the same frame, mesh and matrices that we were passed.
        pChildFrame = pParent;
        pChildMesh  = pMesh;
        mtxChild    = mtxCombined;

    } // End if not creating a new frame
```

Because we only add fronds when we are not processing a bone node you might conclude that there would be gaps in the foliage whenever a branch node is a bone node. However, we must remember that this function also visits the sibling list of the bone node, so fronds can still exist at the same position as a bone node and can exist in the same list of siblings as any node type. At this point we are outside any conditional code block and back in the common flow of the function.

The next section of code steps into the child and sibling lists (this is not new code).

```
    // Build the nodes for child & sibling
    if ( pNode->Sibling )
    {
        hRet = BuildNode( pNode->Sibling,
                          pParent,
```

```
                        pMesh,
                        mtxCombined,
                        pAllocate );

        if (FAILED(hRet)) { if ( pNewMesh ) delete pNewMesh; return hRet; }

    } // End if has sibling

    if ( pNode->Child )
    {
        hRet = BuildNode( pNode->Child,
                        pChildFrame,
                        pChildMesh,
                        mtxChild,
                        pAllocate );

        if (FAILED(hRet)) { if ( pNewMesh ) delete pNewMesh; return hRet; }

    } // End if has child
```

The final section of code is executed at the bottom of the function when the current node being processed is a BRANCH_BEGIN node. Remember, because the child list is traversed before we get to this point in the function, if this is a BRANCH_BEGIN node, all the vertices in that child branch will have been added to the mesh at this point. What we have to do in this next code block is build the CTriMesh's underlying ID3DXMesh, build its ID3DXSkinInfo object, and pass this information into the CAllocateHierarchy::CreateMeshContainer function for skinned mesh creation. Virtually all of this code is unchanged, but we will comment after the first altered portion.

```
    if ( pNode->Type == BRANCH_BEGIN )
    {
        D3DXMATERIAL        Materials[2];
        D3DXMESHDATA        MeshData;
        D3DXMESHCONTAINER * pNewContainer       = NULL;
        DWORD             * pAdjacency          = NULL;
        LPD3DXBUFFER        pAdjacencyBuffer    = NULL;
        LPD3DXSKININFO      pSkinInfo           = NULL;
        ULONG               MaterialCount = ( m_Properties.Include_Fronds ) ? 2 : 1;
```

Notice the new line added to the bottom of the variable declarations. We will have to pass into the 'CreateMeshContainer' function the number of materials/subset in the mesh. If fronds are enabled we will have two subsets/materials in the mesh, so we perform this calculation here. The first subset will contain the branch faces and the second the fronds.

```
        // Generate mesh containers name
        _stprintf( strName, _T("Mesh_%i"), pNode->UID );

        // Generate the skin info for this branch
        hRet = BuildSkinInfo( pNode, pNewMesh, &pSkinInfo );

        if ( FAILED(hRet) ) { delete pNewMesh; return hRet; }

        // Signal that CTriMesh should now build the mesh in software.
```

```
        pNewMesh->BuildMesh( D3DXMESH_MANAGED, m_pD3DDevice );

        // Build the mesh data structure
        ZeroMemory( &MeshData, sizeof(D3DXMESHDATA) );
        MeshData.Type  = D3DXMESHTYPE_MESH;

        // Store a reference to our build mesh.
        // Note: This will call AddRef on the mesh itself.
        MeshData.pMesh = pNewMesh->GetMesh();

        // Build material data for this tree
        Materials[0].pTextureFilename = m_strTexture;
        Materials[0].MatD3D           = m_Material;
        Materials[1].pTextureFilename = m_strFrondTexture;
        Materials[1].MatD3D           = m_FrondMaterial;
```

The call to the BuildSkinInfo function is not changed although the contents of this function have been modified slightly, as we will see in a moment. The BuildSkinInfo function has also been upgraded so that any frond vertices also get influenced by the bones of the tree. The two new lines of code in the above code snippet are the bolded ones at the very bottom.

You will recall that when we pass our new branch mesh into the CreateMeshContainer function we must also pass in an array of materials (texture and material combinations). Originally, we just passed in a single structure since we only had one texture and material used by the entire tree. Now we have two because we also have a texture and material that will be used for the fronds (the second subset). So as you can see, we store both of these in a two element D3DXMATERIAL array before handing it off to CreateMeshContainer. Notice that we pass in the material count we calculated earlier so that CreateMeshContainer knows how many materials we are passing in the array.

```
        // Retrieve adjacency information
        pNewMesh->GenerateAdjacency( );
        pAdjacencyBuffer = pNewMesh->GetAdjacencyBuffer();
        pAdjacency       = (DWORD*)pAdjacencyBuffer->GetBufferPointer();

        // Create the new mesh container
        hRet = pAllocate->CreateMeshContainer( strName,
                                               &MeshData,
                                               Materials,
                                               NULL,
                                               MaterialCount,
                                               pAdjacency,
                                               pSkinInfo,
                                               &pNewContainer );

        // Release adjacency buffer
        pAdjacencyBuffer->Release();

        // Release the mesh we referenced
        MeshData.pMesh->Release();

        // Release the skin info
        if (pSkinInfo) pSkinInfo->Release();
```

```
        // Destroy our temporary child mesh
        delete pNewMesh;

        // If the mesh container creation failed, bail!
        if ( FAILED(hRet) ) return hRet;
```

The final change to this function requires some explanation. We will need to override the DrawActor and DrawActorSubset methods of the base class in CTreeActor so that we can enable alpha testing/blending when rendering the frond subset (subset 1). However, if our actor is in managed mode, the CreateMeshContainer function will have remapped the face attribute IDs to use the global IDs issued by the CScene class during the creation of the skin. We currently have no way of knowing what the frond subset ID will be after the CreateMeshContainer function has altered its attribute buffer. Furthermore, we cannot even lock the attribute buffer and try and determine this because the mesh may have also been attribute sorted (optimized) so we cannot even be sure that the first subset ID in the attribute buffer is the ID of the non-frond subset.

We decided to work around this problem by making a very small tweak to our CAllocateHierarchy::CreateMeshContainer function. In the next Module in this series we will examine a more comprehensive solution to this problem, but for now, our current strategy will be a lot easier to deal with.

You will recall that during the attribute remapping of a non-managed mesh we would build a temporary remap array describing what the original attribute IDs were mapped to. We then used this array to remap the attribute buffer and then the array was discarded. We will no longer discard it. Instead we store the attribute remap array in a new CAllocateHierarchy member variable so that it can be accessed. We added a small function to the CAllocateHierarchy class called GetAttributeRemap. This function will return the new ID in the remap array for an original subset ID passed in. In the following code you can see us using this new function to retrieve the new subset ID for the frond subset (originally subset 1) and storing it in a new CTreeActor member variable called m_nFrondAttribute. Our overridden DrawActorSubset subset function can then access this attribute ID and only enable the alpha blending/testing render states if the frond subset is the one that has been requested to be rendered.

```
        // Store the final attribute ID (as it was remapped) of the frond data
        if ( m_Properties.Include_Fronds )
        m_nFrondAttribute = ((CAllocateHierarchy*)pAllocate)->GetAttributeRemap( 1 );

        // Store the new mesh container in the frame
        pNewFrame->pMeshContainer = pNewContainer;

    } // End if beginning of branch

    // Success!!
    return D3D_OK;

}
```

If you followed along in the last section with your source code project open you will have seen that the changes to the code are very small indeed. However, there is now a new function called from the

BuildNode function which adds the vertex data to the mesh for a frond node. This function is called AddBranchFrond and is a brand new function whose code we will cover next.

CTreeActor - AddBranchFrond

The AddBranchFrond function is called by BuildNode whenever a frond node is encountered during phase two of the tree building process. Just as the AddBranchSegment function is called to add a ring of vertices on the node plane of a normal branch node, the AddBranchFrond function is called to add the frond vertices. This function will create two intersecting quads mounted on the node plane and aligned with the node direction vector (see Figure 12.62).

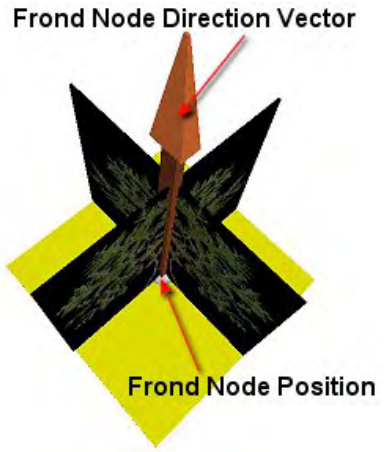

Figure 12.62

Just as we did in the AddBranchSegment function, we must transform the node position and the node plane's direction, right, and ortho vectors from tree space into branch space. This is so the vertices we generate will be relative to the beginning of the branch (the mesh in which they are contained) and not the root of the entire tree. The process we use to perform this back transformation is the same. The function is passed the frond node that needs to have its vertices added and a pointer to the CTriMesh to which the vertices should be added (the current branch mesh being built). It first executes a while loop that starts at the current node and steps back through the parent list until the BRANCH_BEGIN node is encountered. This will be the first node in the branch and the space in which we wish to transform our frond node. That is, we wish to define our frond vertices in a space where the BRANCH_BEGIN node's position is located at (0,0,0) in the coordinate system and its right, ortho and direction vectors are aligned with the X,Y, and Z axes of that system, respectively.

```
HRESULT CTreeActor::AddBranchFrond( BranchNode * pNode, CTriMesh * pMesh )
{
    USHORT      Index;
    D3DXMATRIX  mtxInverse, mtxRot, mtxBranch;
    D3DXVECTOR3 vecPos, vecAxis, vecRight, vecOrtho, vecNormal, vecVertexPos;
    D3DXVECTOR3 vecX, vecY, vecZ;
    float       fScale, fX, fY, fZ;

    // Back track until we find the beginning node for this branch
    BranchNode * pStartNode = pNode;
    while ( pStartNode->Type != BRANCH_BEGIN && pStartNode )
            pStartNode = pStartNode->Parent;

    if ( !pStartNode ) return D3DERR_INVALIDCALL;
```

At this point we now have a pointer to the BRANCH_BEGIN node, so let us extract its direction vector (it local Z axis) and its right vector (its local X axis) and perform a cross product to generate the third axis in its local system (its local Y axis). Using these three vectors we then build a transformation matrix for the branch start node and take its inverse. This gives us a matrix that will transform any position or vector into branch space.

```
    // Store / generate the vectors used to build the branch matrix
    vecX = pStartNode->Right;
    vecZ = pStartNode->Direction;
    D3DXVec3Cross( &vecY, &vecZ, &vecX );

    // Generate the frame matrix for this branch
    D3DXMatrixIdentity( &mtxBranch );
    mtxBranch._11 = vecX.x; mtxBranch._12 = vecX.y; mtxBranch._13 = vecX.z;
    mtxBranch._21 = vecY.x; mtxBranch._22 = vecY.y; mtxBranch._23 = vecY.z;
    mtxBranch._31 = vecZ.x; mtxBranch._32 = vecZ.y; mtxBranch._33 = vecZ.z;
    mtxBranch._41 = pStartNode->Position.x;
    mtxBranch._42 = pStartNode->Position.y;
    mtxBranch._43 = pStartNode->Position.z;

    // Get the inverse matrix, to bring the node back into the frame's space
    D3DXMatrixInverse( &mtxInverse, NULL, &mtxBranch );
```

Now that we have a matrix that will transform vectors into the coordinate system of the branch, we will transform the direction vector, the right vector, and the position of the frond node into branch space by multiplying them with this matrix.

```
    // Build the axis in the frame's space
    D3DXVec3TransformNormal( &vecAxis, &pNode->Direction, &mtxInverse );
    D3DXVec3TransformNormal( &vecRight, &pNode->Right, &mtxInverse );
    D3DXVec3TransformCoord ( &vecPos, &pNode->Position, &mtxInverse );
```

At this point we only have the frond node's branch space position, look vector, and right vector. In order to position the vertices on the plane, we also need the second tangent vector (the plane's Up vector). We calculate this simply by rotating the branch space right vector around the direction vector (perpendicular to the plane) by 90 degrees.

```
    // Build the ortho vector which we use for our Y dimension axis
    D3DXMatrixRotationAxis( &mtxRot, &vecAxis, D3DXToRadian( 90.0f ) );
    D3DXVec3TransformNormal( &vecOrtho, &vecRight, &mtxRot );
```

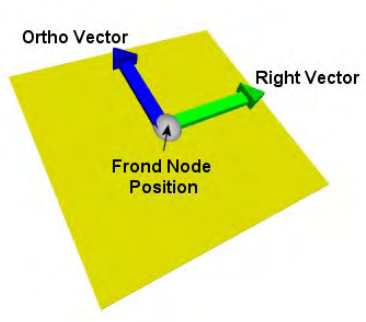

Figure 12.63

Figure 12.63 shows the plane and the two tangent vectors. Actually, because of the way we rotated our ortho vector it is actually pointing down and not up as shown in Figure 12.63, but hopefully you get the idea. As discussed in the AddBranchSegment function, we can combine the node position and the right and ortho vectors together with some scaling to position points anywhere on this plane. For example, we know that if we add the right vector to the node position, the resulting vector will be a point on the plane pointed to by the tip of the right vector in the diagram. If we add the ortho vector to the node position we would describe a position pointed to by the tip of the ortho vector in the diagram. If we add the negated right to the node position we would generate a point on the left side of the plane and similarly, if we add the negated ortho vector to the node position we would get a position at the bottom of the yellow plane shown in Figure 12.63. Those four position calculations we have just discussed describe the positions of four vertices on the

plane in the shape of a perfect cross. That is exactly where we want to base vertices of our intersecting quads to be. However, we do yet know how big we want these quads to be, so we will create some scaling values that will be multiplied with the ortho and right vectors so that we can create a larger or smaller cross on that plane.

In the next section of code we create three scaling values (fX, fY, and fZ) which will be used to scale the right, ortho and direction vectors before they are combined to create vertex positions. We will want the size of the fronds to get smaller as they are positioned higher up the tree and belong to smaller and thinner branches. We defined the minimum and maximum frond sizes as tree growth properties so we wish to find a size for the frond that is within this range but still related to the size of its parent branch. After all, a huge frond sticking out of a tiny parent branch would look unrealistic and quite bad. The technique we use is described next.

We will take the dimensions of the frond node (this was inherited from the parent when the frond node was created) and divide by the dimensions of the root node of the tree. As we know, the root node is the node in the tree with the largest dimensions, so this will create a value in the 0.0 to 1.0 range. The value is closer to zero the higher up the tree the frond is placed and the smaller its parent branch is in relation to the root node's dimensions. We will then use this scaling value to generate a new value between the minimum and maximum frond size growth properties that have been set. This is done on a per component level, so if we imagine that the variable ScaleValue describes the frond node's X dimension divided by the root node X dimension, fX would be calculated as:

fX = MinFrondSize + ((MaxFrondSize – MinFrondSize) * ScaleValue)

This is a basic interpolation calculation that we have used many times before. We are essentially adding the range (MaxFrondSize-MinFrondSize) of values that a frond can be set to, to the minimum frond size. This gives a value between MinFrondSize and MaxFrondSize based on ScaleValue (which is closer to zero the further from the root it is positioned). fX will then be used to scale the right vector of the frond node before it is added to the node position to generate the left and right vertex positions on the plane.

Below we see the code that calculates fX, fY and fZ.

```
    // If this is a frond node
    if ( pNode->Type == BRANCH_FROND )
    {
        // Calculate frond dimensions
        fScale = (pNode->Dimensions.x / m_pHeadNode->Dimensions.x);
        fX     = m_Properties.Frond_Min_Size.x +
                 ((m_Properties.Frond_Max_Size.x - m_Properties.Frond_Min_Size.x)
                 * fScale);

        fScale = (pNode->Dimensions.y / m_pHeadNode->Dimensions.y);
        fY     = m_Properties.Frond_Min_Size.y +
                  ((m_Properties.Frond_Max_Size.y - m_Properties.Frond_Min_Size.y)
                   * fScale);

        fScale = ((pNode->Dimensions.x / m_pHeadNode->Dimensions.x) +
                   (pNode->Dimensions.y / m_pHeadNode->Dimensions.y)) / 2.0f;
        fZ     = m_Properties.Frond_Min_Size.z +
```

```
                ((m_Properties.Frond_Max_Size.z - m_Properties.Frond_Min_Size.z)
                * fScale);
```

Notice that the scaling value used to create fZ is not calculated in the same way. That is, we do not scale the Z dimension of the frond node by the Z dimension of the root node. This is because, the fZ value will be used to control the length of the frond (how high the top of the quads are with respect to the node plane they are mounted on). We do not want this to be a product of the parent node's segment length but rather an average of the difference in the X and Y dimensions with respect to the root node. We would not want to have a really long frond branch if its X and Y dimensions are very small. This would create a skinny frond with a squashed texture.

Now that we have our Direction, Ortho, and Right vectors, our scaling values (fX,fY,fZ), and the node position, we can start building the vertex positions for those quads. We actually need to create four quads because we wish each of the polygons to be visible from both sides. Therefore, we will create four vertex positions per quad for a total of 16 vertex positions. Each quad will be formed from 4 vertices where two of the vertices lay on the plane and two are offset from the plane by some amount along the direction vector. The quads will be assigned their vertices such that they have a clockwise winding when viewed from the front.

In the next line of code we create a local array of 16 CVertex structures. In each element of the array we call the CVertex constructor that takes four parameters:

CVertex(D3DXVECTOR3 &vecPos, const D3DXVECTOR3 &vecNormal, float ftu, float ftv)

CVertex is defined in CObject.h and as you can see the first parameter is where we pass a 3D vector describing its position. The second parameter is where we pass in the normal of the vertex and the last two float parameters is where we pass in the texture coordinates. We will cover the first four vertex positions we add to this array one at a time so we can see how the quad is constructed. Here is the first section of the statement that defines the CVertex array and passes the first vertex.

```
// Calculate the actual frond vertices.
CVertex pVertices[16]={ CVertex( (vecPos - (vecRight*fX)), vecOrtho, 0.0f, 1.0f ),
```

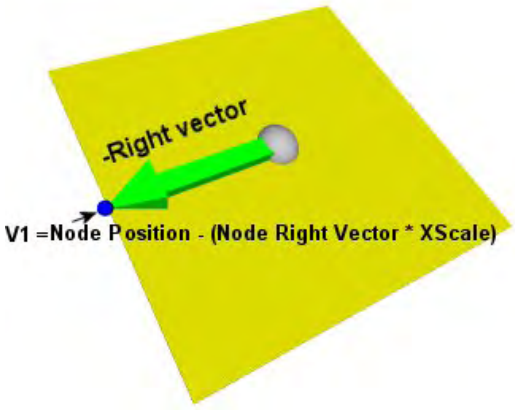

Figure 12.64

The position of the first vertex in the first quad is calculated by subtracting from the node position (shown as the ball in the center of the plane in Figure 12.64) the right vector scaled by the fX scaling value we calculated earlier. Essentially, fX dictates the width of the quad we are creating.

The resulting vertex position is situated on the plane and is shown as the small blue sphere labeled V1 in Figure 12.64. This is the bottom left corner of our first quad.

Notice that we pass in the vecOrtho vector as the vertex normal. Why? Because the right vector and the ortho vector are perpendicular to each other and therefore, in this diagram we can imagine that the ortho vector is actually pointing down towards the bottom edge of the yellow plane. This is the exact direction our quad

will be facing and thus its normal. Finally, since this is the bottom left vertex of our quad, we assign it the bottom left UV coordinate of the texture (0,1).

Let us see how we define the next (second) vertex in the array declaration.

```
CVertex( (vecPos - (vecRight * fX)) + (vecAxis * fZ), vecOrtho, 0.0f, 0.0f ),
```

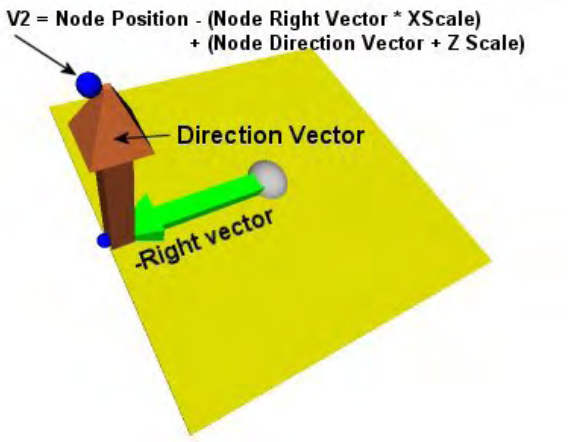

Figure 12.65

Here you can see that the next vertex position we define is initially calculated in the same way as before (by subtracting a scaled right vector from the node position) only this time we add to the resulting position the scaled direction vector (vecAxis). This vector is perpendicular to the plane and as such describes a position that is offset from the plane in the direction of the plane normal. This forms the top left corner of our quad. The same normal is used for every vertex in this quad.

As this is the top left vertex in the quad we assign it the texture coordinate for the top left of the texture (0,0).

It should be clear that in order to generate the top right and bottom right vertices we essentially do the same thing, only this time adding the right vector to the node position instead of subtracting it. This will form two symmetrical vertex positions on the right side of the node position.

```
CVertex( (vecPos + (vecRight * fX)) + (vecAxis * fZ), vecOrtho, 1.0f, 0.0f ),
CVertex( (vecPos + (vecRight * fX))                 , vecOrtho, 1.0f, 1.0f ),
```

Above we can see how the final two vertex positions are defined for the quad. These two calculations are identical to the previous two only with the addition of the right vector to the node position instead of its subtraction.

Note that it is the top right vertex we add third and the bottom right we add fourth, so that the four vertex positions of our quad describe a clockwise winding when viewed from the front.

Also notice that the two vertices are provided with the same vertex normal -- the ortho vector which is pointing toward us in this diagram. You should be able to see that the top right vertex's texture coordinate of (1,0) maps it to the top right of the texture image and the bottom left texture coordinate of (1,1) maps vertex V4 to the bottom right corner of the texture image.

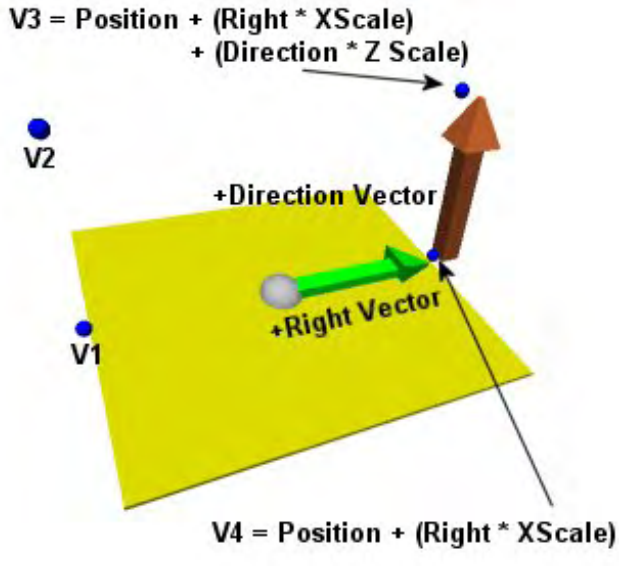

Figure 12.66

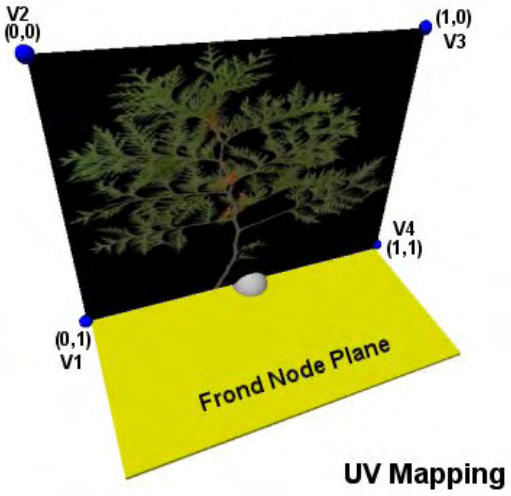

Figure 12.67

The next four vertices we define in the array describe the same quad, but facing in the other direction since we want this frond quad to be able to be viewed from both sides. We add the same four vertex positions, only this time in a counter-clockwise winding order. We also flip the sign of the vertex normals so that they are facing in the opposite direction.

```
CVertex( (vecPos + (vecRight * fX))                 , -vecOrtho, 1.0f, 1.0f ),
CVertex( (vecPos + (vecRight * fX)) + (vecAxis * fZ), -vecOrtho, 1.0f, 0.0f ),
CVertex( (vecPos - (vecRight * fX)) + (vecAxis * fZ), -vecOrtho, 0.0f, 0.0f ),
CVertex( (vecPos - (vecRight * fX))                 , -vecOrtho, 0.0f, 1.0f ),
```

We now have the horizontal quads built, so it is time to build the vertical ones so that we form a criss-cross shape of intersecting quads.

```
CVertex( (vecPos - (vecOrtho * fY))                 , -vecRight, 0.0f, 1.0f ),
CVertex( (vecPos - (vecOrtho * fY)) + (vecAxis * fZ), -vecRight, 0.0f, 0.0f ),
CVertex( (vecPos + (vecOrtho * fY)) + (vecAxis * fZ), -vecRight, 1.0f, 0.0f ),
CVertex( (vecPos + (vecOrtho * fY))                 , -vecRight, 1.0f, 1.0f ),
```

The vertex positions described above are shown in Figure 12.68. As you can see, this creates a quad aligned with the ortho vector instead of the right vector. As noted earlier, our ortho vector is actually pointing down and as such, the calculation of vertices V1 and V2 involve the subtraction of the ortho vector from the node position, while the calculations of vertices V3 and V4 involve its addition.

Notice that the vertex normal in each case we are passing is the negated right vector. The right vector is at right angles to the ortho vector and as such describes the plane of the quad we are building. The negated right vector will generate a vector pointing toward us in the diagram.

Finally, we want this quad to be two-sided so we add the same quad positions again, only this time with a reversed winding order and using the positive right vector as the vertex normals.

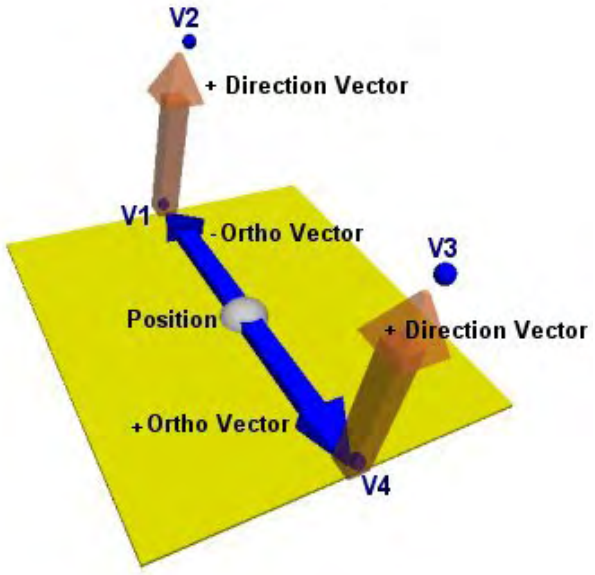

Figure 12.68

```
CVertex( (vecPos + (vecOrtho * fY))                  , vecRight, 1.0f, 1.0f ),
CVertex( (vecPos + (vecOrtho * fY)) + (vecAxis * fZ), vecRight, 1.0f, 0.0f ),
CVertex( (vecPos - (vecOrtho * fY)) + (vecAxis * fZ), vecRight, 0.0f, 0.0f ),
CVertex( (vecPos - (vecOrtho * fY))                  , vecRight, 0.0f, 1.0f )
};
```

We now have the 16 vertex positions stored in a CVertex array, so it is time to add them to the mesh. First we inform the passed CTriMesh of our intention to add 16 vertices so that it makes room at the end of its internal vertex array. We pass a pointer to the vertex array as well so that it can copy them.

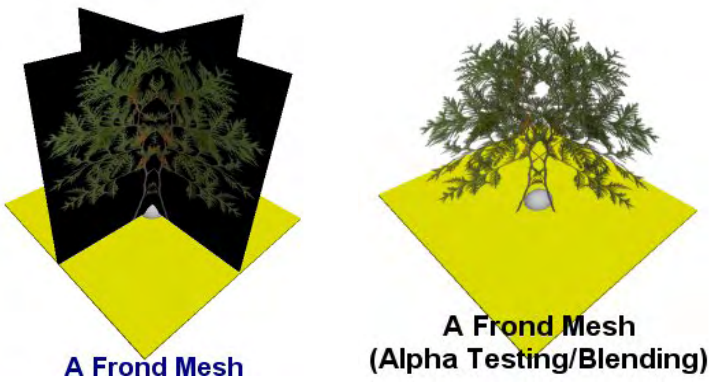

Figure 12.69

```
        // Add the frond vertex data
        long VIndex = pMesh->AddVertex( 16, pVertices );
        if ( VIndex < 0 ) return E_OUTOFMEMORY;
```

The AddVertex function returns the index (VIndex) of the first new vertex we added so that we know where we have to start indexing from when we build the indices.

For each quad we will need to add two triangles, each consisting of three indices (24 indices total). If we have a quad defined by vertices V1, V2, V3, and V4 in a clockwise winding order, then the first triangle will be created from V1, V2, and V3 and the second from vertices V1, V3, and V4. Below we see the code that allocates an array of 24 indices and indexes the vertices for each quad using this scheme. Of course, we must add VIndex to each zero based index value so that we index the positions in the mesh's vertex array where the frond vertices have been added. We cannot automatically assume they are the first 16 vertices in the mesh (since we know that they will not be because of prior branch vertex rings).

```
// Generate the index data for this frond
Index = (USHORT)VIndex;

USHORT pIndices[24] =
{ Index + 0 , Index + 1 , Index + 2 , Index + 0 , Index + 2 , Index + 3,
Index + 4 , Index + 5 , Index + 6 , Index + 4 , Index + 6 , Index + 7,
Index + 8 , Index + 9 , Index + 10, Index + 8 , Index + 10, Index + 11,
Index + 12, Index + 13, Index + 14, Index + 12, Index + 14, Index + 15 };
```

Finally, we inform the CTriMesh that we would like to add eight more triangles to its index buffer and pass the indices array so that it can copy them into its internal index array. Notice that in the third parameter to this function we pass in the number of the subset as 1 instead of 0. Thus, the branch segment faces will be assigned to subset 0 and the frond faces will be in subset 1. It makes perfect sense that we would need to put them in separate subsets since they both use different attributes (texture and material).

```
    // Add the frond face data (subset '1' )
    if ( pMesh->AddFace( 8, pIndices, 1 ) < 0 ) return E_OUTOFMEMORY;

    } // End if frond node

    // Success!!
    return D3D_OK;
}
```

This function will be called to add a frond whenever a frond node is encountered during the mesh building process. As you have seen, the code is actually quite easy to follow.

The last function that needs a minor update is the BuildSkinInfo function which is called from BuildNode when a branch mesh has been fully populated with its vertex and index data and is about to be turned into a skin. This function creates the ID3DXSkinInfo object that will be passed to the CreateMeshContainer function and contains the connection between bones in the hierarchy and the vertices they influence.

CTreeActor::BuildSkinInfo - Updated

This function has been modified in two places to support fronds, but the modifications are very small. It is suggested that you follow this discussion with the source code to Lab Project 12.2 handy so that you can see the changes in context. We will not be showing the entire function here since this was a big function and very little has changed.

You will recall that this function has a very simple job. It traverses the branch (it is only ever called for BRANCH_BEGIN nodes) stepping from node to node within the same branch and adding the vertex indices it collects between bone nodes to the skin info object. The first change happens near the start of the function, where we execute a while loop to step through the current node's child list to find the next node that is a continuation of the branch. Originally, we just ignored any other BRANCH_BEGIN nodes since we were only interested in finding the next node in the current branch we were processing. However, now the child list of a node can contain both BRANCH_BEGIN nodes and BRANCH_FROND nodes, so an extra check has been added to ensure that we also ignore frond nodes.

```
    while ( pSearchNode = pSearchNode->Child )
    {
        // We're not interested in other branches or fronds, so shift us through
        // until we find a node that is our segment, or end node.
        while ( pSearchNode &&
               (pSearchNode->Type == BRANCH_BEGIN ||
                pSearchNode->Type == BRANCH_FROND) )
                pSearchNode = pSearchNode->Sibling;

        // If we couldn't find a node, we have an invalid hierarchy
        if ( !pSearchNode ) return D3DERR_INVALIDCALL;

        // Was a frame created here?
        if ( pSearchNode->BoneNode ) BoneCount++;

    } // Next child segment
```

The final alteration is at the very bottom of the function's inner loop. You will recall from our earlier discussion that this function, once finding a bone node, will start collecting the indices of all child nodes until the point that another bone is encountered. At this point all the indices currently collected in the temporary indices array are added for the previous bone in the ID3DXSkinInfo object. A new section has now been added which essentially just says, if we are processing a frond node, add the frond vertex indices to the temporary indices array also. If you have the source code in front of you, this addition will seem perfectly logical.

```
            else if ( pSearchNode->Type == BRANCH_FROND )
            {
                // Add influences for each of the 16 frond vertices
                for ( i = 0; i < 16; ++i )
                {
                    pIndices[ InfluenceCount ] = IndexCounter++;
                    pWeights[ InfluenceCount ] = 1.0f;
                    InfluenceCount++;
```

```
                } // Next index

            } // End if frond

        } // Next node sibling

        // If we couldn't find a segment node, we've reached the end of the branch
        if ( !pSegmentNode ) break;

    } // Next child segment

    // Clean up
    delete []pIndices;
    delete []pWeights;

    // Success!!
    return D3D_OK;
}
```

We have now covered all the functions that need to be altered in the tree generation process and our CTreeActor class is now capable of creating trees with fronds. This certainly acts to increase our visuals by quite a significant margin.

However, we are not quite done yet in terms of our overall support for fronds. In the previous lab project, we could just allow the base class (CActor) DrawActor and DrawActorSubset methods to be called to render the tree, but this is no longer the case. We will need to override these functions so that when rendering frond subsets we can enable alpha blending and alpha testing before calling the base class versions of the function. Let us have a look at the CTreeActor::DrawActorSubset function first.

CTreeActor::DrawActorSubset

This function is extremely simple since it calls the base class implementation to do the actual rendering. All it does is test to see if the passed attribute ID matches the attribute ID of the frond subset (which we stored earlier in the m_nFrondAttribute member variable). If so, it enables alpha testing and alpha blending.

```
void CTreeActor::DrawActorSubset( ULONG AttributeID )
{
    // Is this our frond attribute?
    if ( m_Properties.Include_Fronds && AttributeID == m_nFrondAttribute )
    {
        // Setup states
        m_pD3DDevice->SetRenderState( D3DRS_ALPHATESTENABLE, TRUE );
        m_pD3DDevice->SetRenderState( D3DRS_ALPHAREF, (DWORD)0x000000A0 );
        m_pD3DDevice->SetRenderState( D3DRS_ALPHAFUNC, D3DCMP_GREATEREQUAL );
        m_pD3DDevice->SetRenderState( D3DRS_ALPHABLENDENABLE, TRUE );
        m_pD3DDevice->SetRenderState( D3DRS_SRCBLEND, D3DBLEND_SRCALPHA );
        m_pD3DDevice->SetRenderState( D3DRS_DESTBLEND, D3DBLEND_INVSRCALPHA );
        m_pD3DDevice->SetTextureStageState( 0,D3DTSS_ALPHAOP, D3DTOP_SELECTARG1 );
```

```
        m_pD3DDevice->SetTextureStageState( 0, D3DTSS_ALPHAARG1, D3DTA_TEXTURE );

    } // End if frond attribute

    // Call underlying draw
    CActor::DrawActorSubset( AttributeID );

    // Reset states if applicable
    if ( m_Properties.Include_Fronds && AttributeID == m_nFrondAttribute )
    {
        m_pD3DDevice->SetRenderState( D3DRS_ALPHATESTENABLE, FALSE );
        m_pD3DDevice->SetRenderState( D3DRS_ALPHABLENDENABLE, FALSE );

    } // End if frond attribute
}
```

We first enable alpha testing because alpha blending by itself will not suffice. We do not want the black background pixels to be rendered at all. Although these pixels have zero alpha components and would not alter the contents of the frame buffer when rendered, with alpha blending enabled, they would actually still be rendered. Although these pixels would be blended with the frame buffer with zero weight (leaving the frame buffer unchanged) their depth values would still be written to the depth buffer. Therefore, the black space around the leaves would block leaves located behind from being drawn as they would be rejected by the depth test. In essence, it would seem as if the leaves were blocked by invisible geometry.

Figure 12.70 : Low Alpha Testing Reference Value (Ref = 5)

By enabling alpha testing we can make sure that these background pixels get rejected in the pixel pipeline. This means their depth values will not be recorded in the depth buffer and therefore, we will not have these issues. We set the alpha testing reference value to a rather arbitrary 0xA0 (160) so that all pixels with an alpha value of less than 160 get rejected. The reason we do not set this to a value such as 1 for example (so only totally transparent pixels such as the background pixels get rejected) is because, when we generate an alpha channel, the pixels between the opaque leaf edges and the transparent black background will often also be blended from opaque to transparent. Therefore, this makes sure that we remove nearly all the pixels that are mostly transparent, but leave the ones in place that are partially transparent since these pixels may contain part of the leaf edge. Setting the alpha reference to a low value (e.g., 1) will remove all the background pixels but will leave the partially transparent pixels around the opaque leaves in place and their depth values will still be written to the frame buffer. This provides an unattractive border around the leaves (see Figure 12.70). As you can see, there is a large number of pixels that are not totally transparent that do not get rejected by the alpha testing pipeline, so setting a higher reference value helps filter these undesirables out.

Figure 12.71 Alpha Blending Disabled

We then enable alpha blending so that the leaves get blended with the frame buffer and any partially transparent pixels around the leaf edges which did not get rejected from the alpha test will allow for objects behind them to show through. If you play around with the alpha testing reference value you will see exactly why this is necessary. If we do not enable alpha blending, the results will not look overly bad, but there will still be a hard edge to leaves (see Figure 12.71). Enabling alpha blending allows us to keep the outer portions of the leaves that are partially transparent but have them blend out smoothly, removing the hard edge around the leaves. You can experiment with the settings to find what works best for you. Obviously, while alpha blending does seem to produce better results, it adds some additional cost.

CTreeActor::DrawActor

The CActor::DrawActor function can be used to automate the rendering of managed mode meshes. It is called once by the application and will render all of its subsets. It can do this because a managed mode mesh contains its own texture and material arrays and can set them before rendering each of its subsets.

We also have to override this function in CTreeActor for the same reason as before (to enable the alpha testing and alpha blending render states). Unfortunately, when rendering a managed mode tree we no longer have per-subset control to decide whether we should enable the states for the entire rendering of the tree or not. This means that if the tree does have fronds, we will have to enable alpha testing and alpha blending and then use the base class implementation to instruct the mesh to draw all its subsets. Sadly, this does mean that both subsets will be rendered with these states enabled. These states will not harm the rendering of the non-frond subset, but it is not ideal to have these states set when we do not wish to use them since they introduce overhead in the pixel pipeline.

```
void CTreeActor::DrawActor( )
{
    // Fronds included?
    if ( m_Properties.Include_Fronds )
    {
        // Setup states
        m_pD3DDevice->SetRenderState( D3DRS_ALPHATESTENABLE, TRUE );
        m_pD3DDevice->SetRenderState( D3DRS_ALPHAREF, (DWORD)0x000000A0 );
        m_pD3DDevice->SetRenderState( D3DRS_ALPHAFUNC, D3DCMP_GREATEREQUAL );
        m_pD3DDevice->SetRenderState( D3DRS_ALPHABLENDENABLE, TRUE );
        m_pD3DDevice->SetRenderState( D3DRS_SRCBLEND, D3DBLEND_SRCALPHA );
        m_pD3DDevice->SetRenderState( D3DRS_DESTBLEND, D3DBLEND_INVSRCALPHA );
        m_pD3DDevice->SetTextureStageState( 0,D3DTSS_ALPHAOP, D3DTOP_SELECTARG1 );
        m_pD3DDevice->SetTextureStageState( 0, D3DTSS_ALPHAARG1, D3DTA_TEXTURE );

    } // End if fronds included

    // Call underlying draw
    CActor::DrawActor();
```

```
    // Reset states
    if ( m_Properties.Include_Fronds )
    {
        m_pD3DDevice->SetRenderState( D3DRS_ALPHATESTENABLE, FALSE );
        m_pD3DDevice->SetRenderState( D3DRS_ALPHABLENDENABLE, FALSE );

    } // End if fronds included
}
```

Conclusion

This concludes our discussion of trees (for now) and also brings us to the end of our skinning discussions in this course. There was quite a lot of challenging material to take in at times, but you should now have a very strong understanding of frame hierarchies and skinned meshes. We now have an actor that fully supports skinning which we can use in all of our applications from this point on. Additionally we have a pretty nice derived actor class that allows us to generate trees for our various scenes. We recognize that there was a lot to digest in this chapter, so take your time and re-read the sections that you found difficult before moving on to the workbook.

Workbook Twelve:
Skinning Part II

Introduction

This workbook marks the halfway point in this course. As such, one of the things we will endeavor to do is bring together many of the components we have developed throughout the course into a single application. In the accompanying textbook we learned how to generate trees. Trees will be just one element of what we intend to incorporate in this lesson.

In previous lessons our applications have essentially taken one of two forms; either a terrain demo or a scene demo. Now we will begin the process of merging these two concepts. We will add support to our IWF loading code for terrain entities so that a single IWF file can contain multiple pieces of terrain and interior scenes and objects. Previously, our applications have used a single terrain and as such the vertices in each sub-mesh of the terrain were defined in world space. Because we now wish to support multiple terrains that may be positioned at different locations throughout the scene, we will have to modify our terrain class (only slightly) so that it takes into account a world matrix for that terrain during rendering. The CScene class will now have to be able to store an array of CTerrain pointers and render them all instead of assuming only a single terrain exists.

We will also add loading support for tree entities so that objects of type CTreeActor will be added to the scene for each tree entity found in the IWF file. Internally, GILES™ uses the CTreeActor code that we developed in the accompanying textbook for its tree support. This means the creation properties stored inside the IWF file for a tree entity will work perfectly with our CTreeActor class and generate the same tree formation as displayed in GILES™. The loading code can simply instantiate a new CTreeActor for each entity it finds and feed in the tree creation parameters pulled straight from the IWF file.

Other entity types will also have support added to the IWF loading code. The GILES™ fog entity is another example. This is a simple entity that stores information about how the Direct3D fog parameters should be set during rendering.

By the end of this workbook our framework will be in a much nicer state to work with. We will be able to feed it IWF files that contain internal geometry, external reference entities for animated X files, multiple terrains, trees, and fog. Our framework will know how to store and render these components as a single scene.

While all of these housekeeping tasks and upgrades are important, they will not be the only ideas introduced. One of the main topics we will explore in this workbook will be in the development of a data driven animation system. This system will allow our applications to manage the setup and playback of complex animation sequences through a very user friendly interface. It will allow our applications (or any subsequent component) to communicate a command such as “Walk and Shoot’ to an animated actor, and the actor will know which animation sets should be set and activated, which ones should be deactivated, and which ones should be blended from one to another. Although this sounds like a complex system to implement, it will expose itself to the application via only two CActor methods. This will all be demonstrated in Lab Project 12.3 where we will see an animated skinned character walking around a terrain. The character will perform several animations such as, “Walk at ease”, “Walk and Shoot” and “Idle” when ordered by the application. Our “Action Animation System” (discussed later)

will be managing which animations sets should be assigned to which tracks on the animation mixer and which animation sets are currently in the process of having their contributions faded in or out.

This also means that we will finally have something nice to look at when we place our camera system into third person mode. When we developed our camera system way back in Chapter Four of Module I we were not yet equipped to add a real animated character to our application. As a result, our third person camera was forced to use a simple cube as a placeholder for where the character should be. The need for that placeholder is now gone and we are ready to attach an animated skinned character to the CPlayer object instead. The scene class will have a new function added that will be called by the application to load a character into a CActor object which will be attached to the CPlayer object. It will load the X file of the character mesh and its animation data and register any callback functions with the CPlayer object that are necessary for this loading process. This function will also load an .ACT file that will be used to populate the actor with information about the various actions the character can perform.

We will discover shortly that .ACT files are simple .ini files that we can create to feed information into our duly named Action Animation System (AAS for short). An .ACT file will contain one or more *actions*. Each action has a name (e.g., "Walk at Ease") and contains the names and properties of a number of animation sets that need to be set on the controller in order for that action to be played. An action called "Observe" for example might consist of multiple animations sets. It may wish to play an animation set that works on the legs to place them into a crouch position, another animation set for the torso that raises the character's binocular holding hands up to his face, and perhaps another animation set that tilts the head of the character to look through the eye pieces. An action is really just a collection of animation set names along with properties like their speed and weight. These actions will be loaded and stored by the actor and used by its AAS to set up the controller in response to the application requesting a certain action. The action system will take care of determining which tracks are free for a given animation set to use and how to configure that track to play the requested action correctly. All the application has do to is call the CActor::ApplyAction method and specify the name of the action it would like to play that matches the name we assign it in the .ACT file.

Goals for this lesson:

- Implement the Action Animation System to act as a middle tier between the application and the actor's underlying controller. The AAS will allow the application to launch complex animations in response to game events or user input with the minimum of work. A simple function call is all that will be needed to perform complex blending between groups multiple animation sets.
- Add a function to load and populate a CActor for use as the CPlayer's third person object.
- Unify components such as heightmap based terrains, trees, and interior scenes into a single application.
- Upgrade our loading code to support loading terrains definitions, tree definitions, and fog parameters directly from the IWF file. These definitions can be used as the construction parameters for our CTerrain and CTreeActor classes.
- Upgrade CTerrain to work in model space and use a world matrix for rendering and querying.

Lab Projects 12.1 and 12.2: Trees

There is very little to discuss for the first two lab projects since the discussion of our tree class was pretty much completed in the textbook. Lab Projects 12.1 and 12.2 simply load a GILES™ tree entity and then use our CTreeActor class to build the tree based on the information stored in the IWF file. It is essentially just our mesh viewer with an updated ProcessEntities function that supports the loading of GILES™ tree entities.

The GILES™ tree entity has an identifier of 0x205, so we will create a #define for this value for entity ID comparisons during the loading process. The entity does not contain any geometry; it is just a collection of tree growth properties which we can feed into our CTreeActor::GenerateTree method.

Excerpt from CScene.h

```
#define CUSTOM_ENTITY_TREE      0x205   // Tree entity identifier
```

The GILES™ tree entity plug-in uses the CTreeActor code we developed in this lab project for its tree creation and rendering, so the properties stored in the IWF file are compatible with CTreeActor.

The tree entity data also has a flags member which describes how the tree should be generated. The flags are shown below. Once again we have created #define's for these in CScene.h to use during the loading process.

Excerpt from CScene.h

```
#define TREEFLAGS_INCLUDEFRONDS     0x1 // Tree actor to include fronds
#define TREEFLAGS_GENERATEANIMATION 0x2 // Tree should generate animation on load
#define TREEFLAGS_INCLUDELEAVES     0x4 // Tree should generate leaf information
```

The data area of the GILES™ tree entity is laid out in a very specific way, so we will set up a structure that mirrors its layout so that we can easily extract the values from the file into this structure. The TreeEntity structure is defined in CScene.h. The Flags member can be set to a combination of the flags listed above. The TREEFLAGS_INCLUDELEAVES flag is currently not supported by our lab project. It will be used in Module III when we revisit the subject of tree rendering.

```
typedef struct _TreeEntity
{
    ULONG       Flags;              // Tree actor flags
    char        BarkTexture[1024];  // The texture to use for the bark of the tree
    char        FrondTexture[1024]; // The texture to use for the frond geometry

    ULONG       GrowthSeed; // The random seed used to build the tree
    TreeGrowthProperties    GrowthProperties;    // The tree growth properties.
    D3DXVECTOR3             AnimationDirection;  // Animation direction vector
    float                   AnimationStrength;   // Animation 'strength'

    D3DXVECTOR3             InitialDimensions;   // Initial branch dimensions
    D3DXVECTOR3             InitialDirection;    // Initial growth direction.

} TreeEntity;
```

The members of this structure should be obvious to you. The Flags member contains whether or not the tree should have fronds created and/or animation data created for it. The next two members contain the names of the image files to use for the bark and frond textures. The Growth seed is the value that the random number generator should be set to during tree creation. As we have seen, we can pass this straight into the CTreeActor::GenerateTree function. The next member is the TreeGrowthProperties structure discussed in the textbook. Following that are the wind direction and wind strength used for generating animation. Finally we have the initial dimensions and growth direction for the root branch node.

CScene::ProcessEntities - Updated

The CScene::ProcessEntities function is very familiar by now since it has been part of our loading framework for quite some time. It is called by the CScene::LoadSceneFromIWF function to extract any entity information our scene may be interested in supporting. It is passed a CFileIWF object, which at this point has loaded all the entity data and stored it in its m_vpEntityList STL vector. This function loops through the vector and extracts any information it wishes to use. Until now, this function has only supported the loading of light entities, reference entities, and sky box entities. We will now add support for GILES™ tree entities.

Because this function is rather large, we will snip out all the code that processes the entities we have already covered and replace this code with "……SNIP……".

```
bool CScene::ProcessEntities( const CFileIWF& File )
{
    ULONG      i, j;
    D3DLIGHT9  Light;
    USHORT     StringLength;
    UCHAR      Count;
    bool       SkyBoxBuilt = false;

    // Loop through and build our lights & references
    for ( i = 0; i < File.m_vpEntityList.size(); i++ )
    {
        // Retrieve pointer to file entity
        iwfEntity * pFileEntity = File.m_vpEntityList[i];

        // Skip if there is no data
        if ( pFileEntity->DataSize == 0 ) continue;
```

The first section of code (shown above), sets up a loop to step through every entity in the CFileIWF object's internal entity vector. Inside the loop we get a pointer to the current entity to be processed (as an iwfEntity structure). We then read the entity's data size and if we find it is zero, we skip it. An entity with a data size of zero is probably one that has been erroneously written to the file.

In the next section of code we test to see if the current entity is a light entity . If it is and we have not already loaded the maximum number of lights, we add a light to the scene. The code that adds the light to the scene's light array has been snipped since this code has been with us for a very long time.

```
        //skip all lights if we've already reached our limit, or maximum
        if ( (m_nLightCount < m_nLightLimit && m_nLightCount < MAX_LIGHTS)
              && pFileEntity->EntityTypeMatches( ENTITY_LIGHT ) )
        {
            …… SNIP ……

        } // End if light
```

The next code block is executed if the current entity has an author ID of ‘GILES’. If it does then we know this is either a sky box entity, a reference entity, or a tree entity; all of which we wish to support in our loading code. When this is the case we set up some entity structures that will be used to extract the information into. Notice that the new addition here is the instantiation of a TreeEntity structure. We then get a pointer to the entity’s data area.

```
        else if ( pFileEntity->EntityAuthorMatches( 5, AuthorID ) )
        {
            SkyBoxEntity SkyBox;
            ZeroMemory( &SkyBox, sizeof(SkyBoxEntity) );

            ReferenceEntity Reference;
            ZeroMemory( &Reference, sizeof(ReferenceEntity ));

            TreeEntity Tree;
            ZeroMemory( &Tree, sizeof(TreeEntity));

            // Retrieve data area
            UCHAR * pEntityData = pFileEntity->DataArea;
```

Now that we have a pointer to the entity data area we will test the entity ID to see what type of GILES™ entity it is. We set up a switch statement to handle skybox, reference, and tree entity types. As we have already covered the code for the first two in previous lab projects, the code has been snipped here.

```
            switch ( pFileEntity->EntityTypeID )
            {
                case CUSTOM_ENTITY_REFERENCE:

                    …… SNIP ……

                    break;

                case CUSTOM_ENTITY_SKYBOX:

                    …… SNIP ……

                    break;
```

In the next section of code we see the case that is executed when the entity type is a GILES™ tree entity. Extracting the values from the data area is simply a case of copying the correct number of bytes from the entity data pointer (retrieved above) into our TreeEntity structure for each property, and then advancing this pointer so that it points at the next value to be read. In the section shown below we

extract the flags ULONG and the string containing the bark texture filename. Notice how we are copying each value into their corresponding members in the TreeEntity structure.

```
                case CUSTOM_ENTITY_TREE:

                    // Retrieve the fog entity details.
                    memcpy( &Tree.Flags, pEntityData, sizeof(ULONG) );
                    pEntityData += sizeof(ULONG);

                    // Bark Texture
                    memcpy( &StringLength, pEntityData, sizeof(USHORT) );
                    pEntityData += sizeof(USHORT);

                    if ( StringLength > 0 )
                    memcpy( Tree.BarkTexture, pEntityData, StringLength );
                    pEntityData += StringLength;
```

The next value in the entity data area of the tree is a value describing how many frond textures our tree uses. We currently only support a single frond texture so we skip all but the first texture listed (feel free to experiment with this setting as you please). We then extract the first texture name into the TreeEntity structure.

```
                    // Frond Texture Count
                    Count = *pEntityData++;

                    // Loop through textures in the file
                    for ( j = 0; j < (ULONG)Count; ++j )
                    {
                        // Get string length
                        memcpy( &StringLength, pEntityData, sizeof(USHORT) );
                        pEntityData += sizeof(USHORT);

                        // skip all others stored.
                        if ( j < 1 )
                        {
                            // Read String
                            if ( StringLength > 0 )
                            memcpy( Tree.FrondTexture, pEntityData,StringLength );
                            pEntityData += StringLength;

                        } // End if first frond texture
                        else
                        {
                            // Skip String
                            pEntityData += StringLength;

                        } // End if unsupported extras

                    } // Next Frond Texture
```

Notice that in the frond texture name loop, we skip all but the first texture found. For all others we still increment the data pointer to move it past any other frond texture names that may be stored there. At the

end of this loop, regardless how many frond texture names were stored, our data pointer will be pointing at the next property to be extracted.

The GILES™ tree entity also supports a concept of separate leaves (in addition to the fronds), but our class does not currently support this technique (Module III will address this). Therefore, we will simply retrieve the number of leaves stored in the file and will then increment the data pointer past the string stored for each leaf.

```
                    // Leaf Texture Count
                    Count = *pEntityData++;

                    // Loop through leaf textures in the file
                    for ( j = 0; j < (ULONG)Count; ++j )
                    {
                        // Get string length
                        memcpy( &StringLength, pEntityData, sizeof(USHORT) );
                        pEntityData += sizeof(USHORT);

                        // Leaves are not yet supported, skip all texture names.
                        pEntityData += StringLength;

                    } // Next Leaf Texture
```

Next we extract the random generator seed value of the tree into the tree entity structure.

```
// Growth Seed
memcpy( &Tree.GrowthSeed, pEntityData, sizeof(ULONG) );
pEntityData += sizeof(ULONG);
```

The next block of data stored in the IWF file is basically a mirror of the TreeGrowthProperties structure. While the following block of code looks rather complex, all it is doing is fetching the values for each property in order and copying them into the TreeGrowthProperties member of the TreeEntity structure.

```
// Growth Properties
memcpy( &Tree.GrowthProperties.Max_Iteration_Count,pEntityData, sizeof(USHORT) );
pEntityData += sizeof(USHORT);

memcpy( &Tree.GrowthProperties.Initial_Branch_Count,pEntityData, sizeof(USHORT) );
pEntityData += sizeof(USHORT);

memcpy( &Tree.GrowthProperties.Min_Split_Iteration,pEntityData, sizeof(USHORT) );
pEntityData += sizeof(USHORT);

memcpy( &Tree.GrowthProperties.Max_Split_Iteration,pEntityData, sizeof(USHORT) );
pEntityData += sizeof(USHORT);

memcpy( &Tree.GrowthProperties.Min_Split_Size, pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Max_Split_Size, pEntityData, sizeof(float) );
pEntityData += sizeof(float);
```

```
memcpy( &Tree.GrowthProperties.Min_Frond_Create_Iteration,
         pEntityData, sizeof(USHORT) );

pEntityData += sizeof(USHORT);

memcpy( &Tree.GrowthProperties.Frond_Create_Chance, pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Frond_Min_Size, pEntityData, sizeof(D3DXVECTOR3) );
pEntityData += sizeof(D3DXVECTOR3);

memcpy( &Tree.GrowthProperties.Frond_Max_Size, pEntityData, sizeof(D3DXVECTOR3) );
pEntityData += sizeof(D3DXVECTOR3);

memcpy( &Tree.GrowthProperties.Two_Split_Chance, pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Three_Split_Chance, pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Four_Split_Chance, pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Split_End_Chance, pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Segment_Deviation_Chance,
        pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Segment_Deviation_Min_Cone,
         pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Segment_Deviation_Max_Cone,
        pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Segment_Deviation_Rotate,
         pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Length_Falloff_Scale, pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Split_Deviation_Min_Cone,
         pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Split_Deviation_Max_Cone,
        pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy(&Tree.GrowthProperties.Split_Deviation_Rotate, pEntityData,sizeof(float) );
pEntityData += sizeof(float);
```

```
memcpy( &Tree.GrowthProperties.SegDev_Parent_Weight, pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy(&Tree.GrowthProperties.SegDev_GrowthDir_Weight,pEntityData,sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Branch_Resolution, pEntityData, sizeof(USHORT) );
pEntityData += sizeof(USHORT);

memcpy( &Tree.GrowthProperties.Bone_Resolution, pEntityData, sizeof(USHORT) );
pEntityData += sizeof(USHORT);

memcpy( &Tree.GrowthProperties.Texture_Scale_U, pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Texture_Scale_V, pEntityData, sizeof(float) );
pEntityData += sizeof(float);

memcpy( &Tree.GrowthProperties.Growth_Dir, pEntityData, sizeof(D3DXVECTOR3) );
pEntityData += sizeof(D3DXVECTOR3);
```

After the TreeGrowthProperties structure we have the animation wind direction vector and the wind strength, so let us read these values next (a 3D vector and a float)

```
// Animation Properties
memcpy( &Tree.AnimationDirection, pEntityData, sizeof(D3DXVECTOR3) );
pEntityData += sizeof(D3DXVECTOR3);

memcpy( &Tree.AnimationStrength, pEntityData, sizeof(float) );
pEntityData += sizeof(float);
```

Finally, we read in the 3D vector describing the initial dimensions of the root node of the tree and its growth direction (also a 3D vector).

```
// 'Initial' values
memcpy( &Tree.InitialDimensions, pEntityData, sizeof(D3DXVECTOR3) );
pEntityData += sizeof(D3DXVECTOR3);

memcpy( &Tree.InitialDirection, pEntityData, sizeof(D3DXVECTOR3) );
pEntityData += sizeof(D3DXVECTOR3);
```

We have now loaded all the data from the entity into our TreeEntity structure. Next we test to see if the flags we extracted have the TREEFLAGS_INCLUDEFRONDS bit set. If so, we set the Include_Fronds Boolean of the TreeGrowthProperties structure to true so that when we feed it into the CTreeActor::GenerateTree function, it will know to generate fronds for the tree.

```
// Setup data from flags
if ( Tree.Flags & TREEFLAGS_INCLUDEFRONDS )
     Tree.GrowthProperties.Include_Fronds = true;
```

At this point the TreeGrowthProperties structure stores all the tree information we need, so let us generate the tree. This task is actually handed off to the CScene::ProcessTree method. This is a new method that we have added to this class and will discuss next.

```
// Process the tree entity (it requires validation etc)
if ( !ProcessTree( Tree, (D3DXMATRIX&)pFileEntity->ObjectMatrix ) ) return false;

break;

} // End Entity Type Switch
```

The ProcessTree method takes two parameters. For the first parameter we pass the TreeEntity structure that we have just populated with the data from the entity and as the second parameter we pass in the entity's world matrix (every entity has a world matrix member describing its location in the scene).

```
        } // End if custom entities

    } // Next Entity

    // Success!
    return true;
}
```

With the changes to the ProcessEntities function covered let us now look at the new CScene::ProcessTree function. This function has the task of creating a new CTreeActor using the values stored in the passed TreeEntity structure and adding it to the scene's CObject array,

CScene::ProcessTree

The first section of this function (shown below) creates a new CTreeActor and registers a scene attribute callback function with it. It then sets the tree actor's branch and frond material to the filenames stored in the passed TreeEntity structure and calls the CTreeActor::GenerateTree method to build the tree meshes.

```
bool CScene::ProcessTree( const TreeEntity& Tree, const D3DXMATRIX & mtxWorld )
{
    HRESULT       hRet;
    CTreeActor  * pTreeActor  = NULL;
    CObject     * pTreeObject = NULL;

    // Allocate a new tree actor
    pTreeActor = new CTreeActor;
    if (!pTreeActor) return false;

    // Setup and generate the tree
    pTreeActor->RegisterCallback( CActor::CALLBACK_ATTRIBUTEID,
                                  CollectAttributeID, this );

    pTreeActor->SetBranchMaterial( Tree.BarkTexture, NULL );
```

```
    pTreeActor->SetFrondMaterial( Tree.FrondTexture, NULL );

    pTreeActor->SetGrowthProperties( Tree.GrowthProperties );

    hRet = pTreeActor->GenerateTree( D3DXMESH_MANAGED,
                                     m_pD3DDevice,
                                     Tree.InitialDimensions,
                                     Tree.InitialDirection,
                                     Tree.GrowthSeed );

    if ( FAILED(hRet) ) { delete pTreeActor; return false; }
```

At this point the tree skins have been built so we will check the flags member of the passed TreeEntity structure to see if animation should be generated for this tree. It so, we pass the wind direction and the wind strength properties into the CTreeActor::GenerateAnimation method.

```
    // Generate the animation if requested
    if ( Tree.Flags & TREEFLAGS_GENERATEANIMATION )
    {
        hRet = pTreeActor->GenerateAnimation( Tree.AnimationDirection,
                                              Tree.AnimationStrength );
        if ( FAILED(hRet) ) { delete pTreeActor; return false; }

    } // End if generate animation
```

With our CTreeActor now completely built, let us make room at the end of the scene's CActor array to store its pointer.

```
    // Store this new Actor
    if ( AddActor( ) < 0 ) { delete pTreeActor; return false; }
    m_pActor[ m_nActorCount - 1 ] = pTreeActor;
```

With the tree actor's pointer added to the scene's actor array, we store the actor and its world matrix in a newly allocated CObject before resizing the scenes CObject array and storing CObject's pointer in it.

```
    // Now build an object for this TreeActor (standard identity)
    pTreeObject = new CObject( pTreeActor );
    if ( !pTreeObject ) return false;

    // Copy over the specified matrix
    pTreeObject->m_mtxWorld = mtxWorld;

    // Store this object
    if ( AddObject() < 0 ) { delete pTreeObject; return false; }
    m_pObject[ m_nObjectCount - 1 ] = pTreeObject;

    // Success!!
    return true;
}
```

That completes the framework changes for Lab Project 12.2. Our framework now has support for loading GILES™ tree entities and generating skinned actors for them.

Lab Project 12.3

Lab Project 12.3 is the first project that will employ our Action Animation System. It will be implemented into the CActor interface and used by the application in this lab project to apply animated sequences to the character as he navigates the level. In this project we will also update our framework and loading code to add IWF file terrain and fog support. The first order of discussion in this section will be the design and implementation of the Action Animation System.

The Action Animation System

The goal of the action system we will develop is not to provide the most flexible animation mixing system imaginable. Indeed such a system would be quite complex and hard to use as a teaching exercise. Instead, our goal is to provide a simple way to describe how the various animation controller tracks should be set up for a specific action, while providing a relatively easy to use interface for the end user. Let us be clear about what we mean by an action.

What is an Action?

In our system, we assign the word ‘action’ to the collection of animation sets, and their associated properties, that must be set on the animation controller for a high level action to be played. It is quite common for an artist to create animation sets for a given model such that they are localized to various regions of the body. As an example, a character may have three animation sets created for it that animate only the legs of the character in a certain way. One animation set might be called ‘Legs Idle’ and simply shuffles the legs from side to side while the character is awaiting further instruction. A second animation set might be called ‘Legs Walk’ and needs to be played when the character is walking. A third animation set might be called ‘Legs Run’ and when played, launches the legs of the character into a full sprint. Remember, these animation sets affect only the legs. Of course, the artist would also need to define animation sets for the torso. For example, there may be two animation sets called ‘Torso Ready’ and ‘Torso Shooting’. When the ‘Torso Ready’ animation set is played, the character should hold his weapon in his hands ready for action but not yet taking an aggressive posture. We might think of this as being like the arms of a soldier as he walks on patrol with his assault rifle. The animation set ‘Torso Shooting’ could really be as simple as a single keyframe set that when played, poses the arms of the soldier up near his chest as if the soldier is firing a weapon. Of course, animation sets may exist for other parts of the body too; there may be animation sets that tilt the head of the soldier to one side when in the firing position such that he is looking through the eye piece of his weapon. For now, we will just go forward with the arms and legs example for ease of explanation.

Although the artist could create animation sets that animate both the torso and the legs, the benefits of the segmented approach is that it relieves the artist from having to create animation sets for every combination of torso and leg animations that the application may wish to play (although to be sure, many game development shops will do exactly that). Imagine that the artist created a single animation set called ‘Walk and Shoot’ that animated both the legs in a walking motion and the arms in a shooting

motion. The artist would also have to create such animation sets for every combination. For example, he may also have to create the following animation sets “Run and Shoot”, “Idle and Shoot”, Walk and Ready”, “Run and Ready”, “Idle and Ready”. When you imagine the various animation sequences which can be applied to the legs alone “Jump, Crouch, and Kick”, the artist would then have to create ‘Ready’ and ‘Shoot’ versions of these animations too. As you might assume, this would put a heavy asset creation burden on the artist.

By using a segmented approach as discussed above, the artist can create isolated animations for the various parts of the character’s body. These separate components can then be mixed and matched by our engine at run time. The artist would create only three animation sets for the legs in this example. ‘Legs Idle’, ‘Legs Walk’, and ‘Legs Run’. If we imagine that the character is running and then wants to fire his weapon, we can still leave the ‘Legs Run’ animation set playing but then also play the ‘Shooting’ animation set. Since these two sets, which are playing simultaneously, work on totally separate parts of the body, they do not conflict with each other. If the character is still firing his weapon but then would like to start walking instead, we can just swap out the ‘Legs Run’ animation for the ‘Legs Walk’ animation. The legs would now play a different sequence while the torso continues to fire the weapon, unhindered by the change applied to the legs.

Although the segmented animation set design is often desirable, it does shift the burden to the application with respect to handling which animation sets should be played simultaneously to perform a given action. For example, we know that in the previous example, if we wanted to have our character perform an action such as ‘Run and Fire’, we would have to assign both the ‘Legs Run’ and ‘Shooting’ animation sets to active tracks on the animation mixer. This is one of the core ideas that our Action Animation System addresses. The important thing at the moment is for us to understand that an action can be thought of quite abstractly as an action to be performed by the object. For instance, we may want our actor to swim, jump, run, and walk. But each of these actions may need to be comprised of many different animation sets under different circumstances. An action (in the terms outlined by this system) is that collection of animation sets (and their properties) which describes to the animation controller which components are required to carry out the act of, for instance, swimming or walking.

By integrating this system directly into our Actor class, it allows us to use a simple data driven approach for setting up the controller, without having to necessarily work through separate components. This keeps the complexity of the system low from a user standpoint. Because are not yet ready to employ a full scripting system (we will introduce you to that in Module III), we currently make use of a static descriptor file format. Because of the static nature of the description components, we will be bound to a ‘pull only’ process (i.e. it cannot change based on the circumstances at any given time during game-play). These descriptor files are essentially just standard Windows™ ‘*.ini*’ files, which we process by making use of the standard Win32 API functions `::GetPrivateProfileInt()`, and `::GetPrivateProfileString()`. We will discuss the format of these files in a moment and examine their contents. An Action file will have an ‘.act’ extension and contain some number of actions. Each action will have a name that the application will use to apply that action to the character (e.g., “Walk at Ease” or “Run and Shoot”). Each action in the .act file will contain a list of the names of animation sets which need to be played simultaneously to achieve that action as well as the properties that should be assigned to the tracks for those animation sets. This means we can also control the speed and contribution strength of a given animation set within an action when it is applied.

Although the ability to store a list of animation sets and their properties with an assigned action name would be a convenient way for the application to specify the various animation sets that should be set on the controller to achieve a given action, our action system provides a powerful blending feature that will allow it to intelligently make decisions about which tracks on the mixer should be used. It will also determine which animation sets from a previously played action should be slowly diminished as we phase in an animation set from a newly applied action. The ability for us to be able to blend the animation sets from a previous action into the animation sets of a new action over time is an essential component of our system.

Action Blending

To understand why blending is useful (and often necessary) let us continue with our previous example of the two animation sets defined for the torso of the character; 'Ready' and 'Shooting'. We will also assume for the sake of this discussion that both these animation sets contain just a single keyframe. That is, they do not really animate the torso; they just contain a snapshot of the character's arms in a different position. When the 'Ready' animation set is playing the arm frame matrices are set such that the soldier is holding his weapon in front of his chest. The 'Shooting' animation set is similarly a single keyframe looping set that when played, positions the arms of the character such that he is holding his weapon up to his face.

Figure 12.2 shows the state of the torso when each animation set is being played. Let us now imagine that the character's torso is currently in the 'Ready' pose and we wish it to assume the 'Shooting' pose when the user presses the fire button. The wrong way to handle this, when the fire button is pressed, would be to remove the 'Ready' pose from its track on the animation mixer and assign the 'Shooting' pose in its place. The next time the scene is rendered, the arms of the character will be in the shooting pose as requested, but this is a terrible way to accomplish that objective.

Figure 12.2

The obvious problem with this approach of course is the lack of any smooth transition between states. Simply swapping one pose for another would mean that the arms of the character would abruptly change from the ready position to the shooting position within the time of a single frame update.

In reality, we would expect to see the character's arms slowly transition from the ready pose to the shooting pose. But if we do not employ any blending support at the code level, the artist would have to make transition animations. When we consider the sheer number of animations an artist would need to make for each pose for each section of the character's body, and then consider that the artist would then need to build transition animation sets from each pose to every other pose, the asset demands on the

artist for just a single character would be staggering. By exposing run-time blending support in our action system, we can get those transitions for free. So let us now discuss how our system may provide asset-free transition sequences.

When we think about the problem in Figure 12.2 and factor in the functionality that is exposed by the D3DX animation system, a solution arises that makes use of sequencer events and the weight properties of mixer tracks.

Each action in the .act file will contain a number of animation set definitions. A *set definition* is comprised of the name of one of the animation sets defined in the X file along with properties that will be applied to the mixer track when the animation set is played. One property that we will also introduce is the ability to assign an animation set a 'Group' name. Within a given action, there should never be more than one animation set with the same group name, but animation sets contained in different actions can belong to the same group. For example, we might have two actions defined in our .act file. In each action there might be an animation set definition that describes how the torso of the character should be animated. (It is important to note that only one action can be applied to the character at any one time.) We will imagine that the animation set in the first action that animates the torso is called 'Ready' and the torso animation set being used by the second action is called 'Shooting'. Because both of these animation sets exist in different actions, but animate the same region of the character, we will assign them the same group name (e.g., 'Arms').

Now let us imagine that our application applies the first action. The 'Ready' animation set will be assigned to the first empty track on the mixer to animate the arms of the character in the ready pose. We will cache some information in the actor at this point that says that the animation set currently assigned to that track belonged to a group with the name 'Arms'. So far, nothing out of the ordinary is happening until the user presses the fire button and the second action is applied. We know that the second action contains as one of its animation sets the 'Shooting' animation set, which also belongs to a group with the name 'Arms'. Here is where things get interesting. Rather than just replacing all the animation sets that were set on the controller when the previous action was applied with the animation sets defined in this new action, we will do the following for any set that has been configured for blending in the action file:

- For each animation set definition in the action we are about to apply we will search for a track on the controller that is not in use (i.e., a free track).
- If the animation set has been configured to blend in the .act file, it will also have a property assigned to it called Mix Length. This is a value describing the number of seconds we would like the animation set's weight to rise from zero to full strength. For example, a value of 5 seconds means that we would like this animation set to slowly fade in to full contribution over five seconds.
- At this point we register a sequencer event with the new track. The event is a track weight event that describes our fade in from zero to full strength with a duration of five seconds, starting immediately.
- Since only one animation set from a given group should be current at one time, we deactivate any animation sets that belong to the same group as the one we have just activated. In our example, we have just set the 'Shooting' animation set on a mixer track. Since this set belongs to the 'Arms' group, we should now deactivate any animation sets assigned by a previous action

that belongs to the same group. In our example, the ‘Ready’ animation set would currently be in use by the mixer and is part of the ‘Arms’ group.

- Since the ‘Shooting’ set was configured to blend in over a period of five seconds, we will do the opposite for any animation set that belongs to the same group that was applied by a previous action. That is, we will set a sequencer event that will fade the weight/contribution of the ‘Ready’ set from its current full strength setting to zero over a period of five seconds.
- We will also set a second sequencer event that will be triggered in 5 seconds time (when the set has fully faded out) to disable the track with the ‘Ready’ set.
- We will cache the information somewhere that this track is now fading out so that it will not be used by any future actions we apply until the fade out is complete.
- When any tracks have their enabled state set to false by the sequencer event, we know that the set that was applied to that track from a previous action has fully faded out and that it can now be used by the system to apply the sets of future actions too (i.e., it becomes a free track).

Figure 12.3 shows the basic ‘blending’ transition that will occur when a set is applied to the animation controller which shares the same group name with an animation set already set on the mixer. We are showing the blending case here, but as you will see, blending is an optional property we can specify for any animation set in the .act file.

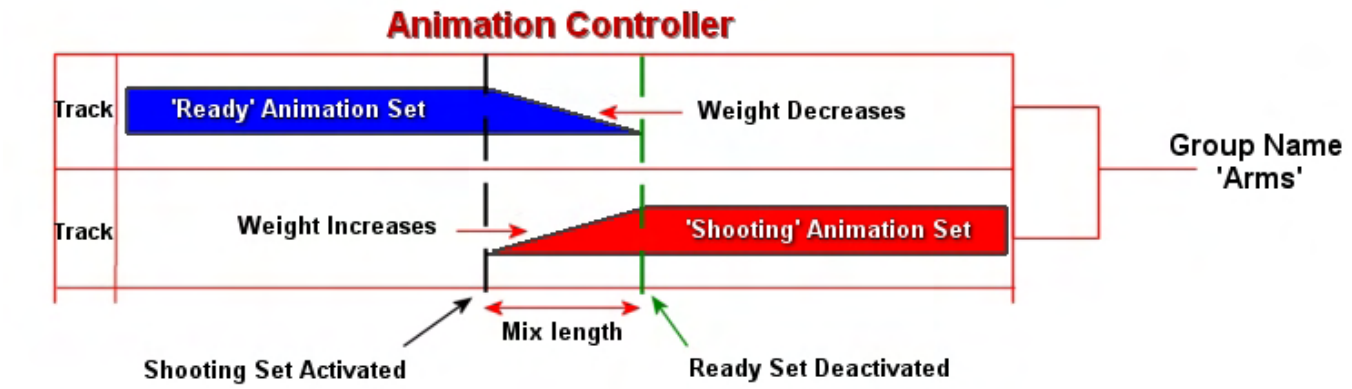

Figure 12.3

In Figure 12.3 it is assumed that the ‘Ready’ animation set and the ‘Shooting’ animation set belong to two different actions but also belong to the same group (‘Arms’). It is also assumed that the action that was applied first to the actor was the one that contained the ‘Ready’ animation.

In this diagram we show the process that occurs between two animation sets from two different actions when the second action is applied and both animation sets share the same group name. We see that halfway through the playing of the ‘Ready’ animation set a new action is applied which contains the ‘Shooting’ animation. This animation is part of the same group. In the new action we are about to apply, the ‘Shooting’ animation set is configured to blend in over a period of time specified by its Mix Length. The ‘Shooting’ animation set is assigned to a mixer track and a sequencer event is set immediately that will fade that track’s weight from 0.0 to its full weight over the time specified in the Mix Length property. If we assume for the sake of this discussion that the Mix Length property assigned to the shooting animation set is 5 seconds, the contribution of the ‘Shooting’ animation set on the actor’s bone

hierarchy will become stronger over a 5 second period. Furthermore, at this exact time, we also set a sequencer event for any previous tracks which belong to the same group to fade out over the same period of time. In this simple example, the ‘Ready’ animation set belongs to the same group, so it has a sequencer event set for it that will fade its weight from its current value to zero over the next 5 seconds. We will also schedule a sequencer event on the ‘Ready’ track that will be triggered in 5 seconds time to disable the track when the fade out is complete. At this point, we will make a note that the track is ready to be used again.

Although only one action can be applied to an actor at any given time and no single action can contain more than one animation set with the same group name, multiple sets belonging to the same group can all be contributing to the hierarchy simultaneously during these transition phases. If you look at the area between the markers (the vertical dashed lines) in Figure 12.3, you will see that while the action that contains the ‘Shooting’ set is considered to be the current action in use by the system, animation sets from the previous action are fading out over time. We can see that during the Mix Length period, two animation sets (one from the current action and one from the previous action) are being used to animate the bone hierarchy simultaneously.

At a point halfway through the Mix Length period, the two sets would have an equal contribution to the hierarchy. We can think of this as positioning the gun halfway between the ready pose and the shooting pose (see Figure 12.4). Therefore, as the weight of the ‘Ready’ pose diminishes and the weight of the ‘Shooting’ pose increases, the arms of our actor will slowly move from the ready pose to the shooting pose and we have a transition animation without the artist ever having to create a custom one. You might also imagine that if you applied several actions to the actor over a very short period of time, which each had fading animation sets belonging to the ‘Arms’ group, after the last action had been applied, you would have one animation set for that group fading in, and multiple animation sets (from the various previous actions) in various stages of fading out. Finally, you can couple that with the fact that multiple actions can contain multiple animation sets, each belonging to multiple shared groups, and we have a lot of flexibility here (and a lot of work to do). Of course, we will have to make sure that we have sufficient spare mixer tracks to handle all the transitioning out we will need to perform when new actions are applied and older actions are still fading out.

This same system can be used to transition between animation sets belonging to the ‘Legs’ group as well. When an action is applied to animate the legs of the character in a running motion, this set could be faded in over a period of time. If the animation set for the ‘Legs’ group from a previous action was a walking sequence, the legs would transition from a walk to a run over a period of time, instead of instantly snapping from one to the other; very nice indeed.

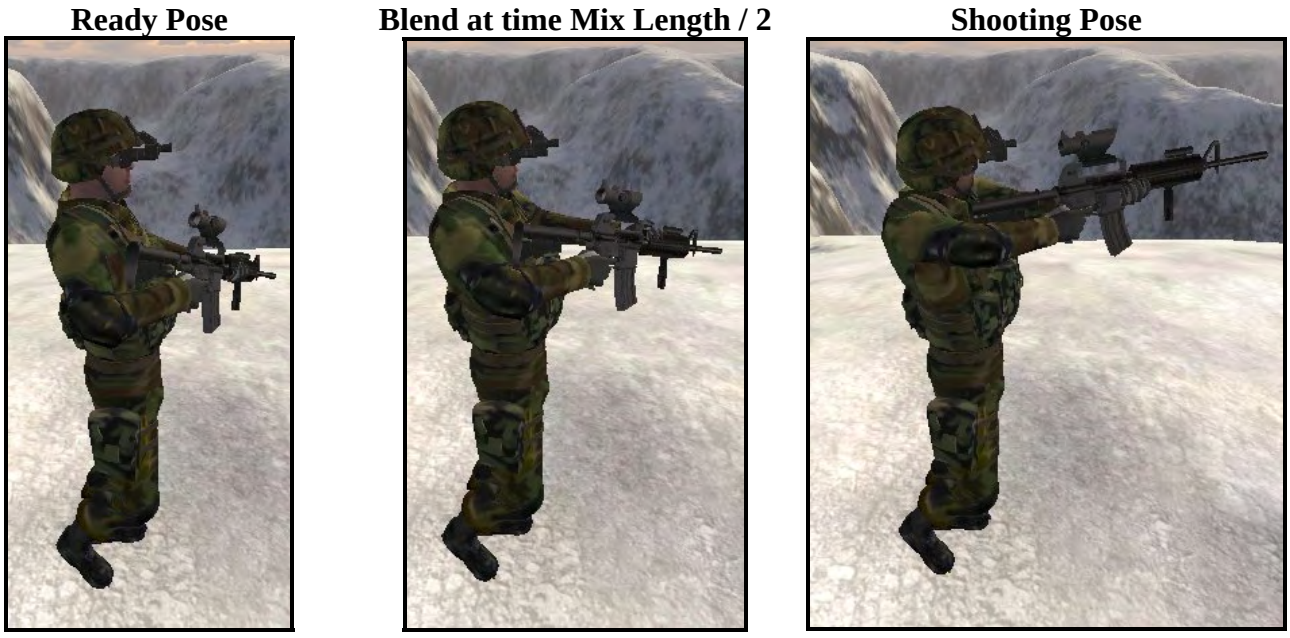

Figure 12.4 : Transition through animation set blending

We will need a way to synchronize the timers for the various tracks when applying actions. For example, if we wish to play the 'Running' animation on the legs and we are currently playing a 'Walking' animation, we would not want the running animation to start from the beginning each time. If the walking animation was halfway through when the running animation set was activated, the two clocks would be wildly out of sync. We would definitely not want the left leg of the character halfway through its walk pose to snap back to its starting position in the run pose. Therefore, in our .act file we will also be able to specify how the clock should be set when an animation set is applied to a mixer track. For example, when applying the running animation to the legs, we would like to set the track position to that of the walk animation set's track that is about to fade out. In other words, we want the new track to take its time from a currently playing track from the same group. That way, the running animation will gracefully take over from the walking animation over the Mix Length period.

As you will see however, all of this functionality is optional. We can have sets defined in actions that are not set to blend or transition. When such animation sets need to be played, any animation sets currently assigned to the controller that share the same group name will be deactivated instantly and the new animation set will take its place. We will also have the option not to synchronize the track clock of a newly assigned animation set to that of the group to which it belongs and may wish to simply play it from the beginning.

Before we get into the discussion of the implementation details and start looking at the contents of an .act file, we have assembled a small glossary of terms that we have collected so far so that there is no confusion as we move forward.

The Action System – Glossary of Terms

ACT File
This is the primary descriptor file which contains the information required to set up the controller tracks for playing out the specified actions. It contains the definitions of one or more actions. Since these are simple text files, we can create them in any text-base editor (e.g., Notepad).

Action
Some combination of animations that convey a higher level animation concept we wish to perform. For example, we may want our actor to swim, jump, run and walk. Each of these actions may need to be comprised of many different animation sets under different circumstances. An action (in the terms outlined by this system) is that collection of animation set names and their properties which describe the components required to carry out the higher level performance.

Every action has a name (e.g., "Walk and Shoot"). It is this name that our application will pass to the CActor::ApplyAction method in order to configure the controller to play that action. The action is comprised of one or more set definitions.

Set Definition
Each action stores one or more set definitions. An individual set definition describes how we would like a single animation set (one set out of a possible many required to perform an action) to be processed and initialized when it is applied to an animation controller mixer track. The various properties stored within a set definition are items such as the name of the animation set to apply, the speed we would like it to play, how much it contributes to the overall animation output (its weight) and other timing and blending properties.

Blending
The action system includes a feature called blending which is primarily used to describe how the individual animation sets should transition between one another when switching between different actions.

Currently, there are only two options for blending: `Off` – which tells the action system that no blending should occur when the animation set is assigned to the controller, and `MixFadeGroup` – which causes a previous set's weight (belonging to the same group) to be decreased, while the new set's weight is increased. This provides a fade-in/fade-out effect between actions.

For many types of actions (although certainly not all) this feature is extremely useful. In many cases, even if we only provide one frame of animation per pose, we can smoothly transition the limbs of a character between those poses without the artist having to provide transition animations. Good candidates are generally animations where the bones are not in wildly different configurations. For example some good blend candidates would typically include Stop to Walk, Stop to Run, Stop to Strafe, Walk to Run, Walk to Strafe, Run to Strafe, Stand to Crouch, (and the reverse for all of these). When the skeletal configurations are very different, blending will not always be a viable solution. For example, going from a swim animation to a walk animation would probably not work all that well and some form of hand crafted transition animation would probably be in order (or just an immediate switch).

While we give up some of the control that hand animated transitions provide, blending usually provides reasonably realistic transitions, with the added advantage of *greatly* reducing animation asset requirements (simple single frame poses will often suffice).

Groups

The AAS includes a concept of groups. A group is essentially just a name that we assign to a set definition describing a relationship between animation sets in different actions. This concept grows out of the requirement for the system to understand which animation set you would like to transition *from*, during the blending process.

Groups are defined between actions, rather than being internal to any one action. That is, the grouping is required for steps that are taken when switching to another action. As a result, set definitions belonging to different actions can be grouped, while within any one action only one set definition may belong to a particular group.

For example, imagine that we have two animation sets named ‘Walk’ and ‘Run’ which contain keyframes for the legs of the character only. In this example, we may define two separate actions for the act of running and walking separately. When we switch between these two actions (and we would like the legs to blend smoothly between the two) the system needs to know that the ‘Walk’ animation set is the one that should be blended out. Because these two set definitions would belong to the same group (perhaps with the name ‘Legs’) it is able to make this determination.

In addition to blending, the group concept is also applied to the various timing properties available via the set definition. These will be explained later.

Now that we know the definitions for the various components of the system, let us have a look at the format of the .act file.

The ACT File Specification

Below is the ACT file specification. Any dynamic properties are surrounded in braces (*i.e. {Label/Restrictions}*), while optional values (depending on certain other values used) are shown in ***bold***.

```
 [General]
ActionCount = {0…n}

; ---------------------------------------------------------------------------
; Action Block
; Repeat for each action, the number of which is defined in the
; above 'ActionCount' variable (relative to 1).
; ---------------------------------------------------------------------------
[Action{1…n}]

Name            = {Action Name}
DefinitionCount  = {0…n}

; ---------------------------------------------------------------------------
; Definition Block
; Repeat for each definition, the number of which is defined in the
; above 'DefinitionCount' variable.
; ---------------------------------------------------------------------------
Definition[{0…(DefinitionCount-1)}].SetName      = {Animation Set Name}
Definition[{0…(DefinitionCount-1)}].GroupName  = {Group Name (Unique to this action)}
Definition[{0…(DefinitionCount-1)}].Weight         = {Track Weight}
Definition[{0…(DefinitionCount-1)}].Speed          = {Track Speed}
Definition[{0…(DefinitionCount-1)}].BlendMode   = {Off | MixFadeGroup}
Definition[{0…(DefinitionCount-1)}].TimeMode    = {Begin | MatchGroup | MatchSpecifiedGroup}

Definition[{0…(DefinitionCount-1)}].MixLength          = {Seconds to Blend if MixFadeGroup}
Definition[{0…(DefinitionCount-1)}].TimeGroup        = {Group Name if MatchSpecifiedGroup}
; ---------------------------------------------------------------------------
; End Definition Block
; ---------------------------------------------------------------------------

; ---------------------------------------------------------------------------
; End Action Block
; ---------------------------------------------------------------------------
```

At the top of file is the General block, which describes properties global to the file. In this block there is just a single property we need to specify -- the number of action definitions that are going to follow. Each action definition contains the data for a single action. If the ActionCount property in the General block is assigned a value of 10, this should be followed by 10 Action blocks.

Following the General block are the Action blocks. Each action block should have the name Action*N* where *N* is the number of the block currently being defined. The number of action blocks should be equal to the ActionCount property specified in the General block.

Each action block has two properties that need to be set -- the name of the action and the number of set definitions it will contain. The name assigned to the action is the same name the application will use to apply that action to the actor, so you should use something descriptive (e.g., "Strafe and Shoot"). The DefinitionCount property is where we specify the number of animation sets that will comprise this action. If we set this value to *N*, it should be followed by *N* Definition blocks nested inside the Action block. Each definition contains the name of an animation set and the properties needed to assign it to the animation mixer.

Each Definition block inside an Action block has a name in the format Definition*N*, where *N* is the numerical index of the definition inside the Action block. Unlike the General and Action blocks, each definition block has many properties to set which describe how the animation set is set up.

We will now discuss the properties of the definition block.

```
Definition[{0…(DefinitionCount-1)}].SetName      = {Animation Set Name}
Definition[{0…(DefinitionCount-1)}].GroupName    = {Group Name (Unique to this action)}
Definition[{0…(DefinitionCount-1)}].Weight       = {Track Weight}
Definition[{0…(DefinitionCount-1)}].Speed        = {Track Speed}
Definition[{0…(DefinitionCount-1)}].BlendMode    = {Off | MixFadeGroup}
Definition[{0…(DefinitionCount-1)}].TimeMode     = {Begin | MatchGroup | MatchSpecifiedGroup}
Definition[{0…(DefinitionCount-1)}].MixLength    = {Seconds to Blend if MixFadeGroup}
Definition[{0…(DefinitionCount-1)}].TimeGroup    = {Group Name if MatchSpecifiedGroup}
```

Set Name

This is the name of the animation set for which this definition is applicable. It should match the name of an animation set in the X file. If you have created the art assets yourself, then you will know the names you have given to your sets, otherwise your artist will supply these names to you. If you are using models that you have downloaded off the internet then you can always convert the X file to a text based X file, open it up in a text editor and search for the Animation Set data objects to retrieve their names.

Group Name

This is the where you specify the group name you would like to apply to this set definition. There should not be another definition in this action which belongs to the same group. Animation sets in different actions that belong to the same group can be transitioned between when a new action is applied. For example, you might have one definition in every action that animates the legs of the character. You might give each of these definitions in each action the group name of 'Legs'.

Weight

This is where we specify the weight of the animation set and thus control the strength of its contribution to the actor's hierarchy. You will usually set this to 1.0 so that the animation, when fully transitioned in, will play at the strength originally intended by the asset creator.

Speed

This is where we specify the speed at which we would like the animation set play when it is first activated. The speed of the track can still be modified by the application after the action has been applied, and we do that very thing in Lab Project 12.3 to speed up the walking animation based on the character's current velocity.

BlendMode

This property can be set to one of two values; Off or MixFadeGroup.

Off

If set to Off, this animation set will not transition to full strength over a period of time and will not be blended with any other animation sets currently playing that have been assigned to the same group. When the action is applied, any sets with the Off BlendMode state will be immediate assigned to a free track at the weight and speed described above. If the previous action was playing an animation set that belonged to the same group, that animation set will be deactivated immediately. There will be no transition from one to the next.

MixFadeGroup

When the BlendMode property is set to MixFadeGroup, we are stating that when this action is applied, this animation set's weight should slowly transition to its full strength (specified by the weight property above) over a period of time. At the same time, if the previous action was playing an animation set that has been assigned the same group name, then that animation set will have its weight configured to fade out over this same period of time. During this transition time, both the animation sets will be active and blended together to create transition poses from one animation set to the next. Once the previous animation set has had its weight faded out to zero, it is deactivated and the track it was assigned to is free to be used by the system again.

Mix Length

This property is only used if the animation set's BlendMode property has been set to MixFadeGroup. It specifies how long we would like this definition to take to transition to full strength. Similarly, it tells us how long any current animation set belonging to the same group should take to transition out.

TimeMode

The TimeMode property allows us to configure the starting track time for an animation set when it is first applied to the mixer. This is a very useful property that allows us to synchronize the track time of the newly applied animation set with the track time of either a previous animation set from the same group that is transitioning out, or to that of a track playing an animation set belonging to a different group. The latter is also very important as it allows us to synchronize the arms and legs animations even though they belong to different groups. We might imagine that the arms animation set is configured to take its time from the legs animation set, so even when we apply a new animation set to the torso (such as walking), it will take its starting time from the current position of the legs so that the walking movement of both the arms and legs are synchronized.

There are three possible values for this property that our action system understands. They are listed below.

Begin

No time matching is performed. When this animation set is applied, the track clock is set such that the animation set starts playing from the beginning. In this mode, the animation set is not synchronized with any other animation sets in the same action and operates in isolation from a timing perspective.

MatchGroup
This mode is extremely useful when an animation set is configured to blend. It informs the action system that when this animation set is applied, we do not want to start playing it from the beginning but instead, its periodic position should match the current periodic position of an animation set currently playing (from a previously set action) that belongs to the same group. If we imagine two actions, where one has a 'Walk' animation and another has a 'Run' animation, if both of these were assigned to the legs group, the 'Run' animation could inherit the time currently being used by the 'Walk' set to assure a smooth transition.

MatchSpecifiedGroup
This mode is used to ensure synchronization between animation sets within an action that belong to different groups. As an example, we may apply an action to a character that contains an 'Arms' group and a 'Legs' group. The 'Legs' group might be set to MatchGroup mode so that it inherits the time from a current 'Legs' group set to ensure a smooth transition. We might then configure the 'Arms' group in our new action to inherit the time from the 'Legs' group so that the animation sets for both the arms and legs not only remain synchronized with each other, but also inherit their periodic position from a 'Legs' group that was playing in the previous action.

If this mode has been set for a given animation set, the name of the group that you would like this animation set to take its timing information from must also be specified using the TimeGroup property.

Time Group
This property is needed only for definitions that have their TimeMode property set to MatchSpecifiedGroup. It should contain the name of the group you would like this animation set to inherit its initial track time from.

We have now covered the complete specification of our new .ACT file format and have examined what each property does. This will go a long way towards helping us understand the implementation of our new animation system. While the .ACT file specification does not provide as much flexibility as a scripting system -- where we would be able to include conditional branches based on certain states of the application for instance -- this simple specification does provide us with enough control to be able to achieve a reasonably realistic set of actions and transitioning effects for use in our current demos.

An .ACT file example

Looking at an example should help to clarify the subject. Below you can see a very simple .act file that contains three actions. Each action contains three set definitions. They describe animation sets that work with the torso, legs and hips. The hips animations were created by the artist to counteract the rotation of the pelvis caused by the leg animations. That is, the hips animation essentially undoes the rotation to the midriff caused by the leg animations. This stops the torso from rotating side to side as the legs walk.

Note: Lines that start in an .ini file with a semicolon are ignored by the loading functions. They are comments and equivalent to the C++ double forward slash.

The three actions defined in this .ACT file are ‘Walk_At_Ease’, ‘Walk_Ready’ and ‘Walk_Shooting’. Each action contains three set definitions for the legs, hips and torso. The legs, hips and torso definitions for each action are assigned to the ‘Legs’, ‘Hips’, and ‘Torso’ groups, respectively.

```
; Action Definition Script 'US Ranger.act'
[General]
ActionCount = 3

; ------------------------------------------------------------------------------
; Name : Walk_At_Ease
; Desc : Standard walking with weapon down by side.
; ------------------------------------------------------------------------------
[Action1]

Name                        = Walk_At_Ease
DefinitionCount             = 3

Definition[0].SetName       = Walk_Legs_Only
Definition[0].GroupName     = Legs
Definition[0].Weight        = 1.0
Definition[0].Speed         = 1.0
Definition[0].BlendMode     = MixFadeGroup
Definition[0].MixLength     = 0.3
Definition[0].TimeMode      = MatchGroup

Definition[1].SetName       = Walk_Variation
Definition[1].GroupName     = Hips
Definition[1].Weight        = 1.0
Definition[1].Speed         = 1.0
Definition[1].BlendMode     = Off
Definition[1].TimeMode      = MatchSpecifiedGroup
Definition[1].TimeGroup     = Legs

Definition[2].SetName       = Gun_At_Ease
Definition[2].GroupName     = Torso
Definition[2].Weight        = 1.0
Definition[2].Speed         = 1.0
Definition[2].BlendMode     = MixFadeGroup
Definition[2].MixLength     = 1.0
Definition[2].TimeMode      = MatchSpecifiedGroup
Definition[2].TimeGroup     = Legs

; ------------------------------------------------------------------------------
; Name : Walk_Ready
; Desc : Standard walking with weapon at the ready (clasped in both hands)
; ------------------------------------------------------------------------------
[Action2]

Name                        = Walk_Ready
DefinitionCount             = 3

Definition[0].SetName       = Walk_Legs_Only
Definition[0].GroupName     = Legs
Definition[0].Weight        = 1.0
Definition[0].Speed         = 1.0
```

```
Definition[0].BlendMode     = MixFadeGroup
Definition[0].MixLength     = 0.3
Definition[0].TimeMode      = MatchGroup

Definition[1].SetName       = Walk_Variation
Definition[1].GroupName     = Hips
Definition[1].Weight        = 1.0
Definition[1].Speed         = 1.0
Definition[1].BlendMode     = Off
Definition[1].TimeMode      = MatchSpecifiedGroup
Definition[1].TimeGroup     = Legs

Definition[2].SetName       = Gun_Ready_Pose
Definition[2].GroupName     = Torso
Definition[2].Weight        = 1.0
Definition[2].Speed         = 1.0
Definition[2].BlendMode     = MixFadeGroup
Definition[2].MixLength     = 1.0
Definition[2].TimeMode      = Begin

; ------------------------------------------------------------------------------
; Name : Walk_Shooting
; Desc : Standard walking with weapon raised in a shooting pose.
; ------------------------------------------------------------------------------
[Action3]

Name                        = Walk_Shooting
DefinitionCount             = 3

Definition[0].SetName       = Walk_Legs_Only
Definition[0].GroupName     = Legs
Definition[0].Weight        = 1.0
Definition[0].Speed         = 1.0
Definition[0].BlendMode     = MixFadeGroup
Definition[0].MixLength     = 0.3
Definition[0].TimeMode      = MatchGroup

Definition[1].SetName       = Walk_Variation
Definition[1].GroupName     = Hips
Definition[1].Weight        = 1.0
Definition[1].Speed         = 1.0
Definition[1].BlendMode     = Off
Definition[1].TimeMode      = MatchSpecifiedGroup
Definition[1].TimeGroup     = Legs

Definition[2].SetName       = Gun_Shooting_Pose
Definition[2].GroupName     = Torso
Definition[2].Weight        = 1.0
Definition[2].Speed         = 1.0
Definition[2].BlendMode     = MixFadeGroup
Definition[2].MixLength     = 1.0
Definition[2].TimeMode      = Begin
```

In each action, the same animation set for the legs group is being used. This is the animation set with the name ‘Walk_Legs_Only’. As an action is applied, the track position for the ‘Walk_Legs_Only’ animation set in that action will take its timing from a previous set assigned to the same group that is currently playing. In this simple example, where each action uses the same animation set for the legs, it simply means that as the ‘Walk_Legs_Only’ animation set is set on the mixer for a given action, its initial position will be set to the ‘Walk_Legs_Only’ set that was being played by the previous action. The ‘Legs’ group in each action is also set to MixFadeGroup so that the animation set will fade in over the period specified in the MixLength parameters (0.3 seconds in this example). In this particular .ACT file, all actions use the same animation set for the legs, so the transition is a mostly futile. However, we might want to add an additional action such as ‘Idle_At_Ease’ which would use a different animation set for the legs; perhaps one in which the character was no longer walking. In such a case, the MixFadeGroup property would ensure that when we transition from the ‘Idle_At_Ease’ action to the ‘Walk_At_Ease’ action, there would be a 0.3 second transition while the legs move from the idle pose into the walking pose. However, if we know in advance that we only wanted to use walking poses (unlikely) then we could set the BlendMode to ‘Off’.

The ‘Hips’ group animation set in each action does not use blending. Once again, it is the same set being used by the ‘Hips’ group in each action. As we discussed in the previous paragraph, in this section we are assuming that there is only one ‘Hips’ animation set used by all actions, so there is no need to blend between ‘Hips’ animation sets in different actions. In each action however, the ‘Hips’ group animation set is configured to take its timing from the ‘Legs’ group. This is very important in this instance because the ‘Hips’ animation set is really nothing more than an inverse transformation applied to the pelvis to undo any rotation applied to it by the walking of the legs. That is, the artist had to rotate the pelvis bone to make the legs animate properly, but this inverse transformation is applied to the next bone up to stop the pelvis rotation (which is the parent bone) being reflected up to the torso.

Finally, the last animation set specified in each action is the one that belongs to the ‘Torso’ group. A different animation set is used in each action for this purpose. In the first action (‘Walk_At_Ease’), the ‘Torso’ animation set is called ‘Gun_At_Ease’ and it animates the torso such that the character is walking with his gun in his hand, with his arms swinging back and forth in time with his legs. Because of this, in the first action, the timing of this animation set is taken from the ‘Legs’ group so that the swinging arms are synchronized with the walking legs.

In the second action, the animation set in the ‘Torso’ group is called ‘Gun_Ready_Pose’. This adjusts the torso of the character so that he is holding the gun to his chest and looking alert, but not yet assuming a hostile posture. Because this animation no longer needs to be synchronized with the movements of the legs (the arms are no longer swinging back and forth), the timing mode of this animation is set to ‘Begin’. It will begin playing from the beginning as soon as this action is activated. Notice however that it is still set to blend with other sets in its group. This means, if the previous action playing was ‘Walk_At_Ease’, when this new action is applied, the arms would slowly transition from swinging back and forth up to the ready position over a period of one second.

The third action has a ‘Torso’ group animation set called ‘Gun_Shooting_Pose’. This is a single frame animation of the torso holding the gun up to his face in an aiming posture. Since this pose requires no relationship with the animations being played out on other parts of the character’s body, its time mode is set to ‘Begin’. It is also set to blend in from animation sets within the same group. That is, if this action

is applied and the previous action being played was ‘Walk_Ready’, the torso of the character would transition from the ready pose to the shooting pose over a period of one second.

We have now covered all the properties that our Action Animation System will have to work with. We have also seen the format in which the data will be presented to our application. We now know how to write .ACT files in a text editor and the format in which the contents need to be laid out. So let us now begin coding the Action Animation System.

The Action Animation System – Implementation

The structures we will add to CActor will very much mirror the layout of the *.ini* file (.ACT file). The actor will maintain an array of CActionDefinition structures and each action definition structure will contain the information for a single action loaded from the .ACT file. A LoadActionDefinitions function will be added to the CActor interface. This method, which will be called from the application and passed the name of an .ACT file, will load the data and store it internally. For each action definition in the .ACT file, a CActionDefinition structure will be allocated, populated, and added to the actor’s CActionDefinition array.

Each CActionDefinition structure will maintain an array of SetDefinition structures. Each set definition will contain the data for a single animation set when the action is applied. As you can see, this follows the exact layout of the .ACT file. The .ACT contains a number of action definitions and each action definition contains a number of set definitions. In code, the actor contains an array of action definitions and each action definition contains an array of set definitions. The ApplyAction method will also be added to the interface of CActor so that the application can inform the actor to apply one of its actions at any time.

Of course, simply maintaining an array of the information loaded from the .ACT file is not enough by itself to describe the state that the controller may be in at any given time to our action system. For example, we will need to know, for each track on the mixer, is there currently an animation set assigned to it or is it free for our system to use? Is the track in the phase of transitioning out? What was the name of the animation set assigned to that track and is it used by the current action we are applying? A support structure of some kind needs to be introduced. We will need this anyway for us to quickly ascertain during the blending process, which group the animation set assigned to a given track belongs to. We know for example that if the time mode of the animation set we are about to assign has been set to MatchGroup, we will need to search the tracks of the animation mixer for an animation set that belongs to the same group. As the mixer has no concept of groups, we will obviously need a support structure that will store this information for each track.

The support class we will use is called CActionStatus. This will be a new member of CActor which contains the status of each track on the animation mixer. Internally, the CActionStatus class will manage an array of TrackActionStatus structures; one for each track on the mixer. Each TrackActionStatus structure will contain the current properties for a given track on the animation mixer.

To clarify, if the actor had a 15 track animation mixer, the actor would contain a single CActionStatus member that would contain an array of 15 TrackActionStatus structures. Each TrackActionStatus structure contains information about whether its associated track is currently in use by the action system, the name of the set currently assigned to it, the group that set belongs to, and so on.

The following diagram shows the relationships between CActor and the various structures just discussed.

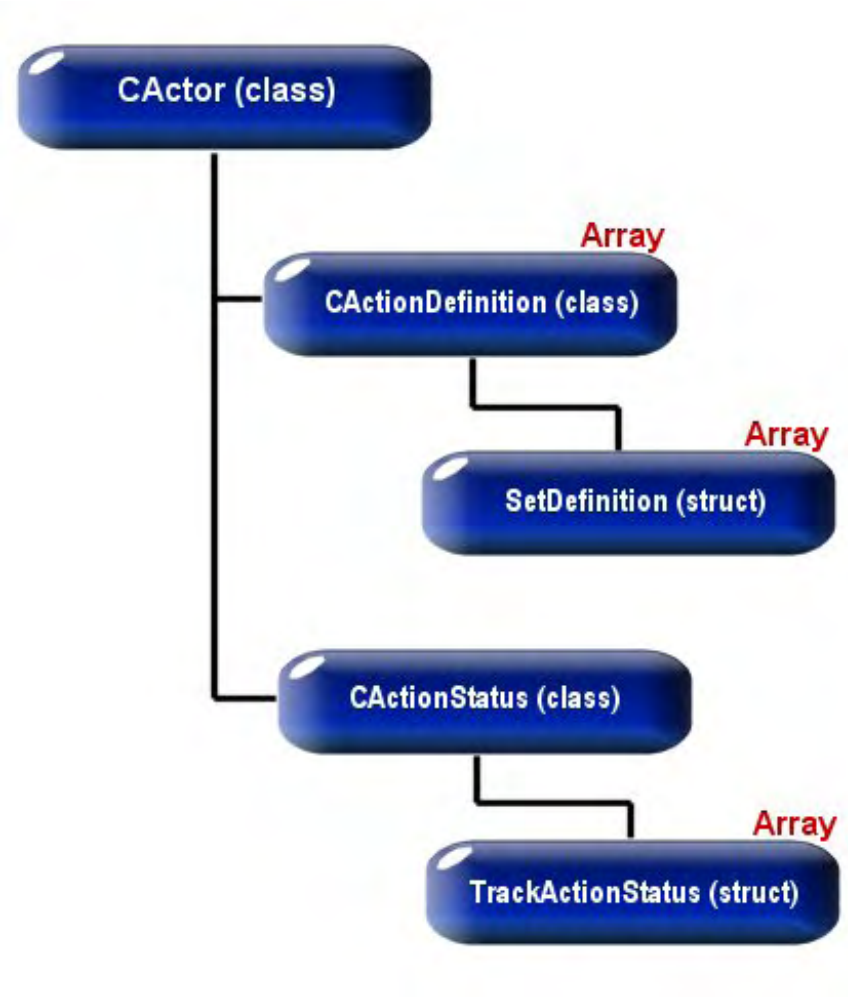

Figure 12.5

Notice that there is a single CActionStatus member that contains the status of the current controller being used by the actor. As the controller is essentially swapped out when referencing is being used, we will also have to do the same with the CActionStatus object. That is, each CObject reference to an actor will now contain not only its own animation controller but also its own CActionStatus object describing the status of all the tracks on its controller's mixer. Our actor's AttachController method will now accept both a pointer to the controller we wish to attach and the CActionStatus object that describes the status of that controller's tracks. This will be a very small adjustment which we will discuss later.

The CActionDefinition array will be allocated when the user calls the CActor::LoadActionDefinitions function. There will be an element in this array for each action defined in the file. Let us now have a look at the changes to CActor.

The CActor Class – Code Changes

We have added some new member variables to CActor to store the data of the action system. As our CActor class definition is now getting quite large, we have only shown the new or modified variables and functions that we are going to introduce in this workbook.

Excerpt from CActor.h

```
class CActor
{
…
…
 private:

    // New 'Action' set data variables
    CActionDefinition   *m_pActions;        // An array of loaded actions
    ULONG                m_nActionCount;    // The number of actions
    CActionStatus       *m_pActionStatus;   // Stores the status of all tracks
…                                           // for the action system
…
  public :
    // New 'Action' Methods
        HRESULT           LoadActionDefinitions      ( LPCTSTR FileName );
        HRESULT           ApplyAction                ( LPCTSTR ActionName );
        CActionDefinition * GetCurrentAction         ( ) const;
        CActionStatus     * GetActionStatus          ( ) const;
…
…
    // Existing functions modified by action system
    LPD3DXANIMATIONCONTROLLER DetachController( CActionStatus ** ppActionStatus );

    void AttachController    ( LPD3DXANIMATIONCONTROLLER pController,
                               bool bSyncOutputs = true,
                               CActionStatus * pActionStatus = NULL );

    HRESULT SetActorLimits      (       ULONG MaxAnimSets = 0,
                                        ULONG MaxTracks = 0,
                                        ULONG MaxAnimOutputs = 0,
                                        ULONG MaxEvents = 0,
                                        ULONG MaxCallbackKeys = 0 );
  }
```

Let us first discuss the three new member variables that have been added.

CActionDefinition *m_pActions

This is a pointer to an array of CActionDefinition objects that will be allocated when the application issues a call to the CActor::LoadActionDefinitions method. Each element in this array is a class that manages the data for a single action loaded from the .ACT file. The CActionDefinition class exposes methods of its own, such as LoadAction and ApplyAction, which the actor uses to perform the heavy lifting associated with loading or applying an action. The actor methods are really just lightweight wrappers that make calls to the methods of the current action being loaded or applied. We will look at the members and methods of the CActionDefinition class shortly.

ULONG m_nActionCount
This member is set in the CActor::LoadActionDefinitions method and contains the number of actions defined in the .ACT file. Therefore, it also describes the size of the above array.

CActionStatus *m_pActionStatus
This is a pointer to a single CActionStatus object that will contain the current states of each track on the animation mixer. It is used by the Action System to remember which animation sets have been assigned to which tracks, which groups those animation sets belong to, and the status of those tracks (e.g., if they are in the middle of a transition).

We will now discuss the new methods that have been added to CActor. Since most of these functions are light wrappers around calls to the methods of the CActionStatus and the CActionDefinition objects, we will not get the full picture until these objects have been covered as well. However, it should be fairly obvious from a high level, with a little explanation, what these methods are doing.

CActor::LoadActionDefinitions

This method is called by the application after the actor has been allocated and populated by the mesh and animation data from the X file. This function is called and passed the name of an .ACT file that contains the data for the action system. This function will open that file, allocate a CActionDefinition array large enough to contain the correct number of actions, and then populate this array with the action data from the file. It will also allocate a new CActionStatus object that has a large enough internal TrackActionStatus array to store the status of every track on the animation mixer.

The function is passed the name of the file we wish to load the action definitions from. The first thing the function does is delete any previous CActionDefinitions array that may exist in the actor prior to this call. It also releases its CActionStatus pointer if one already exists. Notice that because our CActionStatus object will have to be attached and detached from the controller and stored in an external object when referencing is being used, we have implemented the COM-style AddRef and Release mechanism for this object.

```
HRESULT CActor::LoadActionDefinitions( LPCTSTR FileName )
{
    ULONG   ActionCount = 0, i;
    HRESULT hRet;

    // Clear any previous action definitions
    if ( m_pActions ) delete []m_pActions;
    m_pActions     = NULL;
    m_nActionCount = 0;

    // Clear any previous action status
    if ( m_pActionStatus ) m_pActionStatus->Release();
    m_pActionStatus = NULL;
```

We will now retrieve the ActionCount property from the .ACT file. Recall from our studies in Module I that we use the Win32 function GetPrivateProfileInt to read in integer data from an .ini text file.

```
    // Retrieve the number of actions stored in the file
    ActionCount = ::GetPrivateProfileInt( _T("General"),
                                          _T("ActionCount"),
                                          0,
                                          FileName );

    if ( ActionCount == 0 ) return D3DERR_NOTFOUND;
```

Just to recap, the first parameter is the name of the data block in the file that we wish to retrieve the value from. Recall from our .ACT format that the action count property is set in the General block. As the second parameter we pass in the name of the property we wish to fetch the value for (ActionCount). If this property is not found, then the third parameter specifies a default value to be used. In this instance, if the ActionCount property is missing we have an invalid .ACT file and return a default action count of 0 which will cause the function to return without loading any action data. As the final parameter, we pass in the name (and path) of the file we wish to extract the value from.

Now that we know how many actions there are, we can allocate the actor's CActionDefinition array to the correct size so that there is an element for each action in the file. We also allocate the CActionStatus object.

```
    // Allocate the new actions array
    m_pActions = new CActionDefinition[ ActionCount ];
    if ( !m_pActions ) return E_OUTOFMEMORY;

    // Allocate the new status structure
    m_pActionStatus = new CActionStatus;
    if ( !m_pActionStatus ) return E_OUTOFMEMORY;
```

The CActionStatus object will maintain an array of TrackActionStatus objects for each track on the mixer. Each one will contain the status of a track. Let us now fetch the number of tracks available on this actor's animation mixer and send this value to the CActionStatus::SetMaxTrackCount method. We will cover this method in a moment, but it essentially allocates the array of TrackActionStatus structures to be as large as described by the input parameter. We will also copy over the action count property that we extracted from the .ACT file.

```
    // Setup max tracks for action status
    m_pActionStatus->SetMaxTrackCount( (USHORT)GetMaxNumTracks() );

    // Store the count
    m_nActionCount = ActionCount;
```

It is now time to load each action in the .ACT file into each element in the CActionDefinitions array we just allocated. To do this, we loop through each action definition in the array and call its LoadAction method. As you can see, it is the CActionDefinition::LoadAction function which actually loads the data from each action in the .ACT file. We pass it two parameters. The first is a numerical index that, when appended to the word 'Action', will describe the name of the Action block in .ACT file that the current action needs to fetch its data from. As the second parameter, we simply pass the file name of the .ACT file that contains the action data.

```
    // Process the actions
    for ( i = 0; i < ActionCount; ++i )
    {
        // Load the definition from file
        hRet = m_pActions[i].LoadAction( i + 1, FileName );
        if ( FAILED(hRet) ) return hRet;

    } // Next Action in file

    // Success!
    return S_OK;
}
```

And that is it for this function. Obviously, many of the blanks will be filled in when we cover the code to the CActionDefinition methods and the CActionStatus methods. However, by examining the actor's interaction with these objects first, we will have a better understanding of their place within the entire system when we do get around to covering them.

CActor::GetCurrentAction

The next CActor method we will cover is a useful function should the application wish to query which action is currently being played by the actor. Examining the code also establishes the responsibility of the actor's CActionStatus member to keep a record of the current action that has been applied.

```
CActionDefinition * CActor::GetCurrentAction( ) const
{
    // Return the current action if status is available
    if ( !m_pActionStatus ) return NULL;
    return m_pActionStatus->GetCurrentAction();
}
```

Notice that it is the CActionStatus structure that stores the current action (the action that was last applied) and this property can be fetched via CActionStatus::GetCurrentAction. The CActionStatus object will be covered in a moment, but is really little more than a storage container with functions to set and retrieve its data.

CActor::GetActionStatus

This function allows the application to fetch a pointer to the CActionStatus object being used by the actor. This is useful since the CActionStatus object contains the status information for each track of the animation controller. If the application wanted to play an additional animation that was not part of the action, it could fetch the CActionStatus object, use it to find a free track, and flag that track as being in use. If we did not do this, then the action system would have no way of knowing that one of the tracks on the animation mixer was currently being used by an animation set external to the action system and erroneously think it could use that track the next time an action was applied.

```
CActionStatus * CActor::GetActionStatus( ) const
{
    // Validate requirements
    if ( !m_pActionStatus ) return NULL;

    // Add a reference to the action status, we have a floating pointer
    m_pActionStatus->AddRef();

    // Return the pointer
    return m_pActionStatus;
}
```

Another reason to fetch the CActionStatus object is to store it in a CObject. That is, when multiple CObjects reference the same CActor, each object will contain its own controller and status object that will be set before that object is animated.

CActor::ApplyAction

This next function is called by the application when it wishes to change the current action being played to a new one. All the application has to do is call this function and specify the name of the action it wishes to apply. This will be the name assigned to one of the actions in the .ACT file.

This function is the primary runtime interface to the Action Animation System. Once the action data has been loaded, it is the only function that needs to be called to apply new actions to the controller. This function is rather small, since most of the core work takes place inside the CActionDefinition::ApplyAction method (just as most of the loading of data was performed inside this object) which we will examine later.

The first thing this function does is test to see that the actor has an animation controller and a CActionStatus object defined. If not, it returns, since there is no controller to configure with action data. We then get a pointer to the current action being played and test to see if its name is the same as the name passed in. If it is, then the application has asked for an action to be played which is already playing, and there is nothing to do. In this case we will simply return.

```
HRESULT CActor::ApplyAction( LPCTSTR ActionName )
{
    ULONG   i;
    HRESULT hRet;

    // Bail if there is no active controller
    if ( !m_pAnimController || !m_pActionStatus ) return D3DERR_INVALIDCALL;

    // If this action is already set, ignore
    CActionDefinition * pCurrentAction = m_pActionStatus->GetCurrentAction();

    if ( pCurrentAction && _tcsicmp( pCurrentAction->GetName(), ActionName )== 0 )
        return D3D_OK;
```

Notice that it is the CActionStatus object which contains a pointer to the current CActionDefinition that has been applied (we can get a pointer to it via its GetCurrentAction method). Once we have a pointer to the current CActionDefinition, we can use its GetName function to retrieve a string containing its name. In the above code, we use the _tcsicmp string comparison function to compare the name of the current action with the name of the action the application would like to apply. If the _tcsicmp function returns zero, the two strings are identical and there is no need to do anything.

In the next section of code we have determined that the application would like to set a new action. The first thing we must do is loop through each action in the actor's CActionDefinition array and search for the one with a name that matches the action name passed into the function. Here is the remainder of the function:

```
    // Loop through each action
    for ( i = 0; i < m_nActionCount; ++i )
    {
        CActionDefinition * pAction = &m_pActions[i];

        // Compare the name, and apply if it matches
        if ( _tcsicmp( ActionName, pAction->GetName() ) == 0 )
        {
            // Apply the action
            hRet = pAction->ApplyAction( this );
            if ( FAILED(hRet) ) return hRet;

            // Store the action
            m_pActionStatus->SetCurrentAction( pAction );

            // Success!
            return D3D_OK;

        }  // End if names match

    } // Next action

    // Unable to find this action
    return D3DERR_NOTFOUND;
}
```

Once we find a matching action in the CActionDefinition array we will use its ApplyAction method to apply the action to the controller (covered in a moment). This is obviously where the core work of applying the animation sets to the controller and setting blending sequences will take place. After we have applied the current action, we must let the CActionStatus object know that there is a new current action. We do this using the CActionStatus::SetCurrentAction method. This method just stores the passed pointer in a member variable. As discussed, the CActionStatus object is just storage object that has its properties set and retrieved via a few member functions.

Before we get to the core code inside the CActionDefinition object, we will first discuss the layout and methods of the CActionStatus object since it is used extensively by the CActionDefinition::ApplyAction function.

The CActionStatus Class

The CActionStatus class stores the properties of each track on the animation mixer. For a given controller only one CActionStatus object will exist. Internally, the object has only four member variables. It stores the number of tracks on the controller, the current action that is being used by the controller, its own reference count (it uses COM-style lifetime encapsulation semantics), and a pointer to an array of TrackActionStatus structures. There will be one of these structures for each available track on the animation mixer and each structure stores five bits of information about a given track.

Below is the class definition for CActionStatus. Notice that the TrackActionStatus structure is defined in the CActionStatus namespace. Take a look at the member variables and functions that are specified as part of this namespace and also notice that some of the simpler methods are inline.

Excerpt from CActor.h

```
class CActionStatus
{
public:

    struct TrackActionStatus // Status of a single track
    {
        bool   bInUse;             // This track is in use
        bool   bTransitioningOut;  // The track is currently transitioning out
        TCHAR  strGroupName[127];  // The name of the group assigned to this track
        TCHAR  strSetName[127];    // The name of the set assigned to this track

        const CActionDefinition * pActionDefinition;  // The action definition
                                                      // to which this track
                                                      // applies

         ULONG                    nSetDefinition;     // The set definition index,
                                                      // of the above action, to
                                                      // which this track applies
    };

    // Constructors & Destructors for This Class.

    CActionStatus( );
    virtual ~CActionStatus( );

    // Public Functions for This Class.

    ULONG               AddRef           ( );
    ULONG               Release          ( );
    HRESULT             SetMaxTrackCount ( USHORT Count );
    void                SetCurrentAction ( CActionDefinition * pActionDefinition);
    USHORT              GetMaxTrackCount ( ) const  { return m_nMaxTrackCount; }
    TrackActionStatus * GetTrackStatus   ( ULONG Index ) const
                                          {
                                            return ( Index < m_nMaxTrackCount ) ?
                                            &m_pTrackActionStatus[ Index ] :
                                            NULL;
                                           }
```

```
    CActionDefinition * GetCurrentAction ( ) const   { return m_pCurrentAction; }

private:

    // Private Variables for This Class.

    USHORT              m_nMaxTrackCount;     // The maximum tracks for controller
    TrackActionStatus * m_pTrackActionStatus; // Array of track status structures
    CActionDefinition * m_pCurrentAction;     // The current action applied
    ULONG               m_nRefCount;          // Reference count variable
};
```

This class has only four member variables, so let us discuss them before we look at the functions.

USHORT m_nMaxTrackCount
This member will contain the number of tracks on the animation mixer. This value is set when the actor calls the CActionStatus::SetMaxTrackCount method when the actor is first loaded, or when the application resizes the limits of the actor's controller using CActor::SetActorLimits.

Any time the actor clones its controller and extends the number of tracks, the CActionStatus::SetMaxTrackCount method will be called so that the m_nMaxTrackCount member can have its value updated and the TrackActionStatus array (discussed below) can be resized to contain this many elements.

TrackActionStatus * m_pTrackActionStatus
This member is a pointer to an array of TrackActionStatus structures. There will be one TrackActionStatus structure in this array for every track on the animation mixer. That is, the size of this array will be equal to the value of m_nMaxTrackCount discussed above.

Just like the previous value, this array has its size set in the CActionStatus::SetMaxTrackCount method, which is called by the actor whenever the controller is first created or its maximum track limits are extended (via cloning).

Each TrackActionStatus structure in the array contains five very important pieces of information about each track that our Action System will need to know in order to apply actions successfully. Let us discuss the members of this structure.

bool bInUse
This is a simple boolean member which specifies whether the associated mixer track is currently in use. When an action is applied, the animation sets referenced by that action will need to be assigned to tracks on the animation mixer. The action system will need to know which tracks are currently free and can have those sets assigned to them.

If this member is set to false then the track is free to have an animation set assigned to it. If it is set to true then it means it is being used or was being used by a previous action and is still in the process of having its weight faded out.

bool bTransitioningOut

This boolean is set to true if the associated track is currently in the process of being faded out. When an action is applied, and one of the sets in that action shares a group name with a previously assigned animation set, the previous animation set will be set to transition out over a period of time if blending is enabled for the new set. The previous set of the same group name will have a sequencer event activated for it that will fade the track's weight to zero over a specified period of time. This boolean will then be set to true so that the action system knows that this animation set and its track must be left alone to fade out. A sequencer event will also be set for the track at the end of the fade out period that disables the track on the mixer. The next time a new action is applied, we can search the tracks that have this boolean set to true and if we discover that its associated track has been disabled, we can once again mark this track as no longer in use. This is done by setting the bInUse Boolean and the bTransitioningOut Boolean to false.

The need for this boolean will become clear when we cover the code to the CActionDefinition::ApplyAction function. Essentially, it is our way of saying that this animation set was at some time in the past set to transition out over a period of time so leave it alone until that is done, regardless of what other actions may be applied in the fade out period and what their blend settings may be. Once an animation set has been configured to fade, it essentially gets left to its own devices by the action system until the fade out is complete. Then the track can once again be used by future actions.

TCHAR strGroupName[127]

As discussed earlier, one of the key properties for the blending process between actions is the group name assigned to an animation set used by those actions. If an action is applied which contains an animation set that shares the group name with an animation set in the previously active action, and the animation set in the new action has been configured to blend, the action system will fade the previous animation set out while simultaneously fading the weight of the new animation set in.

The action system performs this task by recognizing that for any action there should only be a single track from the same group. Before an animation set is assigned, we first search the tracks of the mixer to see if a track existed in the previous action that shares the same group. If the new action is configured to group blend, the previous track will be faded and the new track introduced over the same period of time. Obviously, for the action system to perform this blending it must be able to search the tracks of the controller and see if tracks exist with the same group name. It is in this member that we store a string containing the group name of the set definition assigned to this track. When the CActionDefinition::ApplyAction method assigns the animation sets of an action to the tracks on the mixer, it will also store the group name associated with that set definition within the action in this member.

TCHAR strSetName[127]

When the action system assigns an animation set to a mixer track it will store the name of the animation set in this member. Although this information could be fetched by querying the animation set interface assigned to the track, it is more convenient to store it here. If the application wishes to use the CActor::GetActionStatus method to get a pointer to the

CActionStatus object, it will be able to easily examine the TrackActionStatus structures for each track to determine which animation sets are currently being used by the controller and the specified action.

const CActionDefinition * pActionDefinition
This member is set when the animation set is assigned to the mixer track. It contains a pointer to the action that set this track. This is useful to have because we know that due to the blending process, not all the animation sets currently set on the mixer will have been set by the currently applied action. If we imagine a case where we have three actions that each use three different animation sets which are configured to blend over a period of 20 seconds, and we apply these three actions over a period of 5 seconds, at 10 seconds (for example) there will actually be 9 animation sets currently in use. The first three will have been set by the first action but will still be in the process of fading out. The second three animation sets will have been set by the action that was applied second and these too will still be in the process of fading out. The final three sets will have been set by the currently applied action. If each track stores a pointer to the action that was responsible for setting its animation set, this may come in handy if the application needs to know this information.

ULONG nSetDefinition
This stores the index of the set definition. For example, if the animation set was referenced by the second set definition in the action (inside the .ACT file) this would be the index that was stored here. Once again, this is really for the purpose of providing as much information as we can to the application in the event that it needs it for some reason.

CActionDefinition *m_pCurrentAction
This member contains a pointer to the currently set action. This is set and retrieved by the CActionStatus::SetCurrentAction and CActionStatus::GetCurrentAction.

We saw the SetCurrentAction method of this object being called from the CActor::ApplyAction method discussed recently. The function first applied the action and then informed the CActionStatus object of the new action that was set using this method. We also saw how the CActor::GetCurrentAction method simply wraps the call to CActionStatus::GetCurrentAction. These Get and Set functions simply set and return the value of this pointer.

ULONG m_nRefCount
Contains the current reference count of the object.

Let us now discuss the methods of the CActionStatus structure. For the most part these will be simple member access functions. We will not cover the AddRef and Release methods here since at this point in the series you should be comfortable with what these methods look like.

CActionStatus:: CActionStatus

The constructor initializes all member variables to NULL or zero, except for the reference count of the object. Since we are in the constructor, the object is being created, so it must have a reference count of 1 when this function returns.

```
CActionStatus::CActionStatus( )
{
    // Clear required variables
    m_pCurrentAction     = NULL;
    m_pTrackActionStatus = NULL;
    m_nMaxTrackCount     = 0;

    // ***********************************
    // *** VERY IMPORTANT
    // ***********************************
    // Set our initial reference count to 1.
    m_nRefCount = 1;
}
```

CActionStatus::~CActionStatus

The destructor releases the TrackActionStatus array (if it exists) and sets the three other members to NULL or zero.

```
CActionStatus::~CActionStatus( )
{
    // Delete any flat arrays
    if ( m_pTrackActionStatus ) delete []m_pTrackActionStatus;

    // Clear required variables.
    m_pCurrentAction     = NULL;
    m_pTrackActionStatus = NULL;
    m_nMaxTrackCount     = 0;
}
```

CActionStatus::SetMaxTrackCount

This function resizes the TrackActionStatus array to the size specified by the Count parameter. It is called by the actor whenever the limits of the controller change. There should always be a 1:1 mapping between tracks on the mixer and TrackActionStatus structures in the internal array.

The function first tests the value of the Count parameter. If it is set to zero then it means the caller wishes to flush the per track data currently stored in the CActionStatus object. When this is the case, we delete the TrackActionStatus array and set the m_nMaxTrackCount member variable to zero.

```
HRESULT CActionStatus::SetMaxTrackCount( USHORT Count )
{
```

```
    TrackActionStatus * pBuffer = NULL;

    // If we're clearing out.
    if ( Count == 0 )
    {
        // Just release and return
        if ( m_pTrackActionStatus ) delete []m_pTrackActionStatus;
        m_pTrackActionStatus = NULL;
        m_nMaxTrackCount     = 0;

        // Success
        return S_OK;

    } // End if count == 0
```

In the next section of code, we allocate a new array of TrackActionStatus structures. Its size will equal the size requested by the Count parameter. We then initialize this array to zero.

```
    // Allocate enough room for the specified tracks
    pBuffer = new TrackActionStatus[ Count ];
    if ( !Count ) return E_OUTOFMEMORY;

    // Clear the buffer
    memset( pBuffer, 0, Count * sizeof(TrackActionStatus) );
```

If this CActionStatus object already has data in its TrackActionStatus array then this must be copied into the new array. This allows us to change the number of tracks the CActionStatus object can handle without losing any data that might already exist. This is obviously very important if the resize is performed while the action system is in use. After all, the application can call the CActor::SetActorLimits method at any time (which will cause this function to be called and passed the new track limit of the controller).

As you can see in the following code, if the current track count of the object is larger than zero and its TrackActionStatus member is not NULL then there must be data already and we should copy it over.

```
    // Was there any previous data?
    if ( m_nMaxTrackCount > 0 && m_pTrackActionStatus )
    {
        // Copy over as much data as we can
        memcpy( pBuffer,
                m_pTrackActionStatus,
                min(m_nMaxTrackCount, Count) * sizeof(TrackActionStatus) );

    } // End if existing data
```

Now that we have our new array and have the previous track data copied into it, we can delete our original array.

```
    // Release previous buffer
    if ( m_pTrackActionStatus ) delete []m_pTrackActionStatus;
```

Now we can assign the m_pActionStatus member to point at our new array instead. We also set the m_nMaxTrackCount member to the new track count of the controller that was passed in. The value in m_nMaxTrackCount should always reflect the number of elements in the m_pActionStatus array.

```
    // Store buffer, and count
    m_pTrackActionStatus = pBuffer;
    m_nMaxTrackCount     = Count;

    // Success!
    return S_OK;
}
```

CActionStatus::SetCurrentAction

This simple function assigns the passed CActionDefinition pointer as the current action. We saw this function being called earlier from CActor::ApplyAction. It first called the CActionDefinition::ApplyAction method to set up the controller for the action being applied and then it called this function to notify the CActionStatus object that the current action has changed.

There is also a 'get' version of this function that is inline; it returns the current action.

```
void CActionStatus::SetCurrentAction( CActionDefinition * pActionDefinition )
{
    // Just store the current action
    m_pCurrentAction = pActionDefinition;
}
```

So there is nothing very complicated about the CActionStatus object. It basically just provides the actor with a means to record the current state of the action system. It stores the current action that has been applied and information about the status of each track on the mixer.

As mentioned earlier, all of the hard work is done inside the CActionDefinition object. This class has two main functions that are called by the CActor. The CActionDefinition::LoadAction method was called from CActor::LoadActionDefinitions once for each action. It has the task of loading the information for the specified action from the .ACT file. The second important function is the CActionDefinition::ApplyAction function which is called by CActor::ApplyAction to actually perform the task of setting up the controller's tracks for the new action. This function is effectively the entire runtime action system. It sets up the transitions between sets that need to be faded in and out, it sets sequencer events to control those fade outs, and a host of other things. Let us now discuss the final component of our action system.

The CActionDefinition Class

This new class is designed for the storage and application of a single action. When the ACT file is loaded, each individual action (Walk, Run, etc.) is stored within a separate instance of a CActionDefinition object, inside the CActor member array. In addition, the member functions belonging to this class are used directly whenever an action is to be applied to the animation controller.

The class declaration is shown below and is contained in CActor.h. It may seem on first glance that this class is rather large and complex but do not be misled by the two enumerations and one new structure (used by the class) defined in its namespace. Actually, the class has only four member variables and five methods (not including the constructor and destructor) and all but two of those are simple access functions.

```
class CActionDefinition
{
public:

    // Public Enumerators for This Class.
    enum ActBlendMode                       // Flags for SetDefinition::BlendMode
    {
        Off          = 0,
        MixFadeGroup = 1
    };

    enum ActTimeMode                        // Flags for SetDefinition::TimeMode
    {
        Begin              = 0,
        MatchGroup         = 1,
        MatchSpecifiedGroup = 2
    };

    // Public Structures for This Class.

    struct SetDefinition
    {
        TCHAR        strSetName[128];       // The name of the animation set
        TCHAR        strGroupName[128];     // The 'group' to which this belongs.
        float        fWeight;               // Anim Set strength
        float        fSpeed;                // The speed of the set itself
        ActBlendMode BlendMode;             // Blending to use when set is applied
        ActTimeMode  TimeMode;              // Timing Source when set is applied
        float        fMixLength;            // Length of transition is blend
                                            // enabled
        TCHAR        strTimeGroup[128];     // If the time mode specified that we
                                            // should match the timing to a
                                            // specific alternate group, that
                                            // group name is stored here.

        // Internal Temporary Vars
        bool         bNewTrack;             // Assign this set to a new track
        double       fNewTime;              // Use this time for the new track.
    };
```

```
    // Constructors & Destructors for This Class.

    CActionDefinition( );
    virtual ~CActionDefinition( );

    // Public Functions for This Class.

    HRESULT         LoadAction              ( ULONG nActionIndex,
                                              LPCTSTR ActFileName );

    HRESULT         ApplyAction             ( CActor * pActor );

    // Accessor functions
    LPCTSTR     GetName                 ( ) const  { return m_strName; }
    ULONG       GetSetDefinitionCount   ( ) const{ return m_nSetDefinitionCount; }

    SetDefinition * GetSetDefinition( ULONG Index ) const
                                    { return ( Index < m_nSetDefinitionCount )?
                                      &m_pSetDefinitions[ Index ] :
                                      NULL; }

private:

    // Private Variables for This Class.

    TCHAR           m_strName[128];         // The name of this action definition
    USHORT          m_nSetDefinitionCount;  // The number of set definitions
    SetDefinition * m_pSetDefinitions;      // Array of set definition structures.
};
```

We will start by discussing the member variables of this class and then we will finally wrap up our coverage of the Action Animation System by examining the code to the member functions.

TCHAR m_strName[128]

This member will hold the name of the action as read in from the .ACT file. In the example .ACT file we looked at earlier, the first action was called ‘Walk_At_Ease’. This is the name that would be stored in this member for that action. This value will be set when the CActionDefinition::LoadAction method is called and the name of the current action being loaded is extracted from the file.

Notice in the above code that there is an inline method called GetName which will return the name of the action. We saw this function being used in the CActor::ApplyAction method earlier. It searched through all of the actions using the GetName method to test against the name of the requested action passed by the application. If a match was found, this was assumed to be the action that the application would like to apply and its ApplyAction method was called. We will look at the CActionDefinition::ApplyAction method in a moment.

USHORT m_nSetDefinitionCount
This member contains the number of SetDefinitions that exist for this action. In our example .ACT file, each action contained three set definitions. Recall that a set definition is really just the name of an animation set that is used to comprise the action and any associated properties that should be associated with that set (such as should it transition in or not). Every action can have a different number of set definitions, so one action may involve setting a single animation set while another action may set many.

This member contains the number of animation sets that will need to be set on the mixer when this action is applied. This also describes the number of elements in the m_pSetDefinitions array (discussed below) which is an array that contains the information for each set definition.

SetDefinition m_pSetDefinitions
As discussed above, each action is usually comprised of several set definitions. Each set definition describes the name and properties of an animation set that should be assigned to the mixer to help achieve the action when it is applied. The number of elements in this array will be equal to the number of set definitions defined in the .ACT file for the current action. This array will be allocated when the action is loaded.

The name and properties of each animation set used by this action are stored in this array as a SetDefinition structure. Let us now describe the members of the SetDefinition structures that comprise this array.

> **TCHAR strSetName[128]**
> This contains the name of the animation set that this set definition is associated with. You will recall that when you defined a set definition in the .ACT file you had to specify the first property as the name of the animation set you would like these properties to be linked to. The animation set you name here will be one (of potentially many) that will be assigned to the animation mixer when this action is applied.
>
> **TCHAR strGroupName[128]**
> Here we store the name of the group this set definition is assigned to. This is pretty important when blending is being used since we will often want an animation set to transition from another animation set with the same group name when the action is applied. As discussed earlier, you should never have more than one set definition within a single action with the same group name.
>
> **float fWeight**
> The initial weight that you would like the animations set to have. For an animation set that is configured to fade-in, this is the target weight that the animation set's track will reach at the end of the fade-in process. For non fade-in sets, the track weight will be assigned this value the moment the set is activated.
>
> **float fSpeed**
> The speed at which the animation set should play. You will usually set this to 1.0 so that the animation plays at the default speed intended by the asset creator.

ActBlendMode BlendMode

This set definition property is used to determine whether the animation set should be played immediately at full weight (disabling any animation set currently playing from the same group) or whether it should slowly transition in. It will be set to one of the following members of the ActBlendMode enumerated type. This enumeration is defined within the CActionDefinition namespace in CActor.h. As you can see, it mirrors the two values we could use in the .ACT file to specify the blend mode.

```
enum ActBlendMode
{
        Off             = 0,
        MixFadeGroup    = 1
};
```

Off

When set to Off, no blending occurs. When the action is applied, any previous animation sets (which have not already been put into a transition out state) from the same group will be immediately halted and replaced with this new set.

MixFadeGroup

When the action is applied, any animation set currently playing from the previous action with a matching group name will be faded out over a period of time and the strength of this set will be faded in over that same period of time. This causes a smooth transition between animation sets in the same groups; animation sets that animate the same portions of the character for example.

ActTimeMode TimeMode

The TimeMode property of a set definition is something else we discussed when covering the .ACT file specification. The CActionDefinition::LoadAction will set the TimeMode property of each of its set definitions to one of three members of the ActTimeMode enumerated type (depending on which of these values is specified in the .ACT file).

```
enum ActTimeMode
{
        Begin               = 0,
        MatchGroup          = 1,
        MatchSpecifiedGroup = 2
};
```

Begin

The animation set will start from the beginning when played. That is, the track timer to which it is assigned will be reset. This is used mainly if the animation set you are playing does not have to be synchronized either to another animation set that is currently animating another part of the actor or if you do not need this animation set to smoothly take its periodic position from an animation set in the same group that is already playing from a previous action.

MatchGroup

In this mode, when the animation set is assigned to the track, its track time will be copied from the track of an animation set in the same group that was being used by the previous action.

A good example of a need for this mode would be if two actions contain the exact same animation set for the 'Legs' group. Both actions may have different animation sets for the torso but may both use the 'Walk' animation set for the legs. If action 1 was currently being played and the player was halfway through a stride, we would not want the animation set working the legs to have its periodic position snapped back to zero when the second action was applied. Instead, we would want the animation set working on the legs in the second action to start at a periodic position that continues the stride of the character and takes over from where the 'Legs' animation set in the previous action left off.

MatchSpecifiedGroup

This mode is useful for synchronizing the different animation sets together. In out example .ACT file, the torso animation for the 'Walk_At_Ease' action uses this mode so that it can take its timing from the 'Legs' group. That way the legs and arms are synchronized as the character walks.

float fMixLength

If the blend mode of this SetDefinition has been set to MixFadeGroup, then this value will contain the number of seconds this animation set will take to transition to full strength and how long any animation set from a previous action in the same group will take to have its strength completely faded out.

If the BlendMode is set to 'Off', this property will not be used.

TCHAR strTimeGroup[128]

If the TimeMode of the SetDefinition has been set to MatchSpecifiedGroup then this member will contain the name of the group that this animation set will take its track time from when first applied to the mixer. For example, a SetDefinition which has been assigned to the 'Arms' group could have its TimeMode set to take its initial starting position from the 'Legs' group animation set that is currently playing.

If TimeMode is not set to MatchSpecifiedGroup, this property is not used.

bool bNewTrack

double fNewTime

These final two members of the SetDefinition structure are used for temporary data storage during the processing of an action inside the CActionDefinition::ApplyAction method. We will see them being used later.

We have now discussed all the member variables and structures used by CActionDefinition. Let us now look at its member functions.

CActionDefinition::CActionDefinition

The constructor places the terminating null character in the first position of the name string (empty string) and sets the definition count to zero. It also sets the definition set array pointer to NULL. These variables will not be populated with meaningful values until the CActionDefinition::LoadAction method is called to populate this object.

```
CActionDefinition::CActionDefinition( )
{
    // Clear required variables
    m_strName[0]            = _T('\0');
    m_nSetDefinitionCount   = 0;
    m_pSetDefinitions       = NULL;
}
```

CActionDefinition::~CActionDefinition

The destructor quite expectedly releases the set definitions array and sets its pointer to NULL and restores all values to their default state.

```
CActionDefinition::~CActionDefinition( )
{
    // Delete any flat arrays
    if ( m_pSetDefinitions ) delete []m_pSetDefinitions;

    // Clear required variables.
    m_strName[0]            = _T('\0');
    m_nSetDefinitionCount   = 0;
    m_pSetDefinitions       = NULL;
}
```

CActionDefinition::LoadAction

This method is called by the CActor::LoadActionDefinitions method. You will recall when we covered that function earlier that it read the number of actions in the .ACT file and then allocated the actor's array of CActionDefinition objects. It then looped through each action and called its LoadAction function to populate it with the action data from the .ACT file.

LoadAction is a little long and rather uneventful. It just uses the Win32 .ini file reading functions to read the various properties of the action from the file and store that data in its internal members.

The function is passed two parameters by the CActor::LoadActionDefinitions function. The first is the index that will be appended to the word 'Action' to describe the Action block in the .ACT file that contains the data for this action definition. The second parameter is the name (and path) of the .ACT file that we are currently in the process of fetching the action information from.

The first thing this function does is build a string (using the _stprintf function) containing the name of the data block in the .ACT file we wish to access. Once we have this string constructed and stored in the local variable (strSectionName) we flush any data that may have previously existed in this action definition object. We release its SetDefinitions array if it exists and make sure that its definition count is set to zero at the start of the loading process.

```
HRESULT CActionDefinition::LoadAction( ULONG nActionIndex, LPCTSTR ActFileName )
{
    TCHAR strSectionName[128];
    TCHAR strKeyName[128];
    TCHAR strBuffer[128];
    ULONG i;

    // First build the action section name
    _stprintf( strSectionName, _T("Action%i"), nActionIndex );

    // Remove any previous set definitions
    if ( m_pSetDefinitions ) delete []m_pSetDefinitions;
    m_pSetDefinitions     = NULL;
    m_nSetDefinitionCount = 0;
```

The first property we fetch is the DefinitionCount. Every action in the .ACT should have a definition count property which describes how many set definitions comprise the action. This also tells us how large we should allocate the m_pSetDefinitions array for this action.

As before, because the value we wish to read is an integer value, we use the Win32 function designed for the task of reading integer values from an .ini file (GetPrivateProfileInt).

```
    // Retrieve the set definition count
    m_nSetDefinitionCount = ::GetPrivateProfileInt(  strSectionName,
                                                     _T("DefinitionCount"),
                                                     0,
                                                     ActFileName );

    // If there are no sets, we were most likely unable to find the action
    if ( m_nSetDefinitionCount == 0 ) return D3DERR_NOTFOUND;

    // Allocate the setdefinition array
    m_pSetDefinitions = new SetDefinition[ m_nSetDefinitionCount ];
    if ( !m_pSetDefinitions ) return E_OUTOFMEMORY;
```

The first parameter to GetPrivateProfileInt is the string we built at the start of the function. It contains the name of the action block in the .ACT file we wish to read data from. As the second parameter we pass a string describing the property we wish to read within this action block. In this call we want to fetch the value of the DefinitionCount property. You must type property names exactly as you have defined them in the .ACT file. As the third parameter we always pass in a default value that will be used if the property cannot be found in the file or in the specified block/section. In this case, if the Definition Count property for an action is missing, this is considered a corrupt action description and we assign the value of zero. This will cause the function to exit on the very next line and the action will not be loaded. As the final parameter to this function we pass the name of the .ACT file we wish to read.

On function return, we should have the set definition count in the member variable m_nSetDefinitionCount and if this value is zero, we return from the function and do not load this action. Otherwise, we use this value to allocate an array of SetDefinition structures of the correct size.

We will now fetch the name of the action. Since the name of the action is a string and not an integer value we will use the Win32 GetPrivateProfileString function to fetch this data. The function works in an almost identical way but takes extra parameters. The first parameter is the block name in the .ACT file we wish to pull the values from. This is the current Action block being read. As the second parameter we pass the name of the property within this block that we wish to read. In this next call, we wish to read the value of the Name property for this action. As the third parameter we pass in the string that should be returned if the property is not found; in this case we simply specify an empty string. As the fourth parameter we pass in the string variable that will contain the value on function return. We wish to store the name of the action in the m_strName member variable. The fifth parameter is the number of character we would like to read. This is to make sure that we do not overflow the memory bounds of our string. We read the first 127 characters, since an action name is not likely to ever be longer than this and our m_strName member variable only has space for 128 characters (i.e., 127 characters plus the terminating NULL).

```
    // Retrieve the name of the action
    ::GetPrivateProfileString( strSectionName,
                               _T("Name"),
                               _T(""),
                               m_strName,
                               127,
                               ActFileName );
```

At this point we have the name of the action stored, the number of set definitions it should contain and we have allocated the SetDefinitions array. Let us now loop through each element in that array and populate each set definition with data from the file.

In the first section of the loop (shown below) we get a pointer to the current element in the SetDefinitions array. First we read the name of the animation set and the name of the group associated with this definition and store them in the definition set's strSetName and strGroupName members.

```
    // Loop through each set defined in the file
    for ( i = 0; i < m_nSetDefinitionCount; ++i )
    {
        // Retrieve a pointer to the definition for easy access
        SetDefinition * pDefinition = &m_pSetDefinitions[i];

        // Get the set name
        _stprintf( strKeyName, _T("Definition[%i].SetName"), i );
        ::GetPrivateProfileString( strSectionName,
                                   strKeyName,
                                   _T(""),
                                   pDefinition->strSetName,
                                   127,
                                   ActFileName );

        // Get the group name
```

```
        _stprintf( strKeyName, _T("Definition[%i].GroupName"), i );
        ::GetPrivateProfileString(  strSectionName,
                                    strKeyName,
                                    _T(""),
                                    pDefinition->strGroupName,
                                    127,
                                    ActFileName );
```

Notice that before we access each property, we build a string containing the name of the property we wish to fetch. For example, if we are fetching the animation set name of the third set definition, the name of this property inside the action's data block would be 'Definition3.SetName'. Similarly, the group name would be assigned to the property 'Definition3.GroupName'. Open up the .ACT file and examine it for yourself so you can follow along with this function.

In the next section of code we need to determine if this set definition is set to blend or not. The blend mode of this definition will be set to either 'Off' or 'MixFadeGroup'. Notice in the following function call to GetPrivateProfileString that a default string of 'Off' is returned if no matching property has been specified in the .ACT file. This means if no blend mode is specified, it is equivalent to specifying no blending.

```
        // Get the blend mode flags
        _stprintf( strKeyName, _T("Definition[%i].BlendMode"), i );
        ::GetPrivateProfileString(  strSectionName,
                                    strKeyName,
                                    _T("Off"),
                                    strBuffer,
                                    127,
                                    ActFileName );

        if ( _tcsicmp( strBuffer, _T("MixFadeGroup") ) == 0 )
            pDefinition->BlendMode = ActBlendMode::MixFadeGroup;
        else
            pDefinition->BlendMode = ActBlendMode::Off;
```

Once we have fetched the blend mode string we test its value and set the definition's BlendMode member to the correct enumeration.

We will now read the TimeMode of the set definition. It can be either 'Begin', 'MatchGroup' or MatchSpecifiedGroup. A default string of 'Begin' will be returned if no TimeMode property exists in the .ACT file for the current set definition being read. In other words, if no time mode property exists in the .ACT file for a given set definition, by default time the animation set will be started from the beginning whenever the action is applied.

```
        // Get the time mode flags
        _stprintf( strKeyName, _T("Definition[%i].TimeMode"), i );
        ::GetPrivateProfileString(  strSectionName,
                                    strKeyName,
                                    _T("Begin"),
                                    strBuffer,
                                    127,
```

```
                                    ActFileName );

        if ( _tcsicmp( strBuffer, _T("MatchGroup") ) == 0 )
            pDefinition->TimeMode = ActTimeMode::MatchGroup;
        else
            if ( _tcsicmp( strBuffer, _T("MatchSpecifiedGroup") ) == 0 )
            pDefinition->TimeMode = ActTimeMode::MatchSpecifiedGroup;
        else
            pDefinition->TimeMode = ActTimeMode::Begin;
```

After we have retrieved the string from the file we test its contents and set the definition's TimeMode member to the correct member of the ActTimeMode enumeration.

In the next section we retrieve the Weight and Speed properties for this set definition. Since these are floating point values and Win32 exposes no GetPrivateProfileFloat function, we will have to read the values as strings and then convert the strings into floats using the _stscanf function.

You can see in the following code that after we extract the weight value (with a default weight of 1.0 if the property is not found in the file), we have ourselves a floating point value stored in the string strBuffer. We then use the _stscanf function to fetch the float from that string and store it in the fWeight member for the current definition. The first parameter to the _stscanf is the string we wish to extract the values from and the second parameter is a format string that informs the function how many values we wish to extract and what their types are. Using the '%g' string tells the function that we wish to extract one floating point value from the beginning of the string. Since we are only extracting one value, there is only one variable specified after this parameter -- the address of the variable we would like this value copied into. We perform the same procedure to extract the Speed property as well.

```
        // Retrieve and scan the weight float var
        _stprintf( strKeyName, _T("Definition[%i].Weight"), i );
        ::GetPrivateProfileString(  strSectionName,
                                    strKeyName,
                                    _T("1.0"),
                                    strBuffer,
                                    127,
                                    ActFileName );

        _stscanf( strBuffer, _T("%g"), &pDefinition->fWeight );

        // Retrieve and scan the speed float var
        _stprintf( strKeyName, _T("Definition[%i].Speed"), i );
        ::GetPrivateProfileString(  strSectionName,
                                    strKeyName,
                                    _T("1.0"),
                                    strBuffer,
                                    127,
                                    ActFileName );

        _stscanf( strBuffer, _T("%g"), &pDefinition->fSpeed );
```

At this point we have read in the standard properties that are applicable in all circumstances, but we now have to read two optional ones. For example, we know that if the BlendMode of this set definition is set

to MixFadeGroup then there will also be a MixLength property specified for this set which describes how long the transition should take to perform. This is a float value that specifies this time in seconds so once again, we fetch the value as a string and scan it into the set definition's fMixLength member.

```
        // If we're blending, there will be an additional parameter
        if ( pDefinition->BlendMode == ActBlendMode::MixFadeGroup )
        {
            // Retrieve and scan the various floats
            _stprintf( strKeyName, _T("Definition[%i].MixLength"), i );
            ::GetPrivateProfileString(    strSectionName,
                                          strKeyName,
                                          _T("0.0"),
                                          strBuffer,
                                          127,
                                          ActFileName );

            _stscanf( strBuffer, _T("%g"), &pDefinition->fMixLength );

            // If we returned a zero value, turn off mix fading of the group
            if ( pDefinition->fMixLength == 0.0f )
                  pDefinition->BlendMode = ActBlendMode::Off;

        } // End if fading
```

Notice that if no MixLength property is found, a default of zero is returned. This causes the definition's BlendMode member to be set to ActBlendMode::Off (i.e., blending is disabled).

The last value we read in for the current definition is the TimeGroup property. It will only be specified in the .ACT file if the definition has had its TimeMode set to MatchSpecifiedGroup. Recall that this means when the animation set is assigned to the mixer, it will have its track time set to the position of an existing track in the specified group. This property contains the name of that group.

```
        // If we're timing against a specified group, get additional parameter
        if ( pDefinition->TimeMode == ActTimeMode::MatchSpecifiedGroup )
        {
            // Retrieve and scan the various floats
            _stprintf( strKeyName, _T("Definition[%i].TimeGroup"), i );
            ::GetPrivateProfileString(    strSectionName,
                                          strKeyName,
                                          pDefinition->strGroupName,
                                          pDefinition->strTimeGroup,
                                          127,
                                          ActFileName );

        } // End if matching against alternate group

    } // Next new set definition

    // Success!!
    return S_OK;
}
```

That is the end of the loop and the end of the function. This loop is executed for each definition in the current action. At the end, the CActionDefinition object will have a fully populated SetDefinition array

where each element can be used by the ApplyAction method to setup the animation sets correctly when the action is applied.

CActionDefinition::ApplyAction

This is the function that provides the core processing of our Action Animation System. Not only does it set the animation sets for the action on the animation mixer, it also performs fade outs of the animation sets from a previous action. Additionally, it keeps the actor's CActionStatus object up to date so that we always know which tracks are in use, which ones are transitioning out, and which ones are free for use.

The function can appear intimidating due to its sheer size. However once you take a closer look, you should see that it is really not so difficult. The code is really repeating the same steps for both the blending and non-blending cases, so it should be pretty easy to grasp once you understand the main logic.

This function is called by the CActor::ApplyAction function after it has found the CActionDefinition object with a name that matches the one requested by the application. Once the correct action is found, its ApplyAction method is called to configure the animation mixer. Let us look at that code now.

The first thing this function does is get a pointer to the actor's CActionStatus object. As this contains the current state of each track (is it in use or not for example) we will definitely need this information.

```
HRESULT CActionDefinition::ApplyAction( CActor * pActor )
{
    SetDefinition                    * pDefinition;
    CActionStatus                    * pStatus;
    CActionStatus::TrackActionStatus * pTrackStatus;
    ULONG                              i, j, nCount;
    D3DXTRACK_DESC                     TrackDesc;

    // Retrieve the actors action status
    pStatus = pActor->GetActionStatus();
    if ( !pStatus ) return D3DERR_INVALIDCALL;
```

This step is very important for finding tracks that have fully transitioned out and updating the relevant track properties in the CActionStatus object to reflect that this track is now free.

We said earlier when discussing how this system will work, that if a given set definition is configured to blend, then its weight will transition in over a period of time and a previous animation set that was playing from the same group will transition out over the same period. This produces a smooth blend from the old set to the new one. The fading out of the set is done by setting an event on the previous animation set's track that will reduce its weight to zero over this period. We then set another event on that track that will be triggered when the weight reaches zero which will disable the track. If a track has been disabled since we last applied any actions, we need to know about it so that we can update the track status in our CActionDefinition object. If we do not do this, our system will think the track is still in use and we will find ourselves running out of tracks in a very short time as actions are repeatedly applied.

The next section of code performs this synchronization process between the tracks on the animation mixer and the TrackActionStatus structures in our CActionStatus object. Let us first look at the code and then we will discuss it.

```
    // Mark disabled tracks as free for use.
    nCount = pActor->GetMaxNumTracks();

    for ( j = 0; j < nCount; ++j )
    {
        // Retrieve action status information for this track.
        pTrackStatus = pStatus->GetTrackStatus( j );

        // Get the current track description.
        pActor->GetTrackDesc( j, &TrackDesc );

        // Flag as unused if the track was disabled
        if ( TrackDesc.Enable == FALSE )
        {
            pTrackStatus->bInUse            = false;
            pTrackStatus->bTransitioningOut = false;

        } // End if track is disabled
    } // Next track
```

We first fetch the number of tracks on the animation mixer and set up a loop to process each track. For each track, we get a pointer to the associated TrackActionStatus structure in our CActionStatus object and also call the actor's GetTrackDesc method to fetch a D3DXTRACK_DESC containing the properties of the actual mixer track. Then we test to see if the track on the mixer has been disabled. If it has, the Enable member of the D3DXTRACK_DESC structure will be set to false. As you can see, if it is, it means that this track is no longer being used by our action system and we should set the bInUse and bTransitioningOut booleans of the corresponding track on our CActionStatus object to false. We will now recognize that this track is available for use by our system. All we are really doing is performing garbage collection and making sure we recycle any tracks that were being used for transitioning out but have since been disabled by a sequencer event that occurred when the weight of the track reached zero.

At this point, our CActionStatus object correctly reflects the current state of the tracks with respect to availability. Now it is time to loop through each of the set definitions in this action and figure out which track the definition should be assigned to, and what its starting position and transition status should be. With the exception of a small piece of code at the bottom, most of the logic in this function is contained inside this loop. That is, all the code you are about to see is carried out for each set definition in the action. Remember, a set definition represents an animation set and its associated properties.

```
    // Loop through each of our set definitions
    for ( i = 0; i < m_nSetDefinitionCount; ++i )
    {
        // Retrieve the definition pointer for easy access
        pDefinition = &m_pSetDefinitions[i];

        // Reset sensitive variables
        pDefinition->bNewTrack = false;
        pDefinition->fNewTime  = 0.0f;
```

The first thing we do at the head of this loop (above) is get a pointer to the current set definition we are processing. From this point on, pDefinition will be the pointer we use for ease of access.

We also reset the bNewTrack and fNewTime variables to false and zero respectively. You may recall when we discussed the members of the SetDefinition structure that these two members were described as temporary storage variables. They were not populated by the loading process with values from the .ACT file but will be used in this function to record whether this definition needs to be assigned to a new track and the starting position the animation set should play from. We set these to default values for now because we do not yet know if a new track will be required or if this animation set is currently assigned to a track already and can be recovered. We have also not yet calculated what the position of the track should be when the set is assigned. We will need to determine this in a moment based on the TimeMode that has been set for this definition. If the TimeMode of this set has been set to 'Begin' then zero will be the track position we wish it to start from.

At the end of this loop, in each definition we will have stored whether or not a new track is needed for it and how the track position should be set. We can then do a final pass through the tracks on the mixer and start our assignments. This will make a lot more sense as we progress; for now just know that we are just trying to determine the track position for each set and whether a new track is needed.

If the TimeMode for this set definition is set to 'Begin' then we have already stored the correct track position in the definition's fNewTime member. However, if one of the other time modes have been activated, we will try to find a track that is already active which has an animation set assigned to it in the same group (or the specified group) and will inherit its time to ensure a smooth takeover. The entire next section of code is executed only if this set definition's time mode is set to either MatchGroup or MatchSpecifiedGroup.

```
        // Get timing data from actor if required
        if ( pDefinition->TimeMode != ActTimeMode::Begin )
        {
            // Choose which group name to pull timing from.
            TCHAR * pGroupName = pDefinition->strGroupName;

            if ( pDefinition->TimeMode == ActTimeMode::MatchSpecifiedGroup )
                 pGroupName = pDefinition->strTimeGroup;
```

In the above code we first test to see which of the two timing match modes this set definition has been configured for. If the TimeMode being used is set to MatchGroup then the local variable pGroupName will point to the name of this definition's group. If MatchSpecifiedGroup is being used, then this same pointer is instead assigned to the value stored in the definition's str_TimeGroup member. Either way, this means at the end of this code, the local variable pGroupName contains the name of the group we wish to inherit the time from (if possible). We will now need to test each track currently assigned to the mixer and inherit its time if it belongs to the same group. After examining all this function code and the steps involved in transitioning between two actions, you will understand that there will only ever be one currently active track on the mixer with the same group name. This does not include tracks which are transitioning out since they are not considered to be currently active. As such, they are left to their own devices to fade out. Therefore we are now going to search for this track and inherit its track position.

In the next section of code we set up a loop to loop through each track on the mixer. For each track, we fetch the corresponding TrackActionStatus structure from our CActionStatus object so we can examine if the track is currently in use or not. If the track is not in use or it is in the process of transitioning out then this track is essentially not currently active and we have no interest in inheriting its track position. So we skip it. If however, the track is currently in use by the action system and has a definition assigned to it with a group name that matches the one we wish to take our timing from, we will fetch the position of that track (using our CActor::GetTrackDesc function) and will assign this position to the start time stored in the current set definition we are processing. This entire process is shown below.

```
            // Find the track in this group not currently transitioning out
            nCount = pActor->GetMaxNumTracks();
            for ( j = 0; j < nCount; ++j )
            {
                // Retrieve action status information for this track.
                pTrackStatus = pStatus->GetTrackStatus( j );

                // Skip if this track is not in
                if ( pTrackStatus->bInUse == false ||
                     pTrackStatus->bTransitioningOut == true ) continue;

                // Does this belong to this group?
                if ( _tcsicmp( pTrackStatus->strGroupName, pGroupName ) == 0 )
                {
                    // Get the current track description.
                    pActor->GetTrackDesc( j, &TrackDesc );

                    // Store the position and break
                    pDefinition->fNewTime = TrackDesc.Position;
                    break;

                } // End if matching group

            } // Next Track

        } // End if need timing data
```

At this point, we have processed the time modes and our fNewTime member stores the position that its track should be set to start at when we do eventually assign it to a track at the tail of the function. The timing processing is now all done.

In the next phase we have to figure out whether this animation set needs to be blended in and a currently active set from the same group faded out. Unfortunately, things are not quite as black and white as it might seem. If the animation set for this set definition that we wish to apply matches the name of an animation set already assigned to the mixer by a previous action and the group names match, it would make little sense to have the two exact sets, one fading out and one fading in, taking up two valuable tracks on the mixer. Therefore, this is actually going to be a two step process. If mixing is being used and an exact animation set is currently in use, we will just recover it. We will just set it to fade back in, from whatever its current strength is to whatever is desired by the set definition we are currently processing. If an exact set and group combination does not exist, then a new track will be needed for this set definition. If an animation set is assigned to another track which is part of the same group, it will be faded out.

Of course, in order to do any of this we must first know whether the animation mixer currently has an animation set name/group combo assigned to one of its tracks which is exactly the same as the one contained in the set definition we are about to apply. The next section of code performs this search.

A loop is constructed to test each TrackActionStatus structure in the CActionStatus object. For each track we find which is flagged as currently in use we will see if its group name matches the group name of the set definition we wish to apply. If it does, then we know the groups match so we will continue on to see if the animation set names match. If they do, we have found an exact match and the set definition we wish to apply will not need a new track. It can simply take over the track of this identical combination. As soon as a match is found the loop breaks and the loop variable's value is assigned to the local variable nSetMatched. This will contain the index of track on the animation mixer that the set definition we are about to apply will recover.

```
            long nSetMatched = -1;

            // First search for an exact match for this group / set combination
            nCount = pActor->GetMaxNumTracks();
            for ( j = 0; j < nCount; ++j )
            {
                  // Retrieve action status information for this track.
                  pTrackStatus = pStatus->GetTrackStatus( j );

                  // Skip if this track is not in use
                  if ( pTrackStatus->bInUse == false ) continue;

                  // Does this belong to this group?
                  if ( _tcsicmp(    pTrackStatus->strGroupName,
                                    pDefinition->strGroupName     ) == 0 )
                  {
                        // Is it physically the same set?
                        if ( _tcsicmp( pTrackStatus->strSetName,
                                       pDefinition->strSetName ) == 0 )
                              nSetMatched = (signed)j;

                        if ( nSetMatched >= 0 ) break;

                  } // End if matching group

            } // Next Track
```

All we have determined at this point is a value for nSetMatched which will either contain the index of a track to be recovered or -1 if no set/group combination currently exists. The value of this variable is used to make decisions in the next two (very large) conditional code blocks. The first code block processes the case when the definition we are about to apply require blending and the second contains almost identical code that processes the non-blending case. Even in the non-blending case, we will still recover a track with a matching set / group instead of assigning it a new track. It would be pointless to turn off one track to enable another with the exact same animation set assigned. We may as well just keep the one we were using before. Note in the above code that even if the track is transitioning out, we will recover it and flag it as a match so that we can recover it and fade it back in later.

Let us start to look at the blending case one section at a time, as it is a rather large code block. Indeed, this code block is further divided into two conditional code blocks which are executed depending on whether we are assigning a new track or recovering a track for this definition.

```
        // Does this definition require mix blending?
        if ( pDefinition->BlendMode == ActBlendMode::MixFadeGroup )
        {
```

The next block of code is executed if, during the previous search, we found that a track on the mixer currently has the same animation set with the same group name as the definition we wish to apply.

```
            // Did we find an exact match for this group / set combination?
            if ( nSetMatched >= 0 )
            {
                // This is the same set as we're trying to blend in, first thing
                // is to kill all events currently queued for this track
                pActor->UnkeyAllTrackEvents( nSetMatched );

                // Clear status
                pTrackStatus = pStatus->GetTrackStatus( nSetMatched );
                pTrackStatus->bInUse           = true;
                pTrackStatus->bTransitioningOut = false;
                pTrackStatus->pActionDefinition = this;
                pTrackStatus->nSetDefinition    = i;
```

If we are going to take over this track with our new set definition, we must be prepared for the fact that this track may have been in the process of being transitioned out when a previous action was applied. If this is the case then it will have a sequencer event set for that track that is due to disable the track when the transitioning out is complete. We no longer wish this to happen since we are going to recover the track and start to fade it back in. Therefore, in the above code we un-key any events that were set for the track so that they are no longer executed (thus preventing disabling the track). We then update the corresponding track properties in the CActionStatus object to reflect that this track is now in use again and is not transitioning out. We also store the CActionStatus object responsible for setting up this track as well as the set definition index. This is helpful if the application wishes to query this information.

Because the track that we have recovered may have been transitioning out or may have had a different weight than the one in the new set definition we are applying, we will set a KeyTrackWeight event that will be triggered immediately (notice the pActor->GetTime function call in the parameter list). It will fade the current weight of the track either in or out to match the weight of the set definition we are processing. Notice that the duration of the fade is determined by the definition's fMixLength property (specified in the .ACT file).

```
                // Queue up a weight event, and bring us back to the blend weight
                // we requested
                pActor->KeyTrackWeight(   nSetMatched,
                                          pDefinition->fWeight,
                                          pActor->GetTime(),
                                          pDefinition->fMixLength,
                                          D3DXTRANSITION_EASEINEASEOUT );
```

At this point, we have set up the track to transition correctly into the weight for the current set definition, but we also have to set the position of the track. Just because we are recovering the track does not mean we want our new definition to inherit the current position property of the track. This depends on the time mode of the definition specified in the .ACT file. In the next section of code, we fetch the track description and set its position to the time we calculated earlier. We also set its speed to the speed value for this definition. Of course, if this definition is set to inherit the time from its group, then we will absolutely leave the track position alone since it is already correct.

```
                // Get the current track description.
                pActor->GetTrackDesc( nSetMatched, &TrackDesc );

                // We are recovering from an outbound transition, so we will
                // retain the timing from this set, rather than the one we chose
                // above, if they specified only 'MatchGroup' mode.
                if ( pDefinition->TimeMode != ActTimeMode::MatchGroup )
                     TrackDesc.Position = pDefinition->fNewTime;

                // Setup other track properties
                TrackDesc.Speed = pDefinition->fSpeed;

                // Set back to track
                pActor->SetTrackDesc( nSetMatched, &TrackDesc );

            } // End if found exact match
```

At this point we have set up the set definition and the mixer track to recover. The definition's bNewTrack member will still be set to false as we do not need to assign it a new track.

The above code concludes the code block that deals with the case when we have found a matching track/group combination for our set definition in the blending case. Just to recap, the above code essentially says the following: "If I am supposed to transition in and a track already has the correct set and group name applied to it, recover this track and fade it back in".

The section of code we will see is still inside the blending case code block but is only executed if the set definition we wish to blend in does not match an animation set name and group name already applied to a mixer track. When this is the case, we simply set the definition's bNewTrack member to true so we will know at the bottom of the function that we will need to assign this set definition to a new track on the mixer.

```
            else
            {
                // This definition is now due to be assigned to a new track
                pDefinition->bNewTrack = true;

            } // End if no exact match
```

The next section of code is executed in the blending code block regardless of whether a track was recovered or we need a new track assignment for this definition. It has the job of finding all tracks currently in use that are in the same group as the current definition and then fading them out. There

should only be one active track in the same group that is not transitioning out. We are essentially searching for this track so that we can start to fade it out.

The following code starts in a similar manner to the previous search code. It searches through all the tracks in the CActionStatus object and searches for one with the same group name that is in use and not in the process of transitioning out. If found, we un-key any events it may have scheduled and set a new event to execute immediately that will reduce its weight to zero or the period specified by the fMixLength property of the set definition we are about to apply. This will fade the old group set out over the same duration as our new set will be faded in.

```
            // Find all tracks in this group that are not currently
            // transitioning out, and fade them
            nCount = pActor->GetMaxNumTracks();
            for ( j = 0; j < nCount; ++j )
            {
                // Skip this track if it's our matched track
                if ( (signed)j == nSetMatched ) continue;

                // Retrieve action status information for this track.
                pTrackStatus = pStatus->GetTrackStatus( j );

                // Skip if this track is not in use or is transitioning out
                if ( pTrackStatus->bInUse == false ||
                     pTrackStatus->bTransitioningOut == true )
                     continue;

                // Does this belong to this group?
                if ( _tcsicmp( pTrackStatus->strGroupName,
                               pDefinition->strGroupName ) == 0 )
                {
                    // Kill any track events already setup
                    pActor->UnkeyAllTrackEvents( j );

                    // Queue up a weight event to fade out the track
                    pActor->KeyTrackWeight( j,
                                            0.0f,
                                            pActor->GetTime(),
                                            pDefinition->fMixLength,
                                            D3DXTRANSITION_EASEINEASEOUT );

                    pActor->KeyTrackEnable( j,
                                            FALSE,
                                            pActor->GetTime() +
                                                      pDefinition->fMixLength );

                    // Update status
                    pTrackStatus->bInUse            = true;
                    pTrackStatus->bTransitioningOut = true;

                } // End if matching group

            } // Next Track

        } // End if requires blending
```

And that is the end of the blending case. Notice in the above code that not only do we set an event to fade the contribution of the previous track out over a period of time, we also key another event for when that period of time has been exceeded that will disable the track on the animation mixer. So, if the set definition we are about to apply had an fMixLength value of 5 seconds, we would trigger an event immediately that would fade the old set out over a 5 second period. We also set a KeyTrackEnable event that will disable the track in 5 seconds time when the fade out is complete. We saw at the start of the code that the next time an action is applied, a loop is performed through all the tracks to find ones that are disabled (and we updated the CActionStatus object accordingly). Finally, at the bottom of the code we updated the TrackActionStatus structure for the track we are fading out to mark it as in use and currently transitioning out. This way the system will not try to use this track for anything else (other than a track recovery) until it has been disabled and once again becomes a free resource.

We have now covered the blending case for the current set definition. We recovered a track if possible or recorded that this set definition will need to be assigned to a new track. We have also found any tracks from a previous action with the same group name and have set them to transition out.

The next section of code is similar and basically does the whole thing all over again, but this time for the non-blended case. If the current set definition is not set to blend then any track currently assigned to the same group will simply be halted and the new animation set will take over. Once again, if we do find a track that contains the exact same animation set and group name, we will recover that track and use it. This code is simpler than the blended case as we do not have to transition anything in or out.

Since it is very similar to the previous code we will discuss it only briefly. First we test to see if we have found a track that can be recovered. If so, we un-key any events (it may have been transitioning out) and update its corresponding TrackActionStatus structure to identify that the track is in use and not transitioning out. As before, our structure will store the address of the CActionDefinition object that applied this definition along with the definition index.

```
        // Non – Blending Case
        else
        {
            // Did we find an exact match for this group / set combination?
            if ( nSetMatched >= 0 )
            {
                // This is the same set as we're trying to apply, first thing is
                // kill all events currently queued for this track
                pActor->UnkeyAllTrackEvents( nSetMatched );

                // Clear status
                pTrackStatus = pStatus->GetTrackStatus( nSetMatched );
                pTrackStatus->bInUse           = true;
                pTrackStatus->bTransitioningOut = false;
                pTrackStatus->pActionDefinition = this;
                pTrackStatus->nSetDefinition    = i;

                // Get the current track description.
                pActor->GetTrackDesc( nSetMatched, &TrackDesc );

                // The user specified a set which is already active, so we will
```

```
                // retain the timing from this set, rather than the one we chose
                // above, if they specified only 'MatchGroup' mode.
                if ( pDefinition->TimeMode != ActTimeMode::MatchGroup )
                     TrackDesc.Position = pDefinition->fNewTime;

                // Setup other track properties
                TrackDesc.Speed  = pDefinition->fSpeed;
                TrackDesc.Weight = pDefinition->fWeight;

                // Set back to track
                pActor->SetTrackDesc( nSetMatched, &TrackDesc );

            } // End if found exact match

            else

            {
                // This definition is now due to be assigned to a new track
                pDefinition->bNewTrack = true;

            } // End if no exact match
```

The above code shows that if we can recover the track, we set the position, weight, and speed of the track immediately (no fading in or out) to that specified by the definition we are applying. Otherwise, if no match was found, we set the definition's bNewTrack Boolean to true so that we know at the bottom of the function we will need to find a free track to assign this set definition to.

In the next section of code we are still inside the non–blending code block. It essentially turns off (no fade out) any track which belongs to the same group as the definition we are currently applying. We wish to turn off any set which currently exists in the same group and apply our new one instead.

```
            // Find all tracks in this group, and kill them dead
            nCount = pActor->GetMaxNumTracks();
            for ( j = 0; j < nCount; ++j )
            {
                // Skip this track if it's our matched track
                // if we didn't find a match, nSetMatched will still be -1)
                if ( (signed)j == nSetMatched ) continue;

                // Retrieve action status information for this track.
                pTrackStatus = pStatus->GetTrackStatus( j );

                // Skip if this track is not in use
                if ( pTrackStatus->bInUse == false ) continue;

                // Does this belong to this group?
                if ( _tcsicmp( pTrackStatus->strGroupName,
                               pDefinition->strGroupName ) == 0 )
                {
                    // Kill any track events already setup
                    pActor->UnkeyAllTrackEvents( j );
                    pActor->SetTrackEnable( j, FALSE );

                    // Update status
```

```
                    pTrackStatus->bInUse            = false;
                    pTrackStatus->bTransitioningOut = false;

                } // End if matching group

            } // Next Track

        } // End if does not require blending

    } // Next Definition
```

After the definition loop has completed execution, the following will have happened for each definition.

1. We will have searched for any tracks currently assigned to the controller which belong to the same group

2. If one was found for a given definition, we recover the animation set, and set it to blend back in (or just turn it back on immediately in the non-blending case); otherwise we flag that we need to configure a new track.

3. Blend all other tracks out (or turn them off in the non blending case) that belong to the same group.

At this point, all we need to do is loop through the SetDefinitions array of this action one more time and test which ones have their bNewTrack Boolean members set to true. These are the ones that were not recovered and need new tracks.

```
    // Loop through each of our set definitions and assign to tracks if required
    for ( i = 0; i < m_nSetDefinitionCount; ++i )
    {
        // Retrieve the definition pointer for easy access
        pDefinition = &m_pSetDefinitions[i];

        // Skip if not required to assign to new track
        if ( !pDefinition->bNewTrack ) continue;
```

If we get here then we have found a definition that requires a new track so we will loop through all the tracks in our CActionStatus object and search for the first one that is not in use. Once we find one, we record the index in the local TrackIndex variable and break from the loop.

```
        // Find a free track
        long TrackIndex = -1;
        nCount = pActor->GetMaxNumTracks();
        for ( j = 0; j < nCount; ++j )
        {
            // Retrieve action status information for this track.
            pTrackStatus = pStatus->GetTrackStatus( j );

            // Free track?
            if ( pTrackStatus->bInUse == false ){TrackIndex=(signed)j; break; }

        } // Next Track
```

Now that we know the track on the mixer we wish to assign this definition too we will set up a D3DXTRACK_DESC structure to correctly set the attributes of the track to the properties of the definition (speed, weight, position, etc). Remember, we have already stored the time we wish the track position to be set to earlier in the function. In the next section of code, notice that we set the weight member of the track descriptor to the weight specified by the definition; we will set this to zero initially in a moment if this definition is configured to transition in.

```
        // Build track description
        TrackDesc.Position = pDefinition->fNewTime;
        TrackDesc.Weight   = pDefinition->fWeight;
        TrackDesc.Speed    = pDefinition->fSpeed;
        TrackDesc.Priority = D3DXPRIORITY_LOW;
        TrackDesc.Enable   = TRUE;
```

The track descriptor is set up, so let us also update the corresponding track in our CActionStatus object so that we know it is in use and know the name of the animation set and the group name currently assigned to that track.

```
        // Update track action status
        pTrackStatus = pStatus->GetTrackStatus( TrackIndex );
        pTrackStatus->bInUse           = true;
        pTrackStatus->bTransitioningOut = false;
        pTrackStatus->pActionDefinition = this;
        pTrackStatus->nSetDefinition    = i;

        _tcscpy( pTrackStatus->strSetName, pDefinition->strSetName );
        _tcscpy( pTrackStatus->strGroupName, pDefinition->strGroupName );
```

Now let us assign the physical animation set used by this set definition to the mixer track that we have chosen. Also, if the definition is set to blend, we will set the weight member of the track descriptor to zero initially and will set a sequencer event that will transition the weight to its desired strength over the mix length period. Remember, if a track currently shares the same group name as this definition, this track was already instructed to fade out over the same period earlier in the function.

```
        // Apply animation set
        pActor->SetTrackAnimationSetByName( TrackIndex, pDefinition->strSetName );

        // If we are blending, key events and override starting weight
        if ( pDefinition->BlendMode == ActBlendMode::MixFadeGroup )
        {
            TrackDesc.Weight = 0.0f;
            pActor->KeyTrackWeight( TrackIndex,
                                    pDefinition->fWeight,
                                    pActor->GetTime(),
                                    pDefinition->fMixLength,
                                    D3DXTRANSITION_EASEINEASEOUT );

        } // End if blending

        // Set track description
        pActor->SetTrackDesc( TrackIndex, &TrackDesc );
```

```
    } // Next Definition

    // Success!!
    return S_OK;
}
```

Notice at the bottom of the definition loop that we finally set the properties of the mixer track that we have just set up using the CActor::SetTrackDesc function.

That was a pretty intimidating function on first glance but fortunately there is nothing too complex going on. Rather, there are just lots of small tasks being performed which cumulatively makes everything appear complex.

We have now covered all the code to the new action system. We now have the ability to compose complex action sequences from combinations of animation sets in simple text files and have our application apply those actions with a single function call.

Before we leave the subject entirely, we need to discuss the small changes that have had to be made to the AttachController and DetachController methods in CActor. You will recall that these methods were introduced to allow our actor to be referenced. We must now make sure that the action system will also work correctly during referencing.

Safely Referencing Action Animating Actors

In Chapter Ten we wrote code that allowed multiple objects to reference the same actor, where each had different animation data or was at a different position on the animation timeline. This allowed us to instance the actor many times in the scene without having to load redundant copies of the actor geometry into memory. Our design solution was actually very simple. We decided that if multiple CObject's in our scene referenced the same actor, the actor would no longer own its own animation controller; instead, each object would manage its own controller. To update an object's animation, we simply attached its controller to the actor and then used the actor's methods to update it. Similarly, when rendering an object, we attached the object's controller to the actor and rendered the actor as normal. This solution works well and we will continue to use it.

The action system is also controller specific because the CActionStatus object maintains the current position of all the tracks on the controller. If we were to detach the controller and attach a different one, the CActionStatus object would be completely out of sync. Of course, we could write some function that would synchronize the CActionStatus object to a new controller whenever one is attached. While that would be easy to do, it would not be the wisest design choice. Remember, if we have multiple objects using the same actor, we want the actor's CActionStatus object to remember the settings of each reference because the controller itself will have no way of letting the action system know whether a track on the newly attached controller was in the process of fading out when it was last detached. We have essentially lost this information and our action system will not reference properly.

Of course, the solution is really rather straightforward. The CActionStatus object contains the state of a controller, and as each CObject referencing an actor owns its own controller, it should also own its own CActionStatus object in exactly the same way. All we need to do is add an extra parameter to our AttachController and DetachController methods that will allow us to pass/retrieve a CActionStatus object to/from a CActor object. That is, every time we attach an object's controller to an actor, its CActionStatus object will also be passed and will become the actor's current CActionStatus object. This way, each object owns both its own controller and the current state of that controller with respect to the action system. This allows the current state of an object's controller to persist during the attach/detach process.

CActor::Detach Controller

This method has been updated to take an optional CActionStatus parameter. If your object does not wish to use the action system we can just call this function as we always have. However, if you do wish to retrieve the current CActionStatus object of the actor, we can pass in the address of a CActionStatus pointer which, on function return, will pointer to the CActionStatus object the actor was using before you detached it.

Our application uses this function inside the CScene::ProcessReference function during loading. If the reference is to an X file that has already been loaded into an actor, we essentially switch the actor into reference mode. We fetch the controller and the CActionStatus from the actor and store it in the object instead. Then, any future references to this same actor causes the controller and the status object to be cloned and stored in a new object. We discussed the CScene::ProcessReference function in the animation workbook when we introduced this reference system. If you consult this function in Lab Project 12.2 you will see that virtually nothing has changed. All we do now is store the CActionStatus object of the actor in the CObject in addition to the controller.

Let us have a look at the detach controller function, which has been slightly updated. The function first makes a copy of the controller pointer and then sets the actor's controller pointer to NULL. It is now going to surrender its controller reference to the caller. At this point the actor has no controller anymore. We also copy the address of the actor's CActionStatus object in the passed pointer and set the actor's CActionStatus pointer to NULL as well. The actor no longer owns a CActionStatus object either. The function then returns the pointer to the new controller. The CActionStatus object is returned via the output parameter.

```
LPD3DXANIMATIONCONTROLLER CActor::DetachController(CActionStatus** ppActionStatus)
{
    LPD3DXANIMATIONCONTROLLER pController = m_pAnimController;

    // Detach from us
    m_pAnimController = NULL;

    // If the user requested to detach action status information, copy it over
    if ( ppActionStatus )
    {
        *ppActionStatus = m_pActionStatus;
        m_pActionStatus = NULL;
```

```
    } // End if requested action status

    // Note, we would AddRef here before we returned, but also
    // release our reference, so this is a no-op. Just return the pointer.
    return pController;

}
```

CActor::AttachController

This function also has a new parameter and a few new lines added at the bottom. The function now takes an additional third parameter allowing an action status object to be attached to the actor.

The first thing the function does is release the current action status object and controller being used by the actor. We then set the actor's controller and status object pointer to NULL.

```
void CActor::AttachController( LPD3DXANIMATIONCONTROLLER pController,
                               bool bSyncOutputs /* = true */,
                               CActionStatus * pActionStatus /* = NULL */ )
{
    // Release our current controller.
    if ( m_pAnimController ) m_pAnimController->Release();
    m_pAnimController = NULL;

    // Release our current action status (if provided).
    if ( m_pActionStatus ) m_pActionStatus->Release();
    m_pActionStatus = NULL;
```

If a new controller was passed, we will assign the address of this new controller to the actor's controller pointer and increase the reference count. If the bSyncOutputs parameter was set to true it means the caller would like the relative matrices of the hierarchy immediately updated to reflect the current position in the animation. We do this by calling AdvanceTime on the controller with a time delta of 0.0 seconds (we do not physically alter the position of the animation). The sequence of events is shown below.

```
    // Attach new controller if one is provided
    if ( pController )
    {
        // Store the new controller
        m_pAnimController = pController;

        // Add ref, we're storing a pointer to it
        m_pAnimController->AddRef();

        // Synchronize our frame matrices if requested
        if ( bSyncOutputs ) m_pAnimController->AdvanceTime( 0.0f, NULL );

    } // End if controller specified
```

In the final section of code we attach the passed CActionStatus object to the actor's member pointer and increase its reference count.

```
    // Attach new status object is one is provided
    if ( pActionStatus )
    {
        // Store the new status information
        m_pActionStatus = pActionStatus;

        // Add ref, we're storing a pointer to it
        m_pActionStatus->AddRef();

    } // End if status specified
}
```

Using the Action Animation System

In Lab Project 12.3 we use the action animation system to animate our game character. In this section we will detail the points of communication between the application and the actor in all matters involving the use of this action system.

Step 1: Updating CObject for Action Referencing

The first thing that has to be done is the expansion of our CObject structure to contain a CActionStatus pointer. As described in the previous section, this allows for proper actor referencing. Below we see the new CObject class as declared in 'CObject.h'.

```
class CObject
{
public:
    //-------------------------------------------------------------------------
    // Constructors & Destructors for This Class.
    //-------------------------------------------------------------------------
    CObject( CTriMesh * pMesh  );
    CObject( CActor   * pActor );
    CObject( );
    virtual ~CObject( );

    //-------------------------------------------------------------------------
    // Public Variables for This Class
    //-------------------------------------------------------------------------
    D3DXMATRIX                 m_mtxWorld;          // Objects world matrix
    CTriMesh                  *m_pMesh;             // Mesh we are instancing
    CActor                    *m_pActor;            // Actor we are instancing
    LPD3DXANIMATIONCONTROLLER  m_pAnimController;   // Controller
    CActionStatus             *m_pActionStatus;     // Action Status
};
```

Step 2: Loading the Player Model

In our application, the player controlled character uses the action system. Unlike previous demos, our CPlayer object will have a proper animating actor attached to it instead of the placeholder cube mesh we have been using in previous demos. This means the CGameApp::BuildObjects function which is called at application startup, will now need to call another function to load the model that will be attached to our CPlayer object.

The function we use to load and create the actor for the CPlayer object is part of the CScene namespace and is called CScene::LoadPlayer. This function accepts the name of an X file to load and the name of an .ACT file to load. The third parameter is the address of the CPlayer object that will be assigned the actor as its third person object.

We see this function being called from the CGameApp::BuildObjects function after the main scene has been loaded. It is highlighted in bold at the bottom of the following listing. The rest of this function should be familiar to you.

```
bool CGameApp::BuildObjects()
{
    CD3DSettings::Settings * pSettings = m_D3DSettings.GetSettings();
    bool                     HardwareTnL = true;
    D3DCAPS9                 Caps;

    // Should we use hardware TnL ?
    if ( pSettings->VertexProcessingType == SOFTWARE_VP ) HardwareTnL = false;

    // Release previously built objects
    ReleaseObjects();

    // Retrieve device capabilities
    m_pD3D->GetDeviceCaps(    pSettings->AdapterOrdinal,
                              pSettings->DeviceType, &Caps );

    // Set up scenes rendering / initialization device
    m_Scene.SetD3DDevice( m_pD3DDevice, HardwareTnL );

    ULONG LightLimit = Caps.MaxActiveLights;

    // Load our scene data
    m_Scene.SetTextureFormat( m_TextureFormats );

    // Attempt to load from IWF.
    if (!m_Scene.LoadSceneFromIWF( m_strLastFile, LightLimit ))
    {
        // Otherwise attempt to load from X file
        if (!m_Scene.LoadSceneFromX( m_strLastFile )) return false;

    } // End if failed to load as IWF

    // Attempt to load the player object (ignore any error at this point)
    m_Scene.LoadPlayer( _T("Data\\US Ranger.x"),
```

```
                        _T("Data\\US Ranger.act"),
                        &m_Player );

    // Success!
    return true;
}
```

To understand how the player object is loaded and configured we must take a look inside the new CScene::LoadPlayer method. The code to this new function is shown below with descriptions.

CScene::LoadPlayer

```
bool CScene::LoadPlayer(      LPCTSTR ActorFile,
                              LPCTSTR ActionFile,
                              LPCTSTR CallbackFile,
                              CPlayer * pPlayer )
{
    long nIndex = -1;

    // Add a new slot to the actor list
    nIndex = AddActor();

    // Allocate new actor
    CActor * pNewActor = new CActor;
    if ( !pNewActor ) return false;

    // Store the actor in the list
    m_pActor[ nIndex ] = pNewActor;
```

This function accepts the name of an X file to load for the player object, the name of an .ACT file to load describing the actions that can be performed by this actor, and a pointer to the CPlayer object. For the time being, we can ignore the third parameter (CallbackFile), since it will be discussed later.

We call CScene:AddActor to make space at the end of the scene's actor pointer array for a new actor. We like to store this in the scene's actor array with the rest of the scene actors so if anything goes wrong, the scene destructor will release it along with the rest of the actors it is managing. The AddActor method returns the array index where we should store our new actor pointer, so we allocate a new CActor object and store its pointer in the array at this position.

The next three lines are familiar. Before loading the actor from the X file we register the CALLBACK_ATTRIBUTE callback function, placing the actor into non-managed mode.

We also register a callback to handle the creation of callback keys during the actor's initial loading process. We will register the same function for this purpose as we did in Chapter Ten (CScene::CollectCallbacks). You will recall that when the actor has been loaded, this function will be called for each animation that was created. It gives the application an opportunity to fill an array of callback keys and return them to the actor. The actor then clones the animation sets with these callback keys registered. In Chapter Ten we used the callback system to register sound effects with the animation

sets. This function will be used for the same purpose again in this lab project, only a slightly more robust sound playing method will be used that requires some additional tweaking to the callback system.

```
// Load the actor from file
pNewActor->RegisterCallback(CActor::CALLBACK_CALLBACKKEYS,CollectCallbacks,this );
pNewActor->RegisterCallback(CActor::CALLBACK_ATTRIBUTEID,CollectAttributeID,this);

if ( FAILED(pNewActor->LoadActorFromX(  ActorFile,
                                        D3DXMESH_MANAGED,
                                        m_pD3DDevice,
                                        true,
                                        (void*)CallbackFile )) ) return false;
```

Notice that we now pass the CallbackFile pointer as a new parameter to the LoadActorFromX function. This will contain the name of another .ini file that contains the sound files we wish to play and the animation sets we wish them to apply to. The actor will pass this to its ApplyCallbacks function after it has been loaded. The ApplyCallbacks function will then call the CScene::CollectCallbacks function (the registered callback) for each animation set loaded from the X file, passing in this string. The callback key creation function can then open the .ini file and read in the sound effects for the current animation set be created. These sounds are then registered as callback keys with the animation set. This will all be discussed at the end of this section. Just know for now that the pointer in the LoadActorFromX parameter list is pumped straight through to any registered CALLBACK_CALLBACKKEYS function to aid in the creation of the callback keys.

Now that the actor has been fully loaded along with any animation data that may exist, we can load the action data from our ACT file into our new actor. We will also extend the limits of the actor's controller so that the action system has 20 mixer tracks to play with when performing its fades between actions. The CActor::SetActorLimits method is used for this purpose. It ultimately issues a call to the CActor::CActionStatus::SetMaxTrackCount method so the status object's TrackActionStatus array is resized to retain a 1:1 mapping with mixer tracks available on the controller.

```
    // Load the action definition file
    if ( FAILED(pNewActor->LoadActionDefinitions( ActionFile )) ) return false;

    // Set the actor limits to something reasonable
    if ( FAILED(pNewActor->SetActorLimits( 0, 20 )) ) return false;
```

At this point, our actor has been correctly configured and contains all its geometry, animation, and action data. We now need to assign this actor to an object. To do this we use the CScene's AddObject method to make space at the end of its CObject array for a new object pointer. Then we allocate a new CObject, store its pointer in the object array, and assign our new actor to its m_pActor member. Finally, before returning, we call the CPlayer::Set3rdPersonObject method to store a pointer to this CObject in the CPlayer. This is the object that the CPlayer::Render method will use to render itself.

```
    // Add a new slot to the object list
    nIndex = AddObject();

    // Create a new object
    CObject * pNewObject = new CObject;
```

```
    if ( !pNewObject ) return false;

    // Store the object in the list
    m_pObject[ nIndex ] = pNewObject;

    // Store the object details
    pNewObject->m_pActor = pNewActor;

    // Inform the player of this object
    pPlayer->Set3rdPersonObject( pNewObject );

    // Success!
    return true;
}
```

We have now seen the adjustments that we have had to make to our application to support the loading of the action data and the population of an actor with this action data. In the next section we will discuss how the CPlayer object has been modified to apply the relevant actions to its attached actor.

Step 3: Applying Actions

You will hopefully recall that when we first introduced our CPlayer object in Chapter Four of Module I, the CPlayer::Update function was called to update the position of the player in response to user input.

In every iteration of our game loop, the CGameApp::ProcessInput function is called to determine if the player is pressing any keys or moving the mouse. In response to the movement keys being pressed for example, this function would call the CPlayer::Move function to update the velocity variable in the player object. If the mouse had been moved with the left button depressed, the CPlayer::Rotate method would be called to apply a rotation to the CPlayer's world matrix. However, the position of the player was not updated until the very end of that function when the CPlayer::Update method was called. It was this function that was responsible for updating the position of the player and its attached camera based on the currently set velocity of the player. Other factors came into play as well such as resistance forces working against the velocity vector.

Although we will not show the code to the CPlayer::Update function again here, one new function call has been added to it that will call a function called CPlayer::ActionUpdate. In this function, the player object has a chance to apply any actions it wishes based on user input or game events. This method will also be responsible for building the world matrix of the attached CObject that houses the actor.

Before we look at the code to the ActionUpdate method, we will discuss what the code is assumed to be doing in this example. Also note that the actual function code contained in Lab Project 12.3 may be different from what is shown next. At the time of writing it was still possible that different assets may be used in our final demo. Since the ActionUpdate function is largely dependant on the animation assets being used (e.g., the names of animation sets, etc.) the function code shown here is to be used only as an example of what an ActionUpdate function can look like.

In this example we will assume that the .ACT file contains the following five actions. Each action is comprised of three sets for the torso, hips, and legs respectively. We can forget about the 'Hips' set in each action as it essentially just undoes the pelvis rotation caused by walking.

- **Walk At Ease**
  In this action, the torso animation set adopts a typical walking sequence. The arms are swinging back and forth in tandem with the legs. The weapon is loosely held in one of the hands and is also swinging back and forth. The legs animation set is performing a typical footsteps animation. In this action, the character is certainly very relaxed and is not expecting any hostile activity.

- **Walk Ready**
  In this action the character is walking on patrol and is ready for anything. The torso animation set now has the gun held firmly to the character's chest so that he can assume the shooting pose at a moment's notice. The legs animation set is identical in all three walk actions – a standard footsteps animation.

- **Walk Shooting**
  When this action is applied the same legs animation is used as in the other two walk cases but the torso is now playing an animation set that holds the gun up to the soldier's shoulder in a targeting pose looking for enemies to fire at.

- **Idle Ready**
  This action will be played when the character is not currently walking and the fire button is not being pressed. The legs animation set simply has the legs in a stationary position so that the character is standing still. Whenever the character is idle, he will assume the ready pose with his torso (i.e., the animation set that has the character holding the gun to his chest).

- **Idle Shooting**
  This action uses the same torso animation set as the Walk Shooting action, but uses the same legs animation set as the Idle Ready action. This action is applied when the player presses the fire button (right mouse) but the character is not currently being moved at the same time. The character stands still, looking through the sight of his gun for hostile targets.

We can imagine when most of these actions will need to be applied. For example, if the player is currently moving and the fire button is pressed, then the 'Walk Shooting' action will be played. If the player stops moving but is still shooting, then the 'Idle Shooting' action will be applied. If the character is walking and his weapon has not been fired, we will apply the 'Walk At Ease' action. So when does the 'Walk Ready' action get applied?

In order to make the character feel a little more lifelike, the 'Walk Ready' action is played for five seconds after the fire button has been pressed and released. If we imagine that the character is currently moving, and we are playing the 'Walk At Ease' action, assume that the fire button is pressed and the 'Walk Shooting' animation is applied (which remains applied until the fire button is released). Instead of simply returning to the 'Walk At Ease' action as soon as the fire button is released, we apply the 'Walk Ready' action for 5 seconds. Assuming the fire button is not pressed again, after five seconds the character will drop his arms into the 'at ease' posture and start walking normally. This makes the

character seem a little more intelligent. In real life, a soldier would hardly assume an ‘At Ease’ posture immediately after firing a shot. He would probably fire and then remain in the ready position for some time, ready to fire again until he is sure that the threat has passed. So we add a little bit of that logic here just to demonstrate how you can use the AAS to accomplish different design ideas.

With these animation assets now explained, we are ready to examine the code to this function that implements the behavior described above.

The function is passed one parameter by the CPlayer::Update method describing the elapsed time in seconds between the last update and the current one. Here is the first section of the function that builds the world matrix for the CPlayer’s attached object. The player currently stores a right vector, up vector, look vector and a position vector, so building the matrix is a simple case of storing these vectors in the rows of the attached CObject’s world matrix.

```
void CPlayer::ActionUpdate( float TimeScale )
{
    ULONG i;

    // If we do not have a 3rd person object, there is nothing to do.
    if ( !m_p3rdPersonObject ) return;

    // Get the actor itself
    CActor * pActor = m_p3rdPersonObject->m_pActor;

    // Update our object's world matrix
    D3DXMATRIX * pMatrix = &m_p3rdPersonObject->m_mtxWorld;

    pMatrix->_11=m_vecRight.x; pMatrix->_21=m_vecUp.x; pMatrix->_31=m_vecLook.x;
    pMatrix->_12=m_vecRight.y; pMatrix->_22=m_vecUp.y; pMatrix->_32=m_vecLook.y;
    pMatrix->_13=m_vecRight.z; pMatrix->_23=m_vecUp.z; pMatrix->_33=m_vecLook.z;
    pMatrix->_41 = m_vecPos.x;
    pMatrix->_42 = m_vecPos.y;
    pMatrix->_43 = m_vecPos.z;
```

As you can see in the above code, if the CPlayer has no third person object attached to it we simply return. Otherwise we fetch a pointer to the object’s CActor and the object’s world matrix. We then build the world matrix for the third person object.

In the next section of code we will define some static variables.

```
    static float fReadyTime = 200.0f;
    static bool  bIncreaseReadyTime = false;
```

The fReadyTime is set to an arbitrarily high value of 200 seconds and will be used as a timer to determine how long the ‘ready’ action should remain applied before the character is put back into an ‘at ease’ action state. Whenever the fire button is pressed, fReadyTime will be set to 0 (zero seconds) and the bIncreaseReadyTime boolean will be set to false so that we will not increase this timer while the fire button is being pressed. As soon as the fire button is no longer being pressed, the boolean will be set to true and the timer will be incremented each time the function is called. As this timer is always set to zero seconds when the player fires, as soon as the player is no longer firing, we will apply the ‘ready’ pose

for five seconds (i.e., while fReadyTimer is less than 5.0). As soon as its value is incremented past five seconds we know that we have been in the ready pose long enough and should now apply the ‘at ease’ pose. This cycle repeats whenever the fire button is pressed and the timer is set back to zero.

We get the speed of the character by calculating the length of the CPlayer’s velocity vector. You will see why this is needed in a moment. We then use the GetKeyState Win32 function to test if the left mouse button is being pressed. If so, we wish to apply a shooting action and reset the ready timer to zero.

```
    // Calculate movement speed
    float fSpeed = D3DXVec3Length( &m_vecVelocity );

    // In Shooting State?
    bool bShooting = false;
    if ( GetKeyState( VK_LBUTTON ) & 0xF0 )
    {
        // We are shooting
        bShooting          = true;

        // Setup timing states
        fReadyTime         = 0.0f;
        bIncreaseReadyTime = false;

    } // End if left button is pressed
    else
    {
        // Set our 'ready' timer going
        bIncreaseReadyTime = true;

    } // End if left button is not pressed
```

At the end of this loop, if we are pressing the fire button the timer will be reset to zero and the bIncreaseReadyTime boolean will be set to false indicating that we do not wish to increment the ready timer in this update and should leave it at zero. Otherwise, if the fire button is not being pressed the Boolean will be set to true, meaning a timer increment should happen. We also set the bShooting boolean to true if the fire button is being pressed so that we will know later in the function that an action should be applied that includes a torso shooting pose.

We now test the current value of the timer and if it is found to contain less than 5 seconds of elapsed time since being reset, we should be in the ready pose. So we set the bReadyState boolean to true. Otherwise, it is set to false. We also increment the ‘ready’ timer using the elapsed time passed into the function. This timer increment only happens if the fire button is not being pressed.

```
    // In ready state?
    bool bReadyState = false;
    if ( fReadyTime < 5.0f ) bReadyState = true;
    if ( bIncreaseReadyTime ) fReadyTime += TimeScale;
```

At this point we have determined what the torso of the character should look like. He is either shooting (bShooting=true), in the ready pose (bReadyState=true), or is walking at ease. Next we have to find out

what the legs of the character should be doing. There are two choices, they are either walking or standing still.

We decided to place the character into an idle legs pose if the speed of the character drops to less than 6 units per second. This is a value that you will want to tweak depending on the scale of your level, the resistance forces you apply, etc. In our case, 6 units of movement per second represents a very small amount of movement at the per frame level and will be cancelled out by friction fairly quickly if no additional force is applied. Therefore, as the player slowly comes to a halt, we place its legs into the idle pose slightly prematurely. This looks more natural than the character stopping while his legs are still spread apart in a walk pose, and then having the legs slide into the idle pose on the spot.

```
    // Idling?
    bool bIdle = false;
    if ( fSpeed < 6.0f ) bIdle = true;
```

We now know whether the legs are idle or not, so we can determine which action to play. If our legs are idle and we are shooting, we should apply the ‘Idle1_Shooting’ action. If the fire button is not being pressed but the legs are still idle we should play the ‘Idle1_Ready’ action.

```
    // Apply the correct action
    if ( bIdle )
    {
        // What is our pose?
        if ( bShooting )
            pActor->ApplyAction( _T("Idle1_Shooting") );
        else
            pActor->ApplyAction( _T("Idle1_Ready") );

    } // End if idling
```

That takes care of the idle case. Next we have the code block that deals with the non-idle case which surrounds the remaining code in this function. If our legs are not idle and we are shooting, we will play the ‘Walk_Shooting’ action. If the fire button is not pressed but the ‘ready’ timer contains a value of less than 5 seconds, we will apply the ‘Walk_Ready’ action. Otherwise, we will play the ‘Walk_At_Ease’ action.

```
    else
    {
        // What is our pose?
        if ( bShooting )
            pActor->ApplyAction( _T("Walk_Shooting") );
        else
            if ( bReadyState )
            pActor->ApplyAction( _T("Walk_Ready") );
        else
            pActor->ApplyAction( _T("Walk_At_Ease") );
```

At this point we have applied the correct walking action to the actor, but we should really adjust the speed of the tracks used by this action so that it matches the speed of the character. It would look very

strange if the legs and arms of the character animated at a constant speed without accounting for the actual speed of the character's forward motion.

We will calculate the animation speed by the taking the dot product between the velocity vector and the look vector of the player since this describes to us how much of the velocity is attributed to the fact that the player is walking forward. If the velocity and look vectors are aligned, a value of 1 will be returned. This will become smaller as the vectors become misaligned. Once we have the value of the dot product (which is the cosine of the angle scaled by the length of the velocity vector), we scale it by 0.027. Finding this scaling value was just a trial and error process and you may wish to change it to suit your scene scale.

```
     // Calculate the speed of the tracks
     float fDot   = D3DXVec3Dot( &m_vecLook, &m_vecVelocity );
     float fSpeed = fDot * 0.027f;
```

Finally, we will loop through each track in the actor's CActionStatus object and examine the TrackActionStatus structure. This will tell us if the track is currently in use and the action that assigned that animation set to the mixer track. We are searching for all tracks that are currently in use and that were set up by the current CActionDefinition object that we just applied. If one is found, we set the speed of that track on the mixer to the speed value just calculated.

```
     CActionStatus * pStatus = pActor->GetActionStatus();
     CActionDefinition * pDefinition = pStatus->GetCurrentAction();

      for ( i = 0; i < pStatus->GetMaxTrackCount(); ++i )
      {
       CActionStatus::TrackActionStatus *pTrackStatus=pStatus->GetTrackStatus(i);

       // Skip if this track is not in use
       if ( !pTrackStatus->bInUse ) continue;

       // Skip if this track wasn't assigned by the currently active definition
       if ( pTrackStatus->pActionDefinition != pDefinition ) continue;

       // Set the track speed
       pActor->SetTrackSpeed( i, fSpeed );

      } // Next Track

   } // End if walking
}
```

Since we are looping through all the tracks, we are guaranteed to find those that were set up by the currently applied action. This means we will update the speed of the torso, hips, and legs tracks for the current action simultaneously ensuring that the sets within a given action remain synchronized.

We have now covered the action system in its entirety. We have not only covered the code to the action system itself, but we have also examined how the application uses it to animate a game character. As mentioned, the actual contents of the CPlayer::ActionUpdate method may be quite different from the one shown above. Indeed, this is a function that will probably have its contents changed quite frequently

to suit the assets and animation sets that you use in your own game projects. When we cover scripting in Module III, much of this code will go away and we can configure animation changes offline without having to update and recompile source code. But that is for another day.

The remainder of this workbook will be spent detailing other upgrades we have made to our application framework which are not specifically related to the Action Animation System.

Adding Multiple Sound Effect Call-Back Keys

In Chapter Ten we implemented a lab project that had sound effects that were triggered by the actor's animation sets via the callback system. The problem is, when the callback handler played those sounds in response to a callback event being triggered, it used the Win32 'PlaySound' function. To be sure, this is not a course on sound and we do not want to get caught up in the specifics of the DirectSound API (which we are going to use), but the Win32 PlaySound function is simply too limiting to continue using it moving forward. The biggest issue is that it only allows us to play one sound at a time. That means, if we wish to play the sound of our characters footsteps as he walks and we wish to have an ambient background sound, such as blowing wind, we are out of luck. This is far too restrictive, so we will also use this lab project to introduce a new way to play sounds, via two very helpful classes that ship with the DirectX SDK framework.

Using CSoundManager

If you look in the "/Sample/C++/Common/" folder of your DirectX 9 installation directory you will see two files named DXUTSound.h and DXUTSound.cpp. These files contain the implementation of a class called CSoundManager that we can include in our projects to easily play (multiple) sounds. This class and the class it uses to represent individual sounds (CSound) wrap the DirectSound API, making it delightfully easy to load and play sound. Although the CSoundManager class exposes many functions to perform techniques like 3D positional sound, at the moment we are only interested in using this class to load and play simple sound. As such, we will only use a very small subset of the functions available.

So that we do not get caught up in the code to these classes (which are way off topic in a graphics course) we have compiled them into a .lib file which is included with this project. These files are called libSound.lib and libSound.h and they are located in the Libs directory of the project. CGameApp.h and CScene.cpp both include this header file, giving them access to the CSoundManager class.

```
#include "..\\Libs\\libSound.h"
```

The CSoundManager object is used to create CSound objects that can be played. As such, we have made it a member variable of the CGameApp class.

```
CSoundManager     m_SoundManager;
CSoundManager     * GetSoundManager     ()       { return &m_SoundManager; }
```

Notice that we have also added a new inline member function called GetSoundManager that returns a pointer to the sound manager object. This allows other modules (such as CScene for example) to retrieve the application's sound manager object and use it to create new sounds during the registration of callback key data with the actor.

As we know, the CGameApp::InitInstance method is called when the application is first started. In turn it calls a number of functions to configure the state of the application prior to the commencement of the main game loop. This method calls functions such as CreateDisplay and TestDeviceCaps and the BuildObjects method which actually loads the geometry. Since the CSoundManager object requires some initialization of its own, we have added a new method to the CGameApp class called CreateAudio. Below we show how this function is called from the InitInstance function. The new line is highlighted in bold.

```
bool CGameApp::InitInstance( HANDLE hInstance, LPCTSTR lpCmdLine, int iCmdShow )
{
    // Store the initial starting scene
    m_strLastFile = _tcsdup( _T("Data\\Landscape.iwf") );

    // Create the primary display device
    if (!CreateDisplay()) { ShutDown(); return false; }

    // Create the primary audio device.
    if (!CreateAudio()) { ShutDown(); return false; }

    // Test the device capabilities.
    if (!TestDeviceCaps( )) { ShutDown(); return false; }

    // Build Objects
    if (!BuildObjects()) { ShutDown(); return false; }

    // Set up all required game states
    SetupGameState();

    // Setup our rendering environment
    SetupRenderStates();

    // Success!
    return true;
}
```

The CreateAudio method contains only three lines of code to call methods of the CSoundManager object to initialize it. This involves informing the operating system of the control we would like over the sound hardware and the format in which we would like sounds to be played. Here is the code to the function.

```
bool CGameApp::CreateAudio()
{
    // Create the audio devices.
    if( FAILED(m_SoundManager.Initialize( m_hWnd, DSSCL_PRIORITY ))) return false;
    if( FAILED(m_SoundManager.SetPrimaryBufferFormat( 2 ,22050,16))) return false;

    // Success!
    return true;
}
```

In the first line we call the CSoundManager::Initialize function, passing in the application's main window handle and the flag DSSCL_PRIORITY. When using a DirectSound device with the priority cooperative level (DSSCL_PRIORITY), the application has first rights to audio hardware resources (e.g., hardware mixing) and can set the format of the primary sound buffer. Game applications should use the priority cooperative level in almost all circumstances. This level gives the most robust behavior while allowing the application control over sampling rate and bit depth.

In the second line we have to inform the sound manager of the format of the sounds we would like it to create and play in its primary buffer. We can think of the primary buffer as being very much like the audio equivalent of a 3D device's frame buffer. It is where all of the individual sounds that are currently playing get blended together to produce the final audio output.

As the first parameter to the CSoundManager::SetPrimaryBufferFormat method, we pass in the number of channels we would like the primary buffer to have. We pass in a value of 2 because we would like it to play sounds in stereo. A stereo sample has two separate channels of audio within the same .wav file (it has separate audio streams for the left and right speakers). In short, if we have stereo sound samples that we wish to load and play, this will ensure that the DirectSound device will be able to reproduce the final stereo output. If you wanted to play only mono sounds, you could pass 1 for this parameter. A mono sound has only one channel of audio data which gets duplicated in each speaker.

As the second parameter we pass in a sample rate of 22050, which means we are setting the quality at which it plays back sounds to 22khz (pretty fair quality). The third parameter specifies that we would like the primary buffer to be able to play back sounds in 16-bit sound quality. 16-bit sound has much nicer audio quality then 8-bit sounds. Of course, if your sound samples have been recorded at 8-bit to begin with, then they are still going to sound bad on a 16-bit quality device. However, this setting means that 16-bit sound samples will not have to be played back at 8-bit resolution.

When the above function returns, the sound manager will be ready for action and the application can use it to load and create sounds. From this point on, the only method we will be interested in calling is the CSoundManager::Create method. This method is defined as shown below. Actually, the function has many optional parameters after the two shown here, but these are the only two we are going to use, so we will worry about them. This function is defined in DXUTSound.h.

HRESULT Create(CSound ppSound, LPWSTR strWaveFileName)**

The first parameter is the address of a CSound object pointer which will point to a valid CSound object on function return. The second parameter is a string containing the name of the wav file we would like to load. When the function returns, the CSound object will encapsulate that sound effect and we can use its CSound::Play method to play the sound. We can create as many CSound objects as we want just by calling this function over and over again for the different sound effects we wish to load.

Below, we see an example of creating a CSound object for a wav file called 'footsteps.wav'.

```
CSound * pSound = NULL;
m_pSoundManager->Create( &pSound, "footsteps.wav" );
```

At this point the sound would be loaded and would be ready to play. Whenever we wish to play that sound we can simply do the following:

```
pSound->Play( )
```

As you can see, it is delightfully easy to use. If we play a sound and a sound is already playing, they will be mixed in the primary buffer of the DirectSound device and both sounds will heard simultaneously. In fact, there is no hard limit on the number of sounds that can be played simultaneously, although you will see a drop in game performance if you try to play too many. When multiple sounds are being played, they all have to be mixed in the primary buffer, so there is some associated overhead.

We can also pass parameters to the CSound::Play method to tell it how we would like it to play. For example, we might specify that we would like the sound to play repeatedly (i.e., loop). The code snippet shown below comes from the very bottom of the CScene::LoadSceneFromIWF function in Lab Project 12.3. It creates and plays a looping wind sound effect while the application is running. Notice how we query the CGameApp class for its CSoundManager pointer and then use it to load a wave file called 'Wind Ambient.wav'. We then play the sound immediately.

Excerpt from CScene.cpp : LoadSceneFromIWF

```
CSoundManager * pSoundManager = GetGameApp()->GetSoundManager();
if ( pSoundManager )
{
  // Release the old sound if it's resident
  if ( m_pAmbientSound ) delete m_pAmbientSound;

  // Create the ambient sound
  pSoundManager->Create(&m_pAmbientSound,_T("Data\\Sounds\\Wind Ambient.wav"));
  m_pAmbientSound->Play( 0, DSBPLAY_LOOPING );

} // End if application has sound manager.
```

Notice that this time we are passing in two parameters to the Play function. The first is the priority of the sound. We pass in the lowest (default) priority of 0, stating that this sound is no more important than any other sound our application might play. The second parameter is a flag that describes how the DirectSound buffer (all sounds are loaded into their own buffers) should be played. There is only one modifier flag that can be used at the moment: DSBPLAY_LOOPING. This instructs DirectSound to play the sound in a loop. The absence of this flag means the sound will play once and then stop.

Now that we have the ability to play multiple sounds, we will need to write a new (CScene::CollectCallbacks) function that uses the sound manager to create and load these CSound objects and store them in callback keys in the actor's animation sets. Additionally, it would be nice if we could extract the sound data from another type of .ini file rather than hard coding the CollectCallbacks function to load the files we wish to play. In the next section we will discuss some upgrades to the actor's callback key collection system that will allow the callback key collection function (CScene::CollectCallbacks) access to the name of the file that contains the descriptions of the sound files we wish to load.

The CollectCallbacks Callback Function

Before we discuss any changes, let us just refresh our memories with respect to the actor's callback key collection system.

As we know, when the LoadActorFromX method is called, it issues a call to the D3DXLoadMeshHierarchyfromX function to build the actor's hierarchy and its animation controller (if applicable). As we discussed in Chapter Ten, we are unable to register callback keys with an animation set that has already been created. Therefore, we implemented a private method of the actor called ApplyCallbacks which (when called from LoadActorFromX) would loop through every animation set that was loaded and call an application registered callback function (CScene::CollectCallbacks). This function would be passed an array of callback keys which it could fill with information. The application would register a special type of callback function with the actor prior to calling its LoadActorFromX function. This callback function would then be called for each loaded animation set. The callback function could create callback keys and pass them back to the actor. The actor would then clone the original animation set into a new one that has the callback keys registered with it.

You will remember that originally, the CScene::CollectCallbacks function loaded some wave files and stored them in CActionData objects. The pointers to these objects were then stored in the callback key itself as context data. When the callback was triggered, this pointer would be passed to the callback handling function which could then access the wave file stored inside and play it. You will also recall that the CActionData class was derived from IUnknown so that the actor could safely release objects of this type when the actor's controller was being destroyed.

This all worked fine, but when we have multiple sounds to load it can certainly become cumbersome to have to hard code the loading of each sound in the callback key's collection function. It would much nicer if we could store the sound files and the animation sets they should be registered for in an external file. That is exactly what we do in this lab project. You will find a file in the Data directory of this lab project called 'US Ranger.cbd' which contains the sound data that should be registered with the Walk_Legs_Only animation set. We will have a look at the contents of this file a little later on. For now, just know that it contains the names of sound files that should be registered with a particular animation set as callback keys.

> **Note:** The .cbd extension that we have given to our file is short for 'CallBack Data'. Although we are using this file to store sound data, it can be used to store any type of callback key data we wish to represent.

This raises an interesting question. If our CScene::CollectCallbacks function is going to create the callback information from a file, how does it know the name of that file, which may be different for different actors? The answer is simple -- we have to give the actor's COLLECTCALLBACKS callback function prototype an additional parameter so that other data can be passed by the actor to the callback function that creates the callback keys. This pointer can be used for anything, but in our code we use it to pass the name of the .cbd file containing the sound effect properties.

If we look in CActor.cpp we are reminded that the actor stores the pointer for a registered callback function of type CALLBACK_CALLBACKKEYS in the fourth element of its callback function array.

```
enum CALLBACK_TYPE { CALLBACK_TEXTURE = 0,
                     CALLBACK_EFFECT = 1,
                     CALLBACK_ATTRIBUTEID = 2,
                     CALLBACK_CALLBACKKEYS = 3,
                     CALLBACK_COUNT = 4 };
```

That is, if we wish to register a function 'SomeFunction' as a callback key collection function, we would do so like this:

```
pNewActor->RegisterCallback(CActor::CALLBACK_CALLBACKKEYS,somefunction,this );
```

As discussed in the past, the first parameter describes the type of callback we wish to register with the actor. In this example, it is a callback to create callback keys during actor creation. This will be called by the actor just after the animation data has been loaded, once for each animation set so the function has a chance to register keys with it. The second parameter is the function name itself, which in this example is called 'somefunction'. The third parameter is optional context information that will be passed through to the callback key creation function when it is called. In this example the 'this' pointer is being passed, which means the callback function will have access to member variables of the object that is registering the function. Remember, callback functions must be static if they are methods of a class.

Of course, the function signature for 'somefunction' must be defined in a very specific way as dictated by the actor. Previously, this function had to return a ULONG (the number of callback keys it placed into the passed array) and accept the four parameters shown below.

```
typedef ULONG (*COLLECTCALLBACKS )( LPVOID pContext,
                                    LPCTSTR strActorFile,
                                    LPD3DXKEYFRAMEDANIMATIONSET pAnimSet,
                                    D3DXKEY_CALLBACK pKeys[] )
```

Every time this function is called by the actor, it will be passed the context that was passed into the RegisterCallback method (the *this* pointer for example), the name of the actor that is calling it, the name of the animation set that we are providing keys for, and a callback key array which we must fill with any callback keys we would like to register. This array is owned by the actor which calls this function just after the X file has been loaded.

When we look at the parameter list we can see that it provides no way for the name of the (.cbd) sound file to be passed. Therefore, we will modify the signature of this callback function (in CActor.h) to contain an additional parameter, as shown below.

```
typedef ULONG (*COLLECTCALLBACKS )( LPVOID pContext,
                                    LPCTSTR strActorFile,
                                    void * pCallbackData,
                                    LPD3DXKEYFRAMEDANIMATIONSET pAnimSet,
                                    D3DXKEY_CALLBACK pKeys[] )
```

As you can see, the actor now has the ability to pass an extra piece of information to the CollectCallbacks function in the form of a void pointer (pCallbackData). Our player's actor will use this to pass the name of a .cbd file to the callback function so that it knows where to load its sound data

from. The problem is, how does the actor know what data we want to send into this function? This too is now optionally passed into the LoadActorFromX method via a new parameter on the end.

```
HRESULT             LoadActorFromX  (     LPCTSTR FileName,
                                          ULONG Options,
                                          LPDIRECT3DDEVICE9 pD3DDevice,
                                          bool ApplyCustomSets = true,
                                          void * pCallbackData = NULL );
```

As you can see, when we call the actor's LoadActorFromX method we now have the option of passing in an additional void pointer. When the animation data has been loaded, the LoadActorFromX function will pass this pointer to the CActor::ApplyCallbacks method. This function originally took no parameters, but has been altered now so that it accepts a void pointer:

```
HRESULT ApplyCallbacks          ( void * pCallbackData );
```

As we know, this function loops through every loaded animation set in the actor, and if the CALLBACK_CALLBACKKEYS callback function has been registered, it will be called, passing in this new parameter as well as those shown above in the COLLECTCALLBACKS function prototype.

This means that the static CScene function that we register with the actor for callback key creation must also have this additional parameter added, so that it matches the layout defined for COLLECTCALLBACKS callback function. We will look at the actual code to the function later but below we see that its parameter list has been changed to match the correct signature for a callback key creation callback function.

```
ULONG CScene::CollectCallbacks(     LPVOID pContext,
                                    LPCTSTR strActorFile,
                                    void * pCallbackData,
                                    LPD3DXKEYFRAMEDANIMATIONSET pAnimSet,
                                    D3DXKEY_CALLBACK pKeys[] )
```

Representing our Sound Data

In Chapter Ten the CollectCallbacks function stored the names of the sound files we wanted to play in a class called CActionData. This was a very simple class that stored a string containing the name of the wave file. It was a pointer to an object of this type that was stored in the callback key so that it could be passed to the callback handler when the callback key was triggered. The callback key handler could then extract the sound file name and load and play it. This object also had to be derived from IUnknown and implement the AddRef, Release, and QueryInterface methods so that the actor could safely release these objects when the animation set was about to be destroyed. Although the actor knows nothing about the type of data we store in a callback key as context data, as long as it knows it is derived from IUnknown, before releasing the animation set it can fetch a pointer to each callback key's context data pointer, cast it to an IUnknown pointer and then call its Release method. This instructs the CActionData object (or

any IUnknown derived object) to destroy itself without the actor needing to have knowledge of what the object actually is and how its memory should be released.

The CActionData class served us well for previous demos, but now we will replace it with something a little more flexible. In CScene.h we declare an abstract base interface called IActionData to act as the base class from which any callback key context objects we register will be derived. This is a pure abstract class so it cannot be instantiated; it just sets out the methods that each callback key object must support.

The interface's GUID and definition is inside CScene.h, as shown below.

```
const GUID IID_IActionData    = {0xCCB7147E, 0x4480, 0x4C08, {0x8F, 0xC6, 0x95,
                                 0x57, 0xAC, 0x59, 0xA3, 0xA}};

class IActionData : public IUnknown
{
public:
      virtual HRESULT CreateCallback(     ULONG Index,
                                          LPVOID pContext,
                                          LPCTSTR strActorFile,
                                          void * pCallbackData,
                                          LPD3DXKEYFRAMEDANIMATIONSET pAnimSet,
                                          D3DXKEY_CALLBACK * pKey ) = 0;

      virtual HRESULT HandleCallback( UINT Track, CActor * pActor ) = 0;
};
```

As you can see, we now insist that not only should a callback object support the methods from IUnknown for lifetime encapsulation purposes, but it must now implement two methods called CreateCallback and HandleCallback. In order to understand the parameter lists to these functions, let us look at what the .cbd file looks like that we created for Lab Project 12.3.

Excerpt from US Ranger.cbd

```
[Walk_Legs_Only]

CallbackCount               = 4

; First Callback (Left foot touches ground)
Callback[0].Ticks           = 20
Callback[0].Action          = PLAY_SOUND
Callback[0].PlayMode        = RANDOM
Callback[0].SampleCount     = 4
Callback[0].Sample[0].File  = Data\Sounds\Footsteps L1.wav
Callback[0].Sample[1].File  = Data\Sounds\Footsteps L2.wav
Callback[0].Sample[2].File  = Data\Sounds\Footsteps L3.wav
Callback[0].Sample[3].File  = Data\Sounds\Footsteps L4.wav

; Second Callback (Right foot touches ground)
Callback[1].Ticks           = 40
Callback[1].Action          = PLAY_SOUND
Callback[1].PlayMode        = RANDOM
Callback[1].SampleCount     = 4
```

```
Callback[1].Sample[0].File  = Data\Sounds\Footsteps R1.wav
Callback[1].Sample[1].File  = Data\Sounds\Footsteps R2.wav
Callback[1].Sample[2].File  = Data\Sounds\Footsteps R3.wav
Callback[1].Sample[3].File  = Data\Sounds\Footsteps R4.wav

; First Callback (Left foot touches ground)
Callback[2].Ticks           = 60
Callback[2].Action          = PLAY_SOUND
Callback[2].PlayMode        = RANDOM
Callback[2].SampleCount     = 4
Callback[2].Sample[0].File  = Data\Sounds\Footsteps L1.wav
Callback[2].Sample[1].File  = Data\Sounds\Footsteps L2.wav
Callback[2].Sample[2].File  = Data\Sounds\Footsteps L3.wav
Callback[2].Sample[3].File  = Data\Sounds\Footsteps L4.wav

; Second Callback (Right foot touches ground)
Callback[3].Ticks           = 80
Callback[3].Action          = PLAY_SOUND
Callback[3].PlayMode        = RANDOM
Callback[3].SampleCount     = 4
Callback[3].Sample[0].File  = Data\Sounds\Footsteps R1.wav
Callback[3].Sample[1].File  = Data\Sounds\Footsteps R2.wav
Callback[3].Sample[2].File  = Data\Sounds\Footsteps R3.wav
Callback[3].Sample[3].File  = Data\Sounds\Footsteps R4.wav
```

The layout of this file is very simple, especially in this case where we are only defining the information for one animation set.

At the top of the file we can see that the only block defined is for the animation set called ‘Walk_Legs_Only’. This entire file is just defining a number of callbacks for the one set. If we had callback key data to define for multiple animation sets, there would be multiple sections in this file arranged one after another.

Inside the Walk_Legs_Only section of the file we specify the callback key data. The first property we must set is called CallbackCount, which specifies the number of callback keys we would like to register with this animation set. The ‘Walk_Legs_Only’ animation set is a short looping walking sequence which walks the legs in a ‘Left-Right-Left-Right’ motion. That is, each foot makes contact with the ground twice. Since we wish to trigger a sound whenever a foot touches the ground, this means we will need to register four callback keys to play four footstep sounds at different times.

Following the CallbackCount property is the actual callback key definitions list. Each property should use the format Callback[*N*].*Value* where *N* is the index of the callback key that we are defining for that particular animation set. That is, the indices are local to the section. *Value* should be replaced with the name of the property we are defining.

Each callback key should have at least two properties in common regardless of what type it is. It should have a Ticks property which describes where in the periodic timeline of the animation set this key should be triggered and an Action property which describes what type of callback key definition it is. Currently, we have only defined one type of callback key definition called PLAY_SOUND, but you can define you own custom callback key types and develop the objects to parse and handle them.

A PLAY_SOUND callback definition encapsulates the registration of a sound event with an animation set. However, we can assign multiple sound effects to this callback key. For example, for each of our callback keys we have defined four wave files to be played. This allows us to either cycle through this sound list each time the callback key is triggered or we can allow our sound playing object to choose one from the list at random. You will notice that for our first callback key definition we specify the names of four wave files. These represent four slightly different sound effects of a foot hitting the ground. We also set the play mode to RANDOM so that we know we can just choose any wave file from the list when this callback key is triggered. You will notice that each of the four keyframes is set up the same way. Having multiple sound effects for a single key really helps in this case. If we had just a single footstep sound it would be very repetitive and would produce a 'Thud Thud Thud Thud' sound as the player walks. Because each key when triggered will be choosing a footstep sound to play at random we get a non-repetitive footsteps sound like 'Thud Crunch Stomp Thud Stomp Crunch Crunch'. The end result is much more pleasing because it sounds like the player is walking over an uneven terrain with many different materials underfoot. The other option for this value is CYCLE, which means we wish to step through the list in order every time the callback key is triggered (with wraparound back to the top of the list when all sounds have been played).

As you can see, if the callback key definition is of type PLAY_SOUND then the PlayMode, SampleCount, and SampleList properties are also expected to be defined. If you wish to register a single sample then just set sample count to 1 and list only one wave file for that key.

Now that we know how our data is laid out in the .cbd file, let us have a look at the methods of the IActionData interface and discuss there parameter lists.

The IActionData Interface

```
virtual HRESULT CreateCallback(          ULONG Index,
                                         LPVOID pContext,
                                         LPCTSTR strActorFile,
                                         void * pCallbackData,
                                         LPD3DXKEYFRAMEDANIMATIONSET pAnimSet,
                                         D3DXKEY_CALLBACK * pKey ) = 0;
```

The IActionData interface is the base class for objects which encapsulate callback key actions (e.g., playing a sound). The CreateCallback function will be called to extract the information for a given key as each IActionData derived object encapsulates the data for a single callback key. That is, it is an object of this type that will have its pointer stored along with the callback key in the animation set and will contain the information that must be triggered when the callback is executed.

The CreateCallback method will be called by the CScene::CollectCallbacks method whenever it wishes to create a new callback key. It will create a new IActionData derived object and call this method for a given animation set, passing in the index of the callback key. This index is used by our derived object to know which callback key we should extract the information from the .cbd file for. If Index was set to 2, the IActionData object should extract and encapsulate the information for the second callback key for the animation set passed (as the fifth parameter). As the second parameter, context data can also be

passed. This is always a pointer to the CScene object in our demo applications. As the third parameter the name of the actor is passed and as the fourth parameter the name of the .cbd file is passed (in our example, but this can be whatever context data was passed into the LoadActorFromX function). As the fifth parameter we pass in the animation set whose callback key we wish to create. The final parameter is a pointer to a D3DXKEY_CALLBACK structure that will eventually store a pointer to this IActionData derived object before being registered with the set.

```
virtual HRESULT HandleCallback( UINT Track, CActor * pActor ) = 0;
```

The HandleCallback function is not called during callback registration (inside CScene::CollectCallbacks); it is called inside the callback handler function when the callback key is triggered. The callback handler will be passed a pointer to the IActionData derived object. The object is expected to know what it has to do. For example, if our object is a sound player object, then it should know that when its HandleCallback function is called, it should play that sound without having to burden the CScene object with the responsibility (as we did previously). We will see this function being used later when we look at the code to the callback handler.

In our project we derive a class called CSoundCallback from IActionData. It is used to encapsulate a single callback key's sound data. In our example, that means we will create four callback keys for our Walk_Legs_Only animation set and each will store the address of a CSoundCallback object as its context pointer. We will look at the code to this object in a moment, but for now just know that its CreateCallback method will extract and load the sound data from the .cbd file for the given callback key that it represents and its HandleCallback function will know how to pick a random sound from the list and play it.

At this point, we can get some clarity by looking at the new implementation of the CScene::CollectCallbacks function. Remember, this function is called from an actor just after its animation data has been loaded. It will be called once for each animation set, allowing this function a chance to add some callback keys to it. The final parameter to this function is a D3DXKEY_CALLBACK array that was allocated by the actor. You simply store any callback keys you would like to register in this array and on function return, the actor will clone the animation set and add the callback keys you specified to the set.

```
ULONG CScene::CollectCallbacks(  LPVOID pContext,
                                 LPCTSTR strActorFile,
                                 void * pCallbackData,
                                 LPD3DXKEYFRAMEDANIMATIONSET pAnimSet,
                                 D3DXKEY_CALLBACK pKeys[] )
{
    IActionData * pData  = NULL;
    LPTSTR strDefinition = (LPTSTR)pCallbackData;
    LPCTSTR strSetName   = pAnimSet->GetName();
    ULONG CallbackCount, i, KeyCount = 0;
    TCHAR strBuffer[128], strKeyName[128];

    // Retrieve the number of callbacks defined
    CallbackCount = GetPrivateProfileInt( strSetName, _T("CallbackCount"),
                                          0,
                                          strDefinition );
```

```
    if ( CallbackCount == 0 ) return 0;
```

The first thing this function does is cast the pCallbackData to a string as this will contain the name of the .cbd file that was passed by the application into the CActor::LoadActorFromX function. It is stored in the strDefinition local variable. It then fetches the name of the passed animation set so that it can be determined whether this function is currently being called for a set we have any interest in registering callback keys for. We then try and retrieve the CallbackCount property for the section in the file that matches the name of the current animation set we are processing. If there is no definition for this animation set then zero will be returned by default and we can exit.

At this point, if CallbackCount is non-zero it means there was a section defined in the file for the current animation set we are processing.

In the next section of code we loop through the number of callback key definitions contained in the .cbd file for the current animation set we are processing. For each one, we first grab the value of its Ticks property. Since this is a float, we have to read it in as string and then use sscanf to convert. Notice how we store the extracted periodic position (Ticks) in the Time member of the current element in the passed D3DXKEY_CALLBACK array. KeyCount is a local variable that was initialized to zero at the top of the function and is incremented every time we fill in a new structure in this array.

```
    // Loop through each of the callbacks specified
    for ( i = 0; i < CallbackCount; ++i )
    {
        // Retrieve the 'time' for this particular callback
        _stprintf( strKeyName, _T("Callback[%i].Ticks"), i );

        GetPrivateProfileString( strSetName,
                                 strKeyName, _T("0.0"),
                                 strBuffer,
                                 127,
                                 strDefinition );

        // Scan directly into key time
        sscanf( strBuffer, _T("%g"), &pKeys[ KeyCount ].Time );
```

The next bit is interesting. We extract the Action property of the current callback key definition which allows us to determine what type of callback key this represents. As we currently only support keys of type PLAY_SOUND, if it is not of the correct type we skip it. However, if it is a PLAY_SOUND key definition, we create a new CSoundCallback object.

```
        // Retrieve the 'action' type for this particular callback
        _stprintf( strKeyName, _T("Callback[%i].Action"), i );
        GetPrivateProfileString(    strSetName,
                                    strKeyName,
                                    _T(""),
                                    strBuffer,
                                    127,
                                    strDefinition );

        // What type of callback is this
```

```
        if ( _tcsicmp( strBuffer, _T("PLAY_SOUND") ) == 0 )
            pData = new CSoundCallback( GetGameApp()->GetSoundManager() );
        else
            continue;

        // Validate
        if ( !pData ) continue;
```

We have not looked at the code to the CSoundCallback class yet, but this is our object derived from IActionData that will encapsulate the loading and playing of sound keys. Note that as the sole parameter to its constructor we pass in a pointer to the application's CSoundManager. The CSoundCallback class will need access to the sound manager so that it can create and play CSound objects.

At this point, we have created the new CSoundCallback object for the current key, so we next call its CreateCallback function. This function will extract all the sound information from the .cbd file for the current key and create CSound objects for each sound. They will be stored in a global array of sounds that can be played for this key. Notice that we pass in loop variable 'i' so that it knows the index of the key it needs to extract the data for. If 'i' was set to 2, it would know that it must extract the properties of the second key definition in the file for the current animation set being processed. Also note that the final parameter is the address of the callback key element in the passed array where this object will eventually have its pointer stored. We do not use this parameter in our CSoundCallback::CreateCallback function, but it is useful to have access to it for any custom objects you might develop later.

```
        // Allow the callback to initialize itself
        if (FAILED(pData->CreateCallback( i,
                                          pContext,
                                          strActorFile,
                                          pCallbackData,
                                          pAnimSet,
                                          &pKeys[ KeyCount ] ) ) )
        {
            delete pData;
            continue;

        } // End if failed to create callback
```

At this point the CSoundCallback object will have been created for the current callback key being processed. It will contain an array of CSound objects which can be played at random when the key is triggered.

All that is left to do at the bottom of the loop is store a pointer to this CSoundCallback object in the callback key array and increase the callback key count. When this callback key is triggered, the callback handler will be passed a pointer to this CSoundCallback object. The handler can then issue a call to the CSoundCallback::HandleCallback function which will instruct the object to select a CSound object at random from its internal array and play it.

```
        // Store in the key's data area
        pKeys[KeyCount].pCallbackData = (LPVOID)pData;

        // We've successfully added a key
```

```
        KeyCount++;

    } // Next Callback

    // Return the total number of keys created
    return KeyCount;
}
```

We have seen how simple the CScene::CollectCallbacks function is. Most of the heavy lifting has been placed inside the CSoundCallback object so let us have a look at the code to this object next.

The CSoundCallback Class

The CSoundCallback class encapsulates all the data for a single PLAY_SOUND callback key. It is defined in CScene.h as shown below. We have snipped the list of functions from the listing to compact listing size. We already know the five methods it exposes: AddRef, Release, and QueryInterface inherited from IUnknown and CreateCallback and HandleCallback inherited from IActionData. Here we see the list of its member variables and structures followed by a description of each.

Excerpt from CScene.h

```
class CSoundCallback : public IActionData
{
public:

    enum PlayStyle { PLAY_LOOPING = 0, PLAY_ONCE = 1 };

    … Snip… (Functions)

private:
    struct SampleItem
    {
        TCHAR   FileName[512];          // Filename for the loaded sample
        CSound *pSound;                 // The actual sound object.
    };

    ULONG           m_nRefCount;        // Reference counter
    bool            m_bRandom;          // We should pick a random sample
    ULONG           m_nSampleCount;     // Number of samples stored
    ULONG           m_nNextPlayIndex;   // Which sample did we last play?
    SampleItem    * m_pSamples;         // The array which stores all the samples loaded.
    CSoundManager * m_pSoundManager;    // The sound manager specified by our application
};
```

ULONG m_nRefCount

This variable holds the current reference count of the object. Our CSoundCallback object must implement the same reference counting mechanism as a COM object so that the actor can safely release this object using the IUnknown::Release method. This is important because, although a pointer to this object will be stored in the callback key, it will be stored as a void pointer and the actor has no idea what sort of object it is or how to delete it. As long as the actor can rely on the fact that the object stored in each callback key is derived from IUnknown, it can cast the void pointer to an IUnknown pointer and instruct the object to destroy itself.

bool m_bRandom
This boolean will be set to true if this CSoundCallback object has been placed into random playlist mode. When in random mode, every time this object's HandleCallback method is called it will randomly select a sample to play from its internal array. We saw when we examined the contents of the .cbd file that each of our four keys were set to random mode. Therefore, the four CSoundCallback objects that we create will each have this variable set to true.

ULONG m_nSampleCount
This contains the number of sampled sounds this object stores in its internal sound list. It describes the number of SampleItem structures in the array discussed below. For each of the CSoundCallback objects we create in our demo this value will be set to 4 because each callback key definition in the .cbd file has four wave file sounds associated with it.

SampleItem * m_pSamples
This is an array of SampleItem structures. Each element in the array contains the name of the sound file that is stored there and a pointer to the CSound object that was created for that sound.

```
struct SampleItem
{
    TCHAR   FileName[512];    // Filename for the loaded sample
    CSound *pSound;           // The actual sound object.
};
```

In a moment we will take a look at the CSoundCallback::CreateCallback function, which is called just after the object is instantiated in CScene::CollectCallbacks (shown earlier). This function extracts the wave file names from the passed .cbd file and uses the application's CSoundManager object (passed in the constructor) to create a CSound object for each wave file listed. These pointers are then stored in this array along with the original name of the sound file (taken from the .cbd file). It is this list that we choose a sound effect to play from each time the key is triggered and the object's HandleCallback function is called. We will see this array having its contents created when we look at the CreateCallback method in a moment.

ULONG m_nNextPlayIndex
This value is used only if the object is placed into CYCLE mode. It stores the index of the current position in the sound list so we know which sound to play next when the HandleCallback method is called. This value will start of at zero and be incremented every time the HandleCallback method is called and a sound is played. When this value reaches the end of the list it will be wrapped back around to zero so we start playing sounds from the start of the list again.

CSoundManager *m_pSoundManager
In this member we store a pointer to the CSoundManager object which will be used to create CSound objects. This pointer must be passed into the constructor as we saw earlier when the object was being created in the CScene::CollectCallbacks function (we passed in the CGameApp's CSoundManager object pointer).

Let us now look at the methods of the CSoundCallback object, which are all very simple.

CSoundCallback::CSoundCallback

We already saw the constructor being called from the CScene::CollectCallbacks function. It is passed the application's CSoundManager pointer which it stores in a member variable. It also switches the object's playlist into CYCLE mode (random=false) by default and sets the sample array pointer to NULL. We also set the initial reference count of the object to 1.

```
CSoundCallback::CSoundCallback( CSoundManager * pSoundManager )
{
    // Setup default values
    m_pSoundManager     = pSoundManager;
    m_bRandom           = false;
    m_pSamples          = NULL;
    m_nSampleCount      = 0;
    m_nNextPlayIndex    = 0;

    // ************************************
    // *** VERY IMPORTANT
    // ************************************
    // Set our initial reference count to 1.
    m_nRefCount = 1;

}
```

Notice how we also set the play index to zero so that the first sound to be played in cycling mode will be the first one loaded into the sample array.

CSoundCallback::~CSoundCallback

The destructor is also very simple. Its main task is to release its array of SampleItem structures if it exists. Keep in mind that each structure in this array will store a pointer to a CSound object, so we must release that too.

```
CSoundCallback::~CSoundCallback( )
{
    ULONG i;

    // Release any memory
    if ( m_pSamples )
    {
        for ( i = 0; i < m_nSampleCount; ++i )
        {
            // Delete the sound object if it exists.
            if ( m_pSamples[i].pSound ) delete m_pSamples[i].pSound;
        } // Next Sample

        delete []m_pSamples;

    } // End if samples loaded

    // Clear variables
    m_bRandom           = false;
```

```
    m_pSamples          = NULL;
    m_nSampleCount      = 0;
    m_nNextPlayIndex    = 0;
}
```

CSoundCallback::CreateCallback

This is the function where all of our object initialization happens. It is called from the CScene::CollectCallbacks function when it is determined that there is a callback key definition in the .cbd file for the current animation set being processed. When this function is called it is passed the index of the callback key inside the .cbd file that this object is to encapsulate. For example, if the Index parameter passed was 4 and the fifth parameter was a pointer to an animation set with the name 'Walk_Legs_Only', that would mean this object is to fetch the data for the fourth callback key in the .cbd section called [Walk_Legs_Only]. The function is also passed the callback function context data. This is an arbitrary data pointer that is registered with the actor at the same time the callback function itself is registered. We always store the CScene pointer along with the callback function so that the static CScene::CollectCallbacks function can access the non-static members of the object instance. The function is also passed a string containing the name of the actor that is having the callback keys registered and an additional context data pointer called pCallbackData. This is the pointer we send into the LoadActorFromX function which (in our application) contains the name of the .cbd file that we want the CollectCallbacks function to use. A pointer to the interface of the animation set currently requesting callback key registration is also passed. The final parameter is a pointer to the D3DXKEY_CALLBACK structure that will eventually store a pointer to this CSoundCallback object.

This function must extract the data from the .cbd file and create a new CSound object for each sound file listed for this key. These CSound objects are then stored in the SampleItem array so that they can be played when the key is triggered by the animation system. Here is the first section of code.

```
HRESULT CSoundCallback::CreateCallback(   ULONG Index,
                                          LPVOID pContext,
                                          LPCTSTR strActorFile,
                                          void * pCallbackData,
                                          LPD3DXKEYFRAMEDANIMATIONSET pAnimSet,
                                          D3DXKEY_CALLBACK * pKey )
{
    LPTSTR strDefinition = (LPTSTR)pCallbackData;
    LPCTSTR strSetName   = pAnimSet->GetName();
    TCHAR strBuffer[128], strKeyName[128];
    ULONG i;

    // Random or cycle sample playlist?
    _stprintf( strKeyName, _T("Callback[%i].PlayMode"), Index );

    GetPrivateProfileString(  strSetName,
                              strKeyName,
                              _T("CYCLE"),
                              strBuffer,
                              127,
                              strDefinition );
```

```
    if ( _tcsicmp( strBuffer, _T("RANDOM") ) == 0 ) m_bRandom = true;
```

Notice that we store the name of the .cbd file (pCallbackData) in the strDefinition local variable and store the name of the animation set in the strSetName local variable. We then fetch the play mode for the current key. The name of the key is built by substituting the Index parameter into the string "Callback[Index].Playmode". Remember, Index is the local index of the key we are fetching for a given animation set. We then use the GetPrivateProfileString method to fetch this property. The parameters specify that we want to retrieve a property from a section with a name that matches the name of the animation set, with a key name of 'Callback[*n*].PlayMode' where *n* is the current index of the callback key. If the property is not found, a default string of "CYCLE" will be returned, placing the object into non-random mode. As the final parameter we pass in strDefinition, which now contains the name of the .cbd file we wish to extract the data from.

When the function returns, the strBuffer array should contain the value of this property (either RANDOM or CYCLE). If it contains the word "RANDOM", then the m_bRandom boolean property of the object is set to true, placing the object into random playlist mode.

In the next section we fetch the sample count of the current key and allocate the object's array of SampleItem structures to hold that many samples.

```
    // Retrieve the number of samples we're using
    _stprintf( strKeyName, _T("Callback[%i].SampleCount"), Index );

    m_nSampleCount=GetPrivateProfileInt(strSetName, strKeyName, 0,strDefinition );
    if ( m_nSampleCount == 0 ) return E_INVALIDARG;

    // Allocate enough space for the sample data
    m_pSamples = new SampleItem[ m_nSampleCount ];
    if ( !m_pSamples ) return E_OUTOFMEMORY;

    // Clear out array.
    ZeroMemory( m_pSamples, m_nSampleCount * sizeof( SampleItem ) );
```

Now we will set up a loop that will fetch the name of each sample from the file and will store it in the SampleItem array. We will then pass this filename to the CSoundManager::Create method so that it can create a CSound object for the respective sound file. Notice how the m_pSamples[i].pSound pointer is passed as the first parameter to the Create method so that on function return, the new CSound object created will have its pointer stored in the correct place in the sample array.

```
    // Loop through and retrieve the items
    for ( i = 0; i < m_nSampleCount; ++i )
    {
        // Retrieve sample filename
        _stprintf( strKeyName, _T("Callback[%i].Sample[%i].File"), Index, i );

       GetPrivateProfileString(     strSetName,
                                    strKeyName,
                                    _T(""),
                                    m_pSamples[i].FileName,
```

```
                                    511,
                                    strDefinition );

        // Attempt to load the sound
        m_pSoundManager->Create( &m_pSamples[i].pSound, m_pSamples[i].FileName );

    } // Next Sample

    // Success!
    return S_OK;
}
```

So far we have covered all the steps involved in storing our CSoundCallback pointers in the callback keys for a given animation set. In summary:

1. The COLLECTKEYS callback function is registered with actor prior to load call.
2. Call to LoadActorFromX is passed a context pointer that will be passed to the callback function registered in step 1.
3. After the actor has loaded the animation data it will loop through each loaded animation set and call the callback function, passing it the context data pointer passed to the actor in step 2. We use this to pass a .cbd filename to the function (in our lab project).
4. The callback function is called by the actor to provide any callback keys for the current animation set being processed. This function opens the .cbd file to see if there is a section specific to the current animation for which the callback function in being invoked. If a section exists with the same name as the animation set, it knows there must be callback keys to set up.
5. For each key definition for a given animation set, a CSoundCallback object is created and the CSoundCallback::Create method is called to build its internal playlist of CSound objects.
6. The CSoundCallback object pointer, along with the Ticks value of that key (extracted from the cbd file), is stored in a D3DXKEY_CALLBACK structure and placed in the callback key array that is returned to the actor.
7. The actor will clone the animation set to create a new one with the desired keys.

At this point then, our actor will be fully created and each animation set that we desire will have their respective callback keys defined. The callback keys themselves store a pointer to a CSoundCallback object which is passed to the callback handler function when the key is triggered. The callback handler function can then simply call the CSoundCallback::HandleCallback method which will instruct it to pick and play a new sound. Let us have a look at the HandleCallback method next.

CSoundCallback::HandleCallback

This function has a very simple job. It will be called by the callback handling function every time the callback key is triggered. It has to decide which sound to play from its play list (based on its mode of operation) and play that sound.

The Handle Callback function accepts two parameters, although this particular object's implementation of the function uses neither of them. However, the parameter list laid out in the base interface dictates that this function should be passed the index of the track on the controller from which the callback key is

being triggered and a pointer to the actor who is currently using that controller. Although this function is very simple and has no need for these parameters, you can certainly imagine how your own callback key objects (derived from IActionData) may well need them. For example, you might use the track index to fetch the weight of the track that triggered the key. Perhaps a sound is only played if the weight is high enough. We might imagine for example that we want to trigger a sound for the arms when moving up into the gun position (a gun reload sound perhaps). However, the shooting pose is a single frame set and as such, we can not just register a sound with it as it will repeat for as long as the character is holding his gun to his shoulder. One way around this would be to fetch the weight of the track and only trigger the reload sound if the weight was between say 0.5 and 0.6. This would mean his arms are roughly 50% of the way through the transition into the shooting pose. Although this is not a great example, it demonstrates why having the track index can be useful. Of course, having the track by itself is not useful at all if we have no idea which animation controller this track index is related to. Therefore, a pointer to an actor is passed so that the function can retrieve its controller's track properties.

In our case the function is simple -- we just wish to play a sound. If the m_bRandom boolean variable is set to true then we generate a random index into the SampleItem array. If not, then we are in cycle mode and the m_nNextPlayIndex variable will hold the index of the next sound to play (0 initially). We use our index to access the SampleItem array and call the Play method of the CSound object that is stored there. Here is all of the code:

```
HRESULT CSoundCallback::HandleCallback( UINT Track, CActor * pActor )
{
    ULONG PlayIndex;

    // Select item from 'play list'
    if ( m_bRandom )
        PlayIndex = rand() % m_nSampleCount;
    else
        PlayIndex = m_nNextPlayIndex;

    // Play the sample if it's valid
    if ( m_pSamples[PlayIndex].pSound ) m_pSamples[PlayIndex].pSound->Play( );

    // Cycle the next play index
    m_nNextPlayIndex++;
    m_nNextPlayIndex %= m_nSampleCount;

    // Success!
    return S_OK;
}
```

Notice that after the sound has been played, the m_nNextPlayIndex variable is incremented and wrapped around to zero if it exceeds the maximum sample count.

That covers the code for the CSoundCallback object. This class also has AddRef, Release, and QueryInterface methods, but you should be very comfortable with these types of functions by now, so will not show or discuss their implementation again here.

Updating CActionHandler

In Chapter Ten we learned how to use the callback handler features of the D3DXAnimationController. In short, we had to derive a class from the ID3DXAnimationCallbackHandler abstract base class. This base interface specified a single method that must be implemented in the derived class, called HandleCallback. We pass an instance of this object to the AdvanceTime method and the HandleCallback method will be invoked whenever a callback key is triggered. Nothing much has changed in this project except that now our CActionHandler class has an added CActor member pointer and an extra method to set it. Here is our updated CActionHandler object:

Except from CScene.h

```
class CActionHandler : public ID3DXAnimationCallbackHandler
{
public:
    CActionHandler( );

    STDMETHOD(HandleCallback)(THIS_ UINT Track, LPVOID pCallbackData);

    // CActionHandler
    void SetCurrentActor( CActor * pActor );

private:
    CActor * m_pActor;  // Storage for the actor that is currently being advanced
};
```

Why have we added the actor pointer? As we discussed earlier, when a callback key is triggered, the CActionHandler::HandleCallback method will be called by the controller and passed the index of the track that triggered the event. We are also passed a void pointer to the individual key's context data (which in our case will be a pointer to the CSoundCallback object for that key). This function can then simply call the CSoundCallback object's HandleCallback method because, as we have seen, it is this method which takes care of actually playing the sound. Below we show our implementation of the CActionHandler::HandleCallback function. Remember, it is this method that is called by the D3DXAnimationController when its parent object is passed into the AdvanceTime call. If we take a look at the HandleCallback method of this object it will become clear why that actor pointer is needed.

CActionHandler::HandleCallback

Below we see all of the code to the handling function that is called by the controller when a callback key is triggered. It simply casts the passed data pointer to an IUnknown pointer and then uses its QueryInterface method to make sure it is a pointer to an IActionData derived object. Once we have an IActionData pointer, we can call its HandleCallback method. In the case of our CSoundCallback object, it will choose a sound to play from its list of sounds. Notice however that the IActionData::HandleCallback function expects to be passed a pointer to an actor; information that is not provided by the animation controller. We need the current actor being updated stored in the handler

object so that the track ID we are passed actually means something. Without us knowing what controller spawned the callback, the track index is useless to us.

```
HRESULT CActionHandler::HandleCallback( UINT Track, LPVOID pCallbackData )
{
    IUnknown    * pData   = (IUnknown*)pCallbackData;
    IActionData * pAction = NULL;

    // Determine if this is in a format we're aware of
    if ( FAILED( pData->QueryInterface( IID_IActionData, (void**)&pAction )))
        return D3D_OK; // Just return unhandled.

    // This is our baby, lets handle it
    pAction->HandleCallback( Track, m_pActor );

    // Release the action we queried.
    pAction->Release();

    // We're all done
    return D3D_OK;
}
```

So, we need to place an additional function call in our CScene::AnimateObjects function. Prior to calling AdvanceTime and passing in the handler object, it will call the handler object's SetCurrentActor method. Below we show the CScene::AnimateObjects method with this additional function call highlighted in bold.

```
void CScene::AnimateObjects( CTimer & Timer )
{
    ULONG i;
    static CActionHandler Handler;

    // Process each object for coll det
    for ( i = 0; i < m_nObjectCount; ++i )
    {
        CObject * pObject = m_pObject[i];
        if ( !pObject ) continue;

        // Get the actor pointer
        CActor * pActor = pObject->m_pActor;
        if ( !pActor ) continue;
        if ( pObject->m_pAnimController )
             pActor->AttachController( pObject->m_pAnimController,
                                       false,
                                       pObject->m_pActionStatus );

        // Set this actor in the handler so the callbacks have access to it
        Handler.SetCurrentActor( pActor );

        // Advance time
        pActor->AdvanceTime( Timer.GetTimeElapsed(), false, &Handler );

    } // Next Object
}
```

As you can see, we create a handler object on the stack at the top of the function and pass the same object into the AdvanceTime call for each actor. Therefore, before we call AdvanceTime, we set the handler's actor pointer to the current actor we are processing so that when the callback handler is called by the controller, it has access to the actor from which it was triggered. The callback function then has the ability to query the actor to find out the state of its controller and the track index passed in becomes useful.

That concludes our coverage of the updated callback key system. Hopefully you will find it relatively straightforward to use. In the absence of a proper application sound manager, it provides us a fair bit of flexibility for such a small amount of effort.

Application Framework Upgrades

We are approximately halfway through the course at this point. Moving forward we will spend the remainder of the course discussing topics less related to the DirectX API and more related to general games programming. So before we do that, we will use Lab Project 12.2 to make some changes to existing classes to make our framework more usable in future lessons. We will also upgrade our framework's IWF code to provide more comprehensive support for the various entity types exported from GILES™. This will allow us to consolidate many of the topics and techniques we have learned about so far in the entire series. Our application framework will soon support heightmap based terrains, actors, and static scenes, all within our CScene class. We will also add support for the loading of fog parameters from IWF files and the rendering of the scene using those fog parameters. From here on in, our application framework should be able to load and render most IWF files exported from GILES™ that we care to throw at it, even if that IWF file contains multiple terrain entities, external references to animated X files, and static geometry.

A Modular Approach to Querying Supported Texture Formats

In previous applications our CGameApp class would query the support of texture formats that its various components would need. The querying was done in CGameApp::TestDeviceCaps which was called at application startup from the CGameApp::InitInstance method. For example, if the terrain class needed an alpha texture format for its water plane, the test for a suitable alpha format was performed by CGameApp and the resulting format was passed to the terrain object for storage. It could then create textures using this format when the terrain was being initialized. Likewise, if the scene required support for compressed textures, the CGameApp::TestDeviceCaps function would have to be modified to test for a suitable compressed texture format, which would then be passed to the scene object for storage and texture creation during scene initialization. This approach served us fairly well when we are only plugging a few components into our framework, but as we start plugging in more components which may each have different texture needs, it becomes cumbersome.

Rather than having to alter the code to our CGameApp class every time we plug in a new component that requires a texture format we have not previously provided support for, it would be much nicer if the component itself could intelligently chose which format it wants to use to complete its task. However,

we do not want each component to have to duplicate the device tests that are done in the CGameApp::TestDeviceCaps method.

The solution we provide in this lab project, which will be used in all future projects, introduces a new class called CTextureFormatEnum. This class contains a list of all texture formats that are supported by DirectX paired with a boolean value indicating whether or not this texture format is supported by the current device.

The CGameApp object will contain a member of this type and in the TestDeviceCaps method it will now simply call the CTextureFormatEnum::Enumerate method. This method will loop through every DirectX supported format and test for device compliance. When this function returns, the CTextureFormatEnum will contain a 'true' or 'false' property paired with each possible texture format.

There is nothing too clever about this, but what this new class also has are methods that allow any object to say things like "Give me the best compressed texture format with an alpha channel". The object will have logic that will loop though each supported format and return the best one that matches the criteria.

Rather than each component that we plug into framework (CScene, CTerrain etc) having to be passed supported texture formats by the CGameApp class, the CGameApp object will essentially just call this object's Enumerate method to allow us to find which formats are supported. Each component we plug in to our framework can then simply be passed a pointer to this CTextureFormatEnum object so that the component can query its method to retrieve the formats it desires. The CGameApp class no longer has to be continually edited and extended to support more formats every time we plug in a new component with different texture needs. Instead, we just make sure that CGameApp calls the SetTextureFormat method for the component and passes in a pointer to this texture format enumeration object. We will have to make sure that all the components (e.g., CTerrain, CScene, etc.) have a function of this type and the ability to store a pointer to the enumeration object.

If you look at the CGameApp class, it now has a new member as shown below:

Excerpt from CGameApp.h

```
CTextureFormatEnum      m_TextureFormats;
```

This new member is an instance of the type of the new class we are about to create. Looking inside the CGameApp::TestDeviceCaps method we can see that it no longer performs any texture format queries on the device; instead it simply calls the Enumerate method of this new object.

Excerpt From CGameApp::TestDeviceCaps

```
ULONG      Ordinal = pSettings->AdapterOrdinal;
D3DDEVTYPE Type    = pSettings->DeviceType;
D3DFORMAT  AFormat = pSettings->DisplayMode.Format;

// Enumerate texture formats the easy way :)
if ( !m_TextureFormats.Enumerate( m_pD3D, Ordinal, Type, AFormat )) return false;
```

We will cover all the code to the CTextureFormatEnum object in a moment. For now, just know that by calling its Enumerate method and passing in the current device, the adapter ordinal, the type of device

(HAL for example) and the current adapter format, the object will have its internal data filled with a list of supported formats.

At this point, any component with a pointer to this object can use its methods to ask for supported formats. The following code snippet is taken from the CGameApp::BuildObjects function and shows the pointer to this object being passed to the CScene object for storage.

```
m_Scene.SetTextureFormat( m_TextureFormats );
m_Scene.LoadSceneFromIWF( m_strLastFile, LightLimit )
```

Notice how we call the SetTextureFormat method before calling the loading function. This allows the scene to use this object to query for supported texture formats during the loading process. What is also nice is that the scene object can pass this pointer to any of its components (e.g., CTerrain objects) so that they too can use the object to query texture formats independently.

Because the scene object now has a pointer to the CTextureFormatEnum object, whenever it needs to create a texture, it can just call the object's GetBestFormat method to return the most desirable format for the current device.

Below we see a line of code from the CScene::CollectTexture function, which we use to load all the scene's textures. In this example, the GetBestFormat method is being used with no parameters. This means it will use the default logic when choosing the best format -- finding the best non-alpha compressed texture format. There will also be a version of this function that allows you to override this logic by specifying request parameters

Excerpt from CScene::CollectTexture

```
D3DXCreateTextureFromFileEx( pScene->m_pD3DDevice,
  Buffer,
  D3DX_DEFAULT, D3DX_DEFAULT,
  3, 0,
  pScene->m_TextureFormats.GetBestFormat(),
  D3DPOOL_MANAGED,
  D3DX_DEFAULT,
  D3DX_DEFAULT,
                              0,
  NULL,
  NULL,
  &pNewTexture->Texture );
```

Notice how easy it is for a component to fetch the best compatible format now.

The CTextureFormatEnum Object

The declaration and code for this class are stored in the files 'CTextureFormatEnum.h' and 'CTextureFormatEnum.cpp' respectively. Below we see the class declaration minus its methods to compact the listing. We will discuss its methods and the code they contain in a moment.

Excerpt from CTextureFormatEnum.h

```
typedef std::map<D3DFORMAT, bool> FormatEnumMap;

class CTextureFormatEnum
{
public:
    …
    …
    // Methods not Shown here
    …
    …
    FormatEnumMap   m_TextureFormats;       // Formats
    bool            m_bPreferCompressed;    // Compressed Texture Bias Mode
    bool            m_bAlpha;               // Should we query alpha formats only?
};
```

The class has three member variables. The last two are simply booleans that contain the default mode of the query methods (discussed in a moment). That is, if m_bAlpha is set to true then when we ask the object to return the best supported format, it will prefer one with alpha if it exists and return that. Likewise, if the m_bPreferCompressed boolean is set to true, the query methods will favor compressed formats. The states of these booleans can be set and retrieved via simple member functions. They can also be overridden by passing parameters into the query functions. Having these defaults just provides a nice way for the application to set the most common parameters that will be required so that it can call the parameterless version of GetBestFormat when it wants to fetch a compatible texture format.

The top-most member is of type FormatEnumMap. This is a typedef for an STL map object that stores a D3DFORMAT and a boolean in key/value pairs. For those of you a little rusty with maps, a map is a way for us to essentially build a table of key-value pairs (like a dictionary). We might imagine that an array is like a linear map where the keys are the array indices and the values are stored in those elements. However, in a map, the keys can be anything you like (floats, strings, or even entire structures). Internally, maps are stored as binary trees, which makes the searching for a key/value pair very quick indeed.

So why are we using a map? We are using map because each key will be a D3DFORMAT structure and the value associated with that key will be a Boolean that is set to true or false depending on whether the format is supported. This allows our object, for example, to record support for the X8R8G8B8 texture format as shown below.

```
m_TextureFormats[ D3DFMT_X8R8G8B8 ] = true;
```

With that in mind, let us examine the code to our new CTextureFormatEnum object.

CTextureFormatEnum::CTextureFormatEnum

The constructor is simple. The default behavior is to prefer compressed formats over non-compressed ones and to prefer non-alpha formats unless an alpha format is explicitly requested when the query is performed. In the final step, the constructor calls the Init method of the object which initializes the STL map of texture formats so that nothing is initially supported until the Enumerate method is called.

```
CTextureFormatEnum::CTextureFormatEnum()
{
    // Setup any required values
    m_bPreferCompressed = true;
    m_bAlpha            = false;

    // Initialize the class
    Init();
}
```

CTextureFormatEnum::Init

This function first empties the STL map by calling its Clear method. At this point there will be no key/value pairs in the map. We then add the keys for each possible texture format. We use a default value of false since we have not yet queried any of these formats on the device to test for support.

```
void CTextureFormatEnum::Init()
{
    // First clear the internal map if it's already been used.
    m_TextureFormats.clear();

    // Setup each of the map elements
    m_TextureFormats[ D3DFMT_R8G8B8        ] = false;
    m_TextureFormats[ D3DFMT_A8R8G8B8      ] = false;
    m_TextureFormats[ D3DFMT_X8R8G8B8      ] = false;
    m_TextureFormats[ D3DFMT_R5G6B5        ] = false;
    m_TextureFormats[ D3DFMT_X1R5G5B5      ] = false;
    m_TextureFormats[ D3DFMT_A1R5G5B5      ] = false;
    m_TextureFormats[ D3DFMT_A4R4G4B4      ] = false;
    m_TextureFormats[ D3DFMT_R3G3B2        ] = false;
    m_TextureFormats[ D3DFMT_A8            ] = false;
    m_TextureFormats[ D3DFMT_A8R3G3B2      ] = false;
    m_TextureFormats[ D3DFMT_X4R4G4B4      ] = false;
    m_TextureFormats[ D3DFMT_A2B10G10R10   ] = false;
    m_TextureFormats[ D3DFMT_A8B8G8R8      ] = false;
    m_TextureFormats[ D3DFMT_X8B8G8R8      ] = false;
    m_TextureFormats[ D3DFMT_G16R16        ] = false;
    m_TextureFormats[ D3DFMT_A2R10G10B10   ] = false;
    m_TextureFormats[ D3DFMT_A16B16G16R16  ] = false;
    m_TextureFormats[ D3DFMT_A8P8          ] = false;
    m_TextureFormats[ D3DFMT_P8            ] = false;
    m_TextureFormats[ D3DFMT_L8            ] = false;
    m_TextureFormats[ D3DFMT_A8L8          ] = false;
    m_TextureFormats[ D3DFMT_A4L4          ] = false;
```

```
    m_TextureFormats[ D3DFMT_V8U8           ] = false;
    m_TextureFormats[ D3DFMT_L6V5U5         ] = false;
    m_TextureFormats[ D3DFMT_X8L8V8U8       ] = false;
    m_TextureFormats[ D3DFMT_Q8W8V8U8       ] = false;
    m_TextureFormats[ D3DFMT_V16U16         ] = false;
    m_TextureFormats[ D3DFMT_A2W10V10U10    ] = false;
    m_TextureFormats[ D3DFMT_UYVY           ] = false;
    m_TextureFormats[ D3DFMT_R8G8_B8G8      ] = false;
    m_TextureFormats[ D3DFMT_YUY2           ] = false;
    m_TextureFormats[ D3DFMT_G8R8_G8B8      ] = false;
    m_TextureFormats[ D3DFMT_DXT1           ] = false;
    m_TextureFormats[ D3DFMT_DXT2           ] = false;
    m_TextureFormats[ D3DFMT_DXT3           ] = false;
    m_TextureFormats[ D3DFMT_DXT4           ] = false;
    m_TextureFormats[ D3DFMT_DXT5           ] = false;
    m_TextureFormats[ D3DFMT_L16            ] = false;
    m_TextureFormats[ D3DFMT_Q16W16V16U16   ] = false;
    m_TextureFormats[ D3DFMT_MULTI2_ARGB8   ] = false;
    m_TextureFormats[ D3DFMT_R16F           ] = false;
    m_TextureFormats[ D3DFMT_G16R16F        ] = false;
    m_TextureFormats[ D3DFMT_A16B16G16R16F  ] = false;
    m_TextureFormats[ D3DFMT_R32F           ] = false;
    m_TextureFormats[ D3DFMT_G32R32F        ] = false;
    m_TextureFormats[ D3DFMT_A32B32G32R32F  ] = false;
    m_TextureFormats[ D3DFMT_CxV8U8         ] = false;

}
```

This function really shows us what the object stores -- a big list of possible texture formats with a boolean describing its support status on the device. Of course, this is all changed when the Enumerate method is executed (usually the first method our application will call).

CTextureFormatEnum::Enumerate

This function is called to update the status of each key in the STL map to reflect the support offered by the device. The function is passed a pointer to the device and the adapter ordinal. It is also passed the type of device we are interested in enumerating formats for (HAL for example) and the current adapter format since this is a factor in determining what texture formats are compatible.

The first thing we do is set up an iterator to begin searching through the key/values pairs in the map. Each key/value pair of a map is accessed by the map iterator object using its ‘first’ and ‘second’ members. That is, as the iterator accesses each row of map data, its ‘first’ member will contain the key (the format itself, such as D3DFMT_X8R8G8B8) and the ‘second’ member can be used to set or retrieve the value associated with that key (the boolean status).

Once we setup the iterator to point at the first row of map data, we will loop through all the rows added in the previous function. We will then use the IDirect3DDevice9::CheckDeviceFormat function to query support for each mode and set the boolean status accordingly. At the end of this function, any modes that are supported in the map will have a ‘true’ value associated with them.

Here is the code. First we use the map's Begin method so the iterator is pointing to the first row of data. We then set up a loop that increments the iterator until the End is reached. We call the CheckDeviceFormat function for the current key and set its value to true if the function succeeds.

```
bool CTextureFormatEnum::Enumerate( LPDIRECT3D9 pD3D,
                                    ULONG Ordinal,
                                    D3DDEVTYPE DeviceType,
                                    D3DFORMAT AdapterFormat )
{
    FormatEnumMap::iterator Iterator = m_TextureFormats.begin();

    // Validate
    if ( !pD3D ) return false;

    // Loop through all texture formats in the list
    for ( ; Iterator != m_TextureFormats.end(); ++Iterator )
    {
        // Test the format
        if ( SUCCEEDED( pD3D->CheckDeviceFormat( Ordinal,
                                                 DeviceType,
                                                 AdapterFormat,
                                                 0,
                                                 D3DRTYPE_TEXTURE,
                                                 Iterator->first ) ) )
        {
            // It's supported, mark it as such
            Iterator->second = true;

        } // End if supported

    } // Next Texture Format Item

    // Success!
    return true;
}
```

CTextureFormatEnum::GetBestFormat

This function is called to retrieve the best supported format. This function (it is overloaded) accepts two parameters that allow the caller to override the default logic of the process. The two booleans are used to specify whether we consider a format with an alpha channel to be a priority and whether compressed formats are preferred over regular formats. This function returns a D3DFORMAT which can then be used to create texture surfaces on the current device.

The first section of the function shown below is the conditional code block that is executed when a compressed format is preferred.

```
D3DFORMAT CTextureFormatEnum::GetBestFormat( bool Alpha, bool PreferCompressed )
{
    // Does the user prefer compressed textures in this case?
    if ( PreferCompressed )
```

```
    {
        // Alpha is required?
        if (Alpha)
        {
            if ( m_TextureFormats[D3DFMT_DXT3] ) return D3DFMT_DXT3;
            if ( m_TextureFormats[D3DFMT_DXT5] ) return D3DFMT_DXT5;

        } // End if alpha required
        else
        {
            if ( m_TextureFormats[D3DFMT_DXT1] ) return D3DFMT_DXT1;

        } // End if no alpha required

    } // End if prefer compressed formats
```

As you can see above, if alpha is preferred we return D3DFMT_DXT3 as the most desirable format if its boolean is set to true in the map. This is a desirable compressed alpha surface because it provides several levels of alpha and it stores the alpha information explicitly. That is to say, each pixel within the texture maintains its own alpha value. If this format is not supported, we return the next best compressed alpha format: D3DFMT_DXT5. This format still provides several levels of alpha, but much of the original alpha data is lost in the compression. Alpha information is interpolated over a wider area of pixels.

Note: There was a detailed discussion of compressed texture formats in Chapter 6 of Module I.

Finally, if alpha is not required then we return D3DFMT_DXT1. This is a compressed format with no support for multiple levels of alpha. This surface only reserves a single bit for alpha information (meaning the pixel is either on or off). This is a most desirable compressed texture format if several levels of alpha are not required since it allows for greater compression (because of the missing alpha information).

That concludes the compressed texture search. The next code block is executed if alpha is required and either non-compressed textures were preferred or a suitable compressed texture could not be found in the above code. In the latter case, even if compressed alpha textures were desired, we will fall back to finding non-compressed alpha formats if the function did not return in the compressed code block.

Our logic is simple -- we are searching for the texture format with the most color and alpha resolution. For alpha requests, we are ideally looking for a 32-bit surface with 8 bits of storage for the red, green, blue, and alpha components. If this is not available, we will make a choice that might seem odd -- we will test support for the A1R5G5B5 format. While this only supports one bit of alpha, as compared to the A4R4G4B4 format which has more bits for alpha and may also be supported, in this latter mode we also only have 4 bits per RGB component. This lack of color resolution generally looks pretty bad. In all situations then, we always give higher priority to the RGB components, even if it means we are returning a texture with only one bit (on/off) of alpha. As the third alpha option we fall back to the A4R4G4B4 format

```
    // Standard formats, and fallback for compression unsupported case
    if ( Alpha )
    {
        if ( m_TextureFormats[ D3DFMT_A8R8G8B8 ] ) return D3DFMT_A8R8G8B8;
        if ( m_TextureFormats[ D3DFMT_A1R5G5B5 ] ) return D3DFMT_A1R5G5B5;
        if ( m_TextureFormats[ D3DFMT_A4R4G4B4 ] ) return D3DFMT_A4R4G4B4;

    } // End if alpha required
```

The next section of code is executed if the caller requested either a non-compressed, non-alpha format, or if a compressed non-alpha format was requested but a solution was not found in the compressed code block. Once again, you can see that we favor resolution for the RGB components in the order that we test and return supported non alpha surfaces.

```
    else
    {
         if ( m_TextureFormats[ D3DFMT_X8R8G8B8 ] ) return D3DFMT_X8R8G8B8;
         if ( m_TextureFormats[ D3DFMT_R8G8B8   ] ) return D3DFMT_R8G8B8;
         if ( m_TextureFormats[ D3DFMT_R5G6B5   ] ) return D3DFMT_R5G6B5;
         if ( m_TextureFormats[ D3DFMT_X1R5G5B5 ] ) return D3DFMT_X1R5G5B5;

    } // End if no alpha required

    // Unsupported format.
    return D3DFMT_UNKNOWN;
}
```

If the bottom line of the function is ever reached, it means we could not find a format that was supported (very unlikely) and we return D3DFMT_UNKNOWN back to the caller. The caller will then know that his request could not be satisfied.

CTextureFormatEnum::GetBestFormat (Overloaded)

The GetBestFormat function is also overloaded so that we can call it with no parameters and use the values of its m_bPreferCompressed and m_bAlpha member variables to control the searching logic. This function simply calls the version of the function we just covered passing in the member variables as the parameters.

This was the version of the function we saw being called in the earlier example of its use.

```
D3DFORMAT CTextureFormatEnum::GetBestFormat( )
{
    return GetBestFormat( m_bAlpha, m_bPreferCompressed );
}
```

Of course, we can also set the m_bAlpha and m_bPreferCompressed booleans via the two simple methods shown below, so that the default logic of the object can be changed.

```
void CTextureFormatEnum::SetCompressedMode( bool Enable )
{
    m_bPreferCompressed = Enable;
}
```

```
void CTextureFormatEnum::SetAlphaMode( bool Enable )
{
    m_bAlpha = Enable;
}
```

CTextureFormatEnum::GetFormatSupported (Overloaded)

There may be times when you do not wish to use the default processing supplied by the GetBestFormat functions, but instead wish to query if a given format is supported. Your application can then use our object simply to test support for surfaces and make up its own mind about which one is preferred.

The GetFormatSupported function takes a single parameter of type D3DFORMAT that describes the surface you would like to query support for. The function then uses the STL map Find method to search the map for a matching key. Of course, the Enumerate method must have been called first for any of these query methods to work.

If the key exists in the map, then the iterator will be pointing at that key/value pair when the Find method returns. If not, the iterator will be pointing at the end of the map data and we know that we do not have a row in our map for the specified format. We have added all the common formats to the map, so this should never happen in the normal case (not unless you are using a custom format).

```
bool CTextureFormatEnum::GetFormatSupported( D3DFORMAT Format ) const
{
    FormatEnumMap::const_iterator Item = m_TextureFormats.find( Format );

    // We don't support the storage of this format.
    if ( Item == m_TextureFormats.end() ) return false;

    // Return the item
    return Item->second;
}
```

As you can see, we simply return the value of the iterator's 'second' member, which will be pointing to the boolean value for the key (the format) that was specified. Therefore, this function returns true or false to indicate support for that format.

CTextureFormatEnum::SetFormatSupported

The final function we will cover in this class is the SetFormatSupported function. The application can use this to force the boolean value associated with a format to be true or false. As the first parameter we pass the format (the key) whose value we wish to set. As the second parameter we pass a boolean that indicates the support (or lack of it) for the specified format.

```
void CTextureFormatEnum::SetFormatSupported( D3DFORMAT Format, bool Supported )
{
    FormatEnumMap::iterator Item = m_TextureFormats.find( Format );

    // We don't support the storage of this format.
    if ( Item == m_TextureFormats.end() ) return;

    // Update the item (done this way because we have already had to perform
    // a 'find'. It saves us a little time over using the indexing operator
    // to find the key again).
    Item->second = Supported;
}
```

We now have a texture format enumeration object that all our future components can use. All we have to do is make sure that any component we plug into our framework can be passed and store a pointer to the enumeration object. From that point on, the component can use this object to query for formats that it is interested in using.

Multiple Terrains in CScene

Since Chapter Three in Module I, our demonstration applications have generally taken one of two forms. They have either been terrain demos or non-terrain demos. The non-terrain demos used the CScene class as a geometry manager and loaded data from IWF files or X files. We have continued to use and expand the CScene class throughout Module II.

In previous terrain oriented demos, because the generation of the terrain geometry happened procedurally (based on heightmap data), a different scene manager was used, called CTerrain. The CTerrain class essentially replaced CScene in those demos. The data was no longer loaded from an IWF file and as such, lab projects that contained terrains used different code than those that did not. Although using the CTerrain class as a substitute scene manager for terrain based applications served us well in earlier lessons to keep the code simple and focused, this system will have to be revised going forward.

In a game we often do not want our scene to consist of either indoor or outdoor environments; often we want a scene to be comprised of both. Our current system does not support this idea, so we will upgrade the CScene and CTerrain classes so that they can be used together in a single application.

The CScene class will now officially be the top level scene manager and it will continue to load its data from IWF files. However, we will add support for the loading of terrain entities from the IWF file so that the IWF file can contain internal geometry and external references in addition to the terrain. In fact, a scene that we make in GILES™ may contain multiple terrain entities, so our scene will have to create, manage, and render multiple CTerrain objects.

> **Note**: You will see later that when a terrain exists as an entity in an IWF file, the geometry is not stored. All that is stored is the information used to construct it -- the heightmap file, the filenames of the base and detail textures, the scale of the detail texture and the scale of the geometry. These are all variables that were member variables in our old CTerrain class and were used to construct the terrain. Therefore, all we have to do is write a function that allows us to send these parameters into a terrain object when it is first created and we can use virtually the same code as before, with the exception of one or two little adjustments that will be discussed in a moment.

It may at first seem that changing the terrain class and the scene class to work harmoniously with one another would require many code changes. In the grand scheme of things, it requires hardly any. We will first discuss changes to the CScene class.

Just as the CScene class maintains an array of objects, meshes, and actors that collectively compose the virtual world, the CScene class will now also maintain an array of CTerrain objects. The following lines of code have been added to the class declaration of CScene:

Excerpt from CScene.h

```
CTerrain          **m_pTerrain;
ULONG               m_nTerrainCount;
```

As you can see, the scene now manages an array of CTerrain pointers and has an added ULONG describing how many CTerrain pointers are currently in the array. Every time the loading code encounters a terrain entity, it will create a new CTerrain object from the data extracted from the IWF file and add its pointer to this array.

CScene::AddTerrain

Just as the CScene class has an AddObject, an AddMesh, and an AddActor function to resize the respective arrays and make room for another element at the end, we now have to have an AddTerrain method which does the same for terrains.

This function is called by the IWF loading code whenever a terrain entity is encountered in the file. The code to this function should be easily understood since it is almost identical to all the other array resize functions we have written in previous lessons.

AddTerrain takes a single optional parameter that allows the caller to specify how many new elements should be added to the end when the array resize is performed. The default value of the parameter is 1, so this function will make space in the terrain array for one additional CTerrain pointer.

If previous terrain pointer data exists in the array it is copied over into the new resized array before the original array is deleted. The new resized array is then assigned to the CScene::m_pTerrain pointer replacing the original assignment to the old array.

```
long CScene::AddTerrain( ULONG Count /* = 1 */ )
{
    CTerrain ** pTerrainBuffer = NULL;

    // Allocate new resized array
    if (!( pTerrainBuffer = new CTerrain*[ m_nTerrainCount + Count ] )) return -1;

    // Existing Data?
    if ( m_pTerrain )
    {
        // Copy old data into new buffer
        memcpy( pTerrainBuffer, m_pTerrain, m_nTerrainCount * sizeof(CTerrain*) );

        // Release old buffer
```

```
        delete []m_pTerrain;

    } // End if

    // Store pointer for new buffer
    m_pTerrain = pTerrainBuffer;

    // Clear the new items
    ZeroMemory( &m_pTerrain[m_nTerrainCount], Count * sizeof(CTerrain*) );

    // Increase Terrain Count
    m_nTerrainCount += Count;

    // Return first Terrain
    return m_nTerrainCount - Count;
}
```

CScene::Render

As you are well aware, our scene is rendered when the CGameApp::FrameAdvance function calls the CScene::Render function. It is this function that instructs the various components comprising the scene to render themselves. It first instructs the skybox to render itself, and then it loops through every object in the scene instructing that object's mesh or actor to render itself.

We will now have to add an additional line to the CScene::Render function that instructs any terrains that may be used by the scene to render themselves as well. We will not cover the entire CScene::Render function at this time, as it has hardly changed at all. However, below we see a new line of code from that function which renders each terrain in the CScene::m_pTerrain array. This line of code is positioned very near the bottom of the function, just after the loop that renders each CObject.

```
// Render each terrain
for ( i = 0; i < m_nTerrainCount; ++i ) m_pTerrain[i]->Render( &Camera );
```

With the exception of the CScene IWF loading code upgrade which we will cover at the end of this workbook, these are the only changes that need to be added to the CScene class so that it now correctly renders multiple terrains. Next let us discuss the updates we will need to apply to our CTerrain class to get everything working together.

The New CTerrain Class

There is no need for concern since we do not have to write a new terrain class. With a few minor modifications, our old CTerrain class can be upgraded to work alongside our new CScene, and alongside other CTerrain objects that might exist in the scene.

> **Note**: This object was first covered in Chapter Three of Module I when we explained how the vertex data for the terrain was generated from a heightmap. We also described how the terrain was actually represented internally as a series of CMesh objects. A CMesh object was really just a lite wrapper around a vertex and index buffer with functions that allowed us to add vertices and indices incrementally to the object during the building process. As this object is no longer used anywhere else other than by the CTerrain class, we have decided to rename CMesh to CTerrainBlock. This is just a simple name change and all the code remains the same, unless stated otherwise. If you are feeling a little rusty on how we generated our terrain, please refer back to Chapter Three. You may also want to refresh yourself on the workbook of Module I Chapter Six where we discussed the concept of texturing the terrain with a base and detail texture map. All of this code will remain the same, so will not be covered again here.

The only real problem we need to address is that in our old CTerrain class the vertex data was assumed to be generated in world space. That is, the terrain space origin was also the world space origin. As the data was assumed to be in world space, rendering the terrain simply meant setting the world matrix to an identity matrix and sending the vertex and index data of each terrain block to the hardware.

In an IWF file, the terrain data is defined in model space and is accompanied by a world matrix describing where in the scene this terrain should be positioned when rendered or queried for collision. Therefore, we will have to add a world matrix member to our CTerrain class. Before the terrain renders itself (in the CTerrain::Render function) it will need to send this world matrix to the device. This simple addition means we can now load an IWF file that contains multiple terrain entities that are all placed at different locations in the world. We can thus position and render these terrains correctly.

Our CTerrain class will also have a method added called SetTextureFormat so that it can be passed (by CGameApp or CScene) a pointer to the CTextureFormatEnum object introduced earlier. The terrain creation functions can then use this object to find the optimal texture format to use when loading the base and detail texture map images.

Furthermore, we will upgrade our CTerrain object to provide lifetime encapsulation using COM-like semantics. That is, we will add the AddRef and Release mechanics so that the CTerrain object can destroy itself when its internal reference count reaches zero.

Finally, the LoadTerrain method will be written to replace the old LoadHeightMap method as the means for generating the terrain geometry. Previously, the application would call the CTerrain::LoadHeightMap method and pass the name of the .RAW file that contains the height data and the width and the height of that image. This function would then generate the terrain based on the heightmap data and the values of several internal variables (e.g., geometry scale, texture scale, etc.). If we wanted to change the generation properties of the terrain, we would have to alter the code and re-compile.

The new LoadTerrain method accepts a single parameter -- a pointer to a TerrainEntity structure. Not only does this single structure contain all the terrain creation parameters we used before, it also matches the format in which the data for a terrain is stored in an IWF file. Therefore, when our loading code encounters a terrain entity, it can just pull the data from the file into a TerrainEntity structure and pass it straight to the CTerrain::LoadTerrain method for geometry generation. This is very handy indeed.

Below we show the new methods added to CTerrain in the file 'CTerrain.h'. Not all of the class methods are show here in order to keep the listing compact, but we have included the ones that are new and those that have been modified. We have also shown the member variables and highlighted new or modified ones in bold face type.

```
class CTerrain
{
public:
    //-----------------------------------------------------------------------
    // Constructors & Destructors for This Class
    //-----------------------------------------------------------------------
    CTerrain();
    virtual ~CTerrain();

    // Public Functions For This Class
    …
    …
    …
    void                SetTextureFormat ( const CTextureFormatEnum &FormatEnum );
    void                SetWorldMatrix   ( const D3DXMATRIX & mtxWorld );

    bool                LoadTerrain      ( TerrainEntity * pTerrain );
    const D3DXMATRIX &  GetWorldMatrix   ( ) const {return m_mtxWorld; }
    …
    …
    …

    // Reference Counting Functions
    ULONG               AddRef              ( );
    ULONG               Release             ( );

    // Public Static Functions For This Class (callbacks)
    static void UpdatePlayer(LPVOID pContext, CPlayer *pPlayer, float TimeScale );
    static void UpdateCamera(LPVOID pContext, CCamera *pCamera, float TimeScale );

private:

    // Private Variables For This Class

    D3DXVECTOR3         m_vecScale;         // Amount to scale the terrain meshes
    D3DXVECTOR2         m_vecDetailScale;   // Amount to scale the detail map.
    float              *m_pHeightMap;       // The physical heightmap data loaded
    ULONG               m_nHeightMapWidth;  // Width of the 2D heightmap data
    ULONG               m_nHeightMapHeight; // Height of the 2D heightmap data

    CTerrainBlock     **m_pTerrainBlocks;   // Simple array of mesh pointers
```

```
    ULONG               m_nBlockCount;      // Number of blocks stored here
    LPDIRECT3DDEVICE9   m_pD3DDevice;       // D3D Device
    bool                m_bHardwareTnL;     // Used hardware vertex processing ?
    bool                m_bSinglePass;      // Use single pass rendering method

    CTextureFormatEnum  m_TextureFormats;   // Texture format lookup object

    LPTSTR              m_strDataPath;      // Path to data items
    ULONG               m_nPrimitiveCount;  // Number of primitives for D3D Render
    LPDIRECT3DTEXTURE9  m_pBaseTexture;     // Base terrain texture
    LPDIRECT3DTEXTURE9  m_pDetailTexture;   // Terrain detail texture.

    D3DXMATRIX          m_mtxWorld;         // Terrain world matrix
    ULONG               m_nRefCount;        // Reference Count Variable

    // Private Functions For This Class
    long                AddTerrainBlock     ( ULONG Count = 1 );
    bool                BuildTerrainBlocks  ( );
    void                FilterHeightMap     ( );
};
```

There are a couple things to pay attention to in the above listing. The terrain now has a world matrix and also has Get/Set functions that allow for the configuration of this matrix by external components. It also has a reference count variable with accompanying AddRef/Release methods. So the terrain now behaves like a COM object and destroys itself when there are no outstanding references to it. Finally, notice that what was once a CMesh pointer array containing the terrain blocks is now an array of CTerrainBlocks. This is just an object renaming for clarity and no code has changed. Thus the function AddMesh has had its name changed to AddTerrainBlock and the function BuildMeshes has had its name changed to BuildTerrainBlocks.

The TerrainEntity Structure

The TerrainEntity structure is defined in CTerrain.h and is our property transport structure when informing the CTerrain object how its geometry should be built. It also describes exactly how the terrain data exported from GILES™ into the IWF file is laid out in that file.

We will see later when we cover the upgraded loading code that for each terrain entity found in the file we will create a new CTerrain object and pass a structure of this type to its LoadTerrain function. Of course, you can fill one of these structures out manually if you wish to generate your terrain creation properties from another source and not use GILES™ or IWF files. The members of this structure should be instantly familiar to you since they are the properties that existed in our previous CTerrain class member variables. We will briefly discuss the members as a reminder.

```
typedef struct _TerrainEntity
{
    ULONG       TerrainType;        // Which type of terrain are we using.
    char        TerrainDef[256];    // Either terrain definition (splats) or
                                       heightmap def (standard).
```

```
    char        TerrainTex[256];    // (Standard terrain only), specifies the base
                                        texture
    char        TerrainDet[256];    // (Standard terrain only), specifies the
                                        detail texture
    ULONG       TerrainWidth;       // (Standard terrain only), Width of the
                                        heightmap
    ULONG       TerrainHeight;      // (Standard terrain only), Height of the
                                        heightmap
    D3DXVECTOR3 TerrainScale;       // (Standard terrain only), Scale of the
                                        terrain
    D3DXVECTOR2 TerrainDetScale;    // (Standard terrain only),
                                    //  scale information for detail texture
    ULONG       Flags;              // Reserved Flags

} TerrainEntity;
```

ULONG TerrainType
The GILES™ terrain entity can be one of two types -- a regular terrain or a splatting terrain. You will recall that the data is generated rather differently for each terrain type. Our CTerrain object encapsulates regular heightmapped terrains. This value will be stored in the entity to inform the loading code which type of terrain entity has been encountered. A value of zero indicates a regular terrain entity. Therefore, our CScene class will only be interested in loading regular terrain entities, as that is the type of terrain this object currently encapsulates. Thus, this value should always be zero when this structure is used to create CTerrain objects (at least for now).

char TerrainDef[256]
This member contains the filename of the heightmap image that the CTerrain object will need to load and extract the height values from. For splatting terrains, this will contain the name of the splat definition file that contains all the splat terrain info.
(The following members are applicable only to regular terrains)

char TerrainTex[256]
This member contains the filename of the image file that should be loaded into a texture and used as the base texture for the terrain.

char TerrainDet[256]
This member contains the filename of the image file that should be loaded into a texture and used to tile over the terrain as a detail texture.

ULONG Width
ULONG Height
As the image data for the terrain heightmap is stored in a .RAW file that contains no data describing the arrangements of the pixels in the image, these members inform us how the data in the .RAW file is to be interpreted in terms of rows and columns. For example, if Width=1024 and Height=512, the pixels in the .RAW file should be used to create a mesh of 512 rows of 1024 vertices.

D3DXVECTOR3 TerrainScale
This vector describes how the pixel positions in the heightmap are scaled into terrain space vertex positions. For example, a scale vector of (1,1,1) would produce a terrain where every unit in world space maps to every pixel in image space and the height data for any pixel will be used exactly as the world space Y component of that vertex. A scale vector of (1,5,2) on the other hand, would scale the pixel position by 1 along the X axis, 2 along the Z axis, and the Y component of the vertex would be generated by scaling the value stored in the pixel by 5. Using this second example scale vector, a raw file containing 10 rows and 10 columns would create a terrain 10 units wide (X axis) and 20 units deep (Z axis) and at its peak would be five times higher than the highest point described by the height data.

D3DXVECTOR2 TerrainDetScale
This 2D vector describes how many times we would like the detail texture tiled over the terrain in the direction of the X and Z axes.

CTerrain::LoadTerrain

The LoadTerrain method is used to instruct a newly created CTerrain object to build its geometry and load its texture resources. This function is almost identical to the LoadHeightMap method in our old CTerrain class with the exception that it now extracts the properties for creation from the passed TerrainEntity structure.

We will show the code to this function below but provide only very brief descriptions since it should be familiar to you. We will not show the code to any of the helper functions it calls since these were all covered in Module I and are unchanged. Please refer back to Chapters Three and Six if you need to jog your memory about how these functions work. This function is shown as a reminder of the terrain creation process from a high level.

The first thing this function does is return if the TerrainType member of the passed TerrainEntity structure is not zero. This means it is not a regular terrain and as such, not a terrain this class was designed to support. We also return if the device is not valid or if its array of terrain blocks has already been allocated. If data already exists in the terrain, it should be released prior to calling this function. We then extract the width and height values from the passed structure and store them in member variables.

```
bool CTerrain::LoadTerrain( TerrainEntity * pTerrain )
{
    HRESULT   hRet;
    FILE    * pFile = NULL;
    TCHAR     FileName[MAX_PATH];
    D3DFORMAT fmtTexture;
    ULONG     i;

    // Skip if this is not a 'standard' terrain
    if ( !pTerrain || pTerrain->TerrainType != 0 ) return false;

    // Cannot load if already allocated (must be explicitly released for reuse)
    if ( m_pTerrainBlocks ) return false;

    // Must have an already set D3D Device
```

```
    if ( !m_pD3DDevice ) return false;

    // First of all store the information passed
    m_nHeightMapWidth  = pTerrain->TerrainWidth;
    m_nHeightMapHeight = pTerrain->TerrainHeight;
```

In the next section we combine the name of the highway file with the string containing our application's data path so that we have the complete path of the RAW file we wish to load. We then open the file and read in its total size, so that we know how much data we will need to read.

```
    // Build full filename
    _tcscpy( FileName, (m_strDataPath) ? m_strDataPath : pTerrain->TerrainDef );
    if ( m_strDataPath ) _tcscat( FileName, pTerrain->TerrainDef );

    // Open up the heightmap file
    pFile = _tfopen( FileName, _T("rb") );
    if (!pFile) return false;

    // Get file length
    ULONG FileSize = filelength( pFile->_file );
```

We next calculate how many rows and columns our heightmap must have using the passed width and height values in the TerrainEntity structure. For example, if FileSize contains the number of pixels in the image, dividing this by the height of the heightmap will tell us the length of a single row. The number of rows is then calculated by dividing the file size by the length of a row. We also perform some logic to calculate the height and width if only one of them has been specified in the terrain entity structure (and the other property is set to zero). If the TerrainEntity structure has zero in both its width and height members, then we will assume the image file is to be interpreted as a square heightmap. In that case the width and height will be equal to the square root of the total file size.

```
    // Work out heightmap size if possible
    if ( m_nHeightMapWidth > 0 && m_nHeightMapHeight == 0 )
    {
        // We can work this one out
        m_nHeightMapHeight = FileSize / m_nHeightMapWidth;

    } // End if m_nHeightMapWidth only
    else if ( m_nHeightMapWidth == 0 && m_nHeightMapHeight > 0 )
    {
        // We can work this one out
        m_nHeightMapWidth = FileSize / m_nHeightMapHeight;

    } // End if m_nHeightMapHeight only
    else
    {
        // We can only assume square
        m_nHeightMapWidth  = (ULONG)sqrt( (double)FileSize );
        m_nHeightMapHeight = m_nHeightMapWidth;

    } // End if no sizes at all
```

In the next step we test that the file size is large enough to have enough data for the width and height values we have just calculated. If the file size is smaller than 'Width x Height' then something has gone wrong and we return. We also retrieve the terrain geometry scale and the detail texture scale vectors and copy them into member variables.

```
    // Validate sizes
    if ( m_nHeightMapWidth * m_nHeightMapHeight > FileSize )
        { fclose( pFile); return false; }

    // Retrieve scale
    m_vecScale = pTerrain->TerrainScale;
    m_vecDetailScale = pTerrain->TerrainDetScale;
```

Now we allocate an array of floats large enough to store a floating point value for each pixel in the heightmap. This is the array we will copy the height values into for each vertex of the terrain we are about to create. We then set up a loop to read the value of each pixel and store it in the heightmap array before we close the file.

```
    // Attempt to allocate space for this heightmap information
    m_pHeightMap = new float[m_nHeightMapWidth * m_nHeightMapHeight];
    if (!m_pHeightMap) return false;

    // Read the heightmap data
    for ( i = 0; i < m_nHeightMapWidth * m_nHeightMapHeight; i++ )
    {
        UCHAR HeightValue;
        fread( &HeightValue, 1, 1, pFile );

        // Store it as floating point
        m_pHeightMap[i] = (float)HeightValue;

    } // Next Value

    // Finish up
    fclose( pFile );
```

We now call the FilterHeightMap method which applies a smoothing filter to the height data so that our terrain does not look jagged because of the integer height values stored in the file. That is why we read the integer height data into a float array -- once we have the height data stored as floats we can apply a smoothing filter to soften the peaks and valleys. The code to this function was covered in Module I and is unchanged.

```
    // Filter the heightmap data
    FilterHeightMap();
```

Our next step is to load the base texture and the detail texture. Before calling the D3DXCreateTextureFromFileEx function to load these textures, we call the GetBestFormat method of our CTextureFormatEnum object. This will return a D3DFORMAT type that we can pass to the loading functions for texture generation. Before we load each texture, we append the filename to the

application's data path so we have the full path and filename of the image file to pass to the texture loading function.

```
    // Get the best format for these textures
    fmtTexture = m_TextureFormats.GetBestFormat( );

    // Load in the textures used for rendering the terrain
    _tcscpy( FileName, (m_strDataPath) ? m_strDataPath : pTerrain->TerrainTex );
    if ( m_strDataPath ) _tcscat( FileName, pTerrain->TerrainTex );
    hRet = D3DXCreateTextureFromFileEx( m_pD3DDevice,
                                        FileName,
                                        D3DX_DEFAULT,
                                        D3DX_DEFAULT,
                                        D3DX_DEFAULT,
                                        0,
                                        fmtTexture,
                                        D3DPOOL_MANAGED,
                                        D3DX_DEFAULT,
                                        D3DX_DEFAULT,
                                        0, NULL, NULL, &m_pBaseTexture );

    _tcscpy( FileName, (m_strDataPath) ? m_strDataPath : pTerrain->TerrainDet );
    if ( m_strDataPath ) _tcscat( FileName, pTerrain->TerrainDet );
    hRet = D3DXCreateTextureFromFileEx(   m_pD3DDevice,
                                          FileName,
                                          D3DX_DEFAULT,
                                          D3DX_DEFAULT,
                                          D3DX_DEFAULT,
                                          0,
                                          fmtTexture,
                                          D3DPOOL_MANAGED,
                                          D3DX_DEFAULT, D3DX_DEFAULT,
                                          0,
                                          NULL,
                                          NULL,
                                          &m_pDetailTexture );
```

At this point the heightmap data is loaded and filtered and the texture assets have been loaded. All that is left to do is generate the terrain blocks.

We first call the AddTerrainBlock method to allocate enough space in the terrain block pointer array for each terrain block we will create. The number of terrain blocks the heightmap data is divided into depends on how many quads we wish to place in each block. The QuadsWide and QuadsHigh variables can be altered and are also defined in CTerrain.h. By default, they are set to 16 so that each terrain block contains a 16x16 block of quads.

```
    // Allocate enough terrain blocks to store the separate blocks of this terrain
    if ( AddTerrainBlock( ((m_nHeightMapWidth - 1) / QuadsWide) *
                          ((m_nHeightMapHeight - 1)/ QuadsHigh) ) < 0 )
       return false;
```

The AddTerrainBlock function is not a new function. It was previously called AddMesh but has now been renamed for consistency with our naming scheme.

Finally, we call the BuildTerrainBlocks function, which is just a renamed version of the old BuildMeshes method. It is this function that generates the geometry for each terrain block.

```
    // Build the terrain block data itself
    return BuildTerrainBlocks( );
}
```

CTerrain::Render

The Render method in the CTerrain class has an additional line now. You will remember that the render function essentially just binds the base and detail textures to stages 0 and 1 on the device and then iterates through each terrain block setting its vertex and index buffers on the device and then rendering them. The main difference now is that we must set the terrain's world matrix prior to rendering it since the vertices are now defined in terrain (model) space. The following line has been inserted very near the top of the CTerrain::Render function before we loop through and render each block.

```
// Set this terrain's transformation
m_pD3DDevice->SetTransform( D3DTS_WORLD, &m_mtxWorld );
```

Note: The CTerrain class exposes methods that allow the application to set and retrieve the world matrix.

Before each terrain block is rendered we also perform a frustum test on it, just as we did before. When we call the CCamera::BoundsInFrustum function to perform this test, we also pass the world matrix along with the bounding box min and max vectors. Since the terrain block's bounding box is in terrain space it must be converted into world space for the test. The BoundsInFrustum method of CCamera has an optional third matrix parameter that, when used, will cause the function to transform the bounding box extents using the passed world matrix prior to performing the frustum test.

The line of code that is executed before we process each block in the CTerrain::Render function is shown below. It is the first line that is executed in the loop that processes each block. If the terrain block is not visible, the current iteration of the loop is skipped.

```
if ( pCamera && (!pCamera->BoundsInFrustum( m_pTerrainBlocks[i]->m_BoundsMin,
                                            m_pTerrainBlocks[i]->m_BoundsMax,
                                            &m_mtxWorld )) ) continue;
```

Other Changes to CTerrain

Before leaving this section, we will point out other small changes that have taken place to CTerrain. Most are so small, that to cover the function code again would be redundant.

You will recall from Module I that our CTerrain class registered two static callback functions with the CPlayer object that were used for collision detection purposes. These functions were called UpdatePlayer and UpdateCamera. They were called by CPlayer whenever it wanted to update the position of the player or its attached camera. If the position of either was found to be below the terrain, it would be adjusted so that it lay on the terrain surface (see Chapter Three).

The function involved finding the quad over which the player was positioned and interpolating the height values to find the exact height of the terrain at the new position. If this was higher than the player's position, then the position of the player (or its camera) was updated.

These functions must be updated slightly because we can no longer compare the position of the player against the interpolated vertex heights as they no longer exist in the same space; the player/camera position is in world space and the vertex data of the terrain is in terrain space. In order for these functions to continue working correctly we must add an additional line to the top of each function that transforms the passed player/camera position into terrain space. This is done by multiplying the player position with the inverse world matrix of the terrain. The function will then continue on as usual.

Updating the CScene IWF Loading Code

In this lab project, the IWF loading code in CScene will be upgraded to support two additional entity types: Terrain and Fog. Since these are both entities, this will amount to nothing more than adding two addition case statements to the CScene::ProcessEntities function.

We will show the ProcessEntities function in a moment. Note that we will snip out the code that processes references we are familiar with (light, external reference, and skybox) although we will leave the case statements in place so you can see the general flow of the function.

CScene and DirectX Fog

Although we have been able to add fog to our scenes since Chapter Seven of Module I, until this lab project, we were forced to hardcode the fog parameters and generate the results we wanted through tedious trial and error. GILES™ allows us to configure fog and view it in an easy to tweak manner, so it is a good tool for experimenting with our fog parameters (without having to recompile code).

GILES™ saves the fog settings for the scene in an entity chunk with the entity ID seen below. This is accompanied by the GILES™ author ID. We will define this value in CScene.h so that we can easily test for this entity type when searching through the entity vector.

```
#define CUSTOM_ENTITY_FOG       0x204
```

The data area for a fog entity is laid out as shown in the following structure. This structure is also defined in CScene.h and will be used to contain the fog data we fetch from the IWF file.

Excerpt from CScene.h

```
typedef struct _FogEntity
{
    ULONG       Flags;                  // Fog type flags
    ULONG       FogColor;               // Color of fog.
    ULONG       FogTableMode;           // Mode to use with table fog
    ULONG       FogVertexMode;          // Mode to use with vertex fog
    float       FogStart;               // Fog range start
    float       FogEnd;                 // Fog range end
    float       FogDensity;             // Density float

} FogEntity;
```

We know from our coverage of DirectX fog in Chapter Seven what most of these values mean and how they contribute to the fog factor, but there are a few members here that need explanation since their meaning is specific to this type of entity.

ULONG Flags
These flags can be zero or one of the following modifier flags that help inform us about what type of fog is preferred by the IWF file creator. There are two flags defined in CScene.h that map to these values.

```
#define FOG_USERANGEFOG         0x1
```

If this flag is set it means that if our scene is going to use vertex fog instead of table fog then range based fog is preferred (as is normally the case). This flag is only valid when vertex fog is used as there is no range based pixel fog in DirectX 9.

```
#define FOG_PREFERTABLEFOG      0x2   // Modifier used for FogEntity::Flags member
```

When the flags member of the entity has this flag set, it means the IWF creator would prefer to use table (pixel) fog. This is generally the preferred mode for most applications as it gives the best results (see Chapter Seven of Module I).

ULONG FogTableMode
ULONG FogVertexMode
These two members of the entity data area define the fog models the artist would like us to use for vertex and table fog modes. They can be set to any of the values you see below. You should understand what these definitions mean and the way the fog factor is computed in each of the fog models since we covered them in Chapter Seven. These values are also defined in CScene.h

```
#define FOGMODE_NONE            0x0         // Mode flags for FogEntity
#define FOGMODE_EXP             0x1         // ''
#define FOGMODE_EXP2            0x2         // ''
#define FOGMODE_LINEAR          0x3         // ''
```

Remember, both the FogTableMode and the FogVertexMode will be set to one of these values. Although an application will typically use only one of these fog modes, specifying the options for each allows us more control over specifying what should be used when one is not supported.

The CScene class itself actually has a 'FogEntity' structure as a member. It is this variable that will be populated with the fog entity data extracted from the IWF file. Below we see the two new members that have been added to CScene to contain any fog data that has been loaded.

```
bool                m_bFogEnabled;    // Is fog enabled or not in this level?
FogEntity           m_FogEntity;      // Storage for our fog setup.
```

When the m_FogEntity structure is populated with fog data from the IWF file, the m_bFogEnabled boolean is also set to true; otherwise it stays set as false. Forgetting about the actual loading code for just a moment, the CScene::Render function has the following lines inserted near the start of the function to set up the fog parameters prior to rendering any objects:

Excerpt from CScene::Render

```
if ( m_bFogEnabled )
    {
        // Setup fog parameters
        m_pD3DDevice->SetRenderState( D3DRS_FOGCOLOR  , m_FogEntity.FogColor);
        m_pD3DDevice->SetRenderState( D3DRS_FOGSTART  , *(ULONG*)&m_FogEntity.FogStart  );
        m_pD3DDevice->SetRenderState( D3DRS_FOGEND    , *(ULONG*)&m_FogEntity.FogEnd    );
        m_pD3DDevice->SetRenderState( D3DRS_FOGDENSITY, *(ULONG*)&m_FogEntity.FogDensity);
        m_pD3DDevice->SetRenderState( D3DRS_RANGEFOGENABLE,
                                     (m_FogEntity.Flags & FOG_USERANGEFOG)? TRUE : FALSE );
        m_pD3DDevice->SetRenderState( D3DRS_FOGENABLE, TRUE );
```

The fog color, start and end distances, and density are taken straight from the CScene::m_pFogEntity structure and passed to the pipeline. We also enable the device's fog render state. Notice that we only enable range based fog if the FOG_USERANGEFOG flag has been set in the entity structure.

The final section of the fog render code is shown below. If table fog is preferred then we enable it and disable the vertex fog mode (and vice versa).

Excerpt from CScene::Render Continued

```
        // Set up conditional table / vertex modes
        if ( m_FogEntity.Flags & FOG_PREFERTABLEFOG )
        {
            m_pD3DDevice->SetRenderState( D3DRS_FOGTABLEMODE, m_FogEntity.FogTableMode );
            m_pD3DDevice->SetRenderState( D3DRS_FOGVERTEXMODE, D3DFOG_NONE );

        } // End if table fog
        else
        {
            m_pD3DDevice->SetRenderState( D3DRS_FOGVERTEXMODE, m_FogEntity.FogVertexMode );
            m_pD3DDevice->SetRenderState( D3DRS_FOGTABLEMODE, D3DFOG_NONE );

        } // End if vertex fog

    } // End if fog enabled
```

Looking at the above two sections of code it may at first seem as if we are not validating the requested fog techniques on the device to see if they are supported. It looks like we are essentially just extracting the information in the FogEntity structure that was loaded from the file and trying to use them. However, you will see in a moment when we look at the code that loads the fog entity that, after the data

has been loaded into the FogEntity structure, the device is tested and the members are modified to reflect what can and cannot be used on the current device.

CScene::ProcessEntities (Updated)

This function has been in use since Module I (to parse light entities). Along the way we added support for external reference entities, sky boxes, and most recently, trees. Because these sections of the function have already been covered, the code that parses these entities is not shown again here to compact the listing. In such places where code has been removed we have replaced the code with the line '……snip……'.

As we know, this function is called from CScene::LoadSceneFromIWF after the data from the IWF file has been loaded into the CFileIWF object's internal STL vectors. This function's job is to extract the entity information from that object into a format that can be used by the application. The function sets up a loop to visit each entity in the CFileIWF object's entity vector. Each entity in this vector is of type iwfEntity, which is essentially a structure that contains a world matrix, the entity name, and a data area for storing arbitrary data. It also stores an entity type ID member and an author ID.

```
bool CScene::ProcessEntities( const CFileIWF& File )
{
    ULONG      i, j;
    D3DLIGHT9  Light;
    USHORT     StringLength;
    bool       SkyBoxBuilt = false;
    bool       FogBuilt    = false;

    // Loop through and build our lights & references
    for ( i = 0; i < File.m_vpEntityList.size(); i++ )
    {
        // Retrieve pointer to file entity
        iwfEntity * pFileEntity = File.m_vpEntityList[i];

        // Skip if there is no data
        if ( pFileEntity->DataSize == 0 ) continue;
```

The first thing we do inside the entity loop is get a pointer to the current entity we wish to process. We also test the DataSize member and if it is zero, then the data area is empty and we skip it.

The first entity we test for is the light entity, which is part of the IWF SDK specification. The standard light entity has an entity ID of 0x0010, so if we find an entity with this ID we know we have found a standard light. In the following code you can see that we only continue to parse the light entity if we have not already set up the maximum number of lights we wish to use. As this is not new code to us, the code that extracts the light information from the entity is not shown here.

```
        if ( (m_nLightCount < m_nLightLimit && m_nLightCount < MAX_LIGHTS)
              && pFileEntity->EntityTypeMatches( ENTITY_LIGHT ) )
        {
            //..... snip .....
        } // End if light
```

The light entity is the only entity type we currently process which is part of the core IWF standard. The rest of the entities we will load will be custom entities with the 'GILES' author ID. We can use the iwfEntity object's EntityAuthorMatches method and pass it a char array containing the ID we are looking for. In the following code, AuthorID has been defined at the start of 'CScene.cpp' as a 5 element char array containing the letters 'G','I','L','E','S'. This is the author ID GILES™ assigns to its custom entity chunks. If this function returns true, then the current entity is a GILES™ entity and we will initiate some logic to parse this entity.

```
        else

        if ( pFileEntity->EntityAuthorMatches( 5, AuthorID ) )
        {
            CTerrain * pNewTerrain = NULL;

            SkyBoxEntity SkyBox;
            ZeroMemory( &SkyBox, sizeof(SkyBoxEntity) );

            ReferenceEntity Reference;
            ZeroMemory( &Reference, sizeof(ReferenceEntity) );

            TerrainEntity Terrain;
            ZeroMemory( &Terrain, sizeof(TerrainEntity) );

            FogEntity Fog;
            ZeroMemory( &Fog, sizeof(FogEntity) );
```

Notice in the above code that we instantiate a temporary TerrainEntity structure and a FogEntity structure in addition to the others we previously supported. These structures are used to hold the data we extract.

Next we retrieve a pointer to the entity data area before entering a switch statement that will determine which of the GILES™ custom entities we are dealing with here. Since we have covered the code that processes the reference entity and the sky box entity in previous lessons, the code has been snipped to increase readability.

```
            // Retrieve data area
            UCHAR * pEntityData = pFileEntity->DataArea;

            switch ( pFileEntity->EntityTypeID )
            {
                case CUSTOM_ENTITY_REFERENCE:

                    // ..... snip .....

                    break;

                case CUSTOM_ENTITY_SKYBOX:

                    // ..... snip .....

                    break;
```

Now we add some new content. In the next section of code we add a case statement to test if the current entity has an ID of CUSTOM_ENTITY_TERRAIN. This value is defined in CTerrain.h as:

```
#define CUSTOM_ENTITY_TERRAIN   0x201
```

The value 0x201 is the ID that GILES™ assigns its terrain entity so we know that if this case is executed, it is a GILES™ terrain entity we are processing. Here is the first section of the code that processes the terrain entity.

```
                case CUSTOM_ENTITY_TERRAIN:

                    // Copy over the terrain data
                    memcpy( &Terrain.TerrainType, pEntityData, sizeof(ULONG) );
                    pEntityData += sizeof(ULONG);
```

Earlier in the function we fetched a pointer to the beginning of the entity data area. This data area is laid out in an identical manner to our TerrainEntity structure, so all we have to do is extract the values from the data area into one of these structures. In the above code we copy the first four bytes of the data area which contains the TerrainType value into the TerrainType member of our TerrainEntity structure. We then advance the data pointer past the value we have just extracted so that it is pointing at the beginning of the second piece of data to be extracted.

Before continuing to extract the rest of the data we should test the terrain type value we just extracted. Our CTerrain class encapsulates standard terrains (type 0) so we are currently only interested in parsing those.

In the following code we show a similar technique for copying the data to that which was described above. Each time, we copy the data into the TerrainEntity structure and advance the pointer by the correct number of bytes to point at the next piece of data. The following lines of code show us copying over the terrain Flags, its Width and its Height into their respective members in the TerrainEntity structure.

```
                    // Terrain, per-type processing
                    if ( Terrain.TerrainType == 0 )
                    {
                        memcpy( &Terrain.Flags, pEntityData, sizeof(ULONG) );
                        pEntityData += sizeof(ULONG);

                        memcpy( &Terrain.TerrainWidth,
                                pEntityData, sizeof(ULONG) );

                        pEntityData += sizeof(ULONG);

                        memcpy( &Terrain.TerrainHeight,
                                pEntityData, sizeof(ULONG) );

                        pEntityData += sizeof(ULONG);
```

After the width and height values in the file there is an unsigned short value informing us of the length of the filename string that follows (the heightmap image file). First we copy this value into a temporary

value called StringLength so we know how long the filename that follows will be, then we advance the data pointer to point at the beginning of this string, and finally we copy the filename from the data area into the TerrainDef character array of the TerrainEntity structure. This is shown below.

```
memcpy( &StringLength, pEntityData, sizeof(USHORT) );
pEntityData += sizeof(USHORT);

if ( StringLength > 0 )
   memcpy(Terrain.TerrainDef, pEntityData, StringLength );

pEntityData += StringLength;
```

All strings stored in the entity are defined in this way (i.e., prior to the string data will be an integer value describing the length of the string that follows).

After the filename of the heightmap in the data area, we will find two more strings (with their associated lengths) containing the filenames of the base and detail textures. Once again, the same technique is used for copying into the TerrainTex and TerrainDet members of our TerrainEntity structure.

```
memcpy( &StringLength, pEntityData, sizeof(USHORT) );
pEntityData += sizeof(USHORT);

if ( StringLength > 0 )
memcpy( Terrain.TerrainTex, pEntityData, StringLength );
pEntityData += StringLength;

memcpy( &StringLength, pEntityData, sizeof(USHORT) );
pEntityData += sizeof(USHORT);

if ( StringLength > 0 )
memcpy( Terrain.TerrainDet, pEntityData, StringLength );
pEntityData += StringLength;
```

The final two pieces of data to extract from the data area are the terrain scale (3D vector) and the detail map scale (2D vector). The following code copies these into the TerrainScale and TerrainDetScale members of the TerrainEntity structure.

```
memcpy( &Terrain.TerrainScale, pEntityData,
         sizeof(D3DXVECTOR3) );
pEntityData += sizeof(D3DXVECTOR3);

memcpy( &Terrain.TerrainDetScale, pEntityData,
        sizeof(D3DXVECTOR2) );
pEntityData += sizeof(D3DXVECTOR2);
```

At this point we have extracted all the data from the terrain entity data area and now have it stored in a TerrainEntity structure. We will now generate the terrain object.

First we call the CScene::AddTerrain method to make space at the end of the scene's CTerrain pointer array for an additional pointer. We then allocate a new CTerrain object.

```
                        // Add a new slot ready for the terrain
                        if ( AddTerrain( 1 ) < 0 ) break;

                        // Allocate a new terrain object
                        pNewTerrain = new CTerrain;
                        if ( !pNewTerrain ) break;
```

We send the terrain object the 3D device and the CTextureFormatsEnum object we are using so it can store the pointers internally for its own use. We also call the SetWorldMatrix method and send it the entity's matrix. We then set the data path so that the terrain knows where to find its texture images and heightmap files. Finally, we store the pointer of our new CTerrain object at the end of the scene object's terrain array.

```
                        // Setup the terrain
                        pNewTerrain->SetD3DDevice( m_pD3DDevice, m_bHardwareTnL );
                        pNewTerrain->SetTextureFormat( m_TextureFormats );
                        pNewTerrain->SetRenderMode(GetGameApp()->GetSinglePass());
                        pNewTerrain->SetWorldMatrix((D3DXMATRIX&)
                                                    pFileEntity->ObjectMatrix );

                        pNewTerrain->SetDataPath( m_strDataPath );

                        // Store it
                        m_pTerrain[ m_nTerrainCount - 1 ] = pNewTerrain;
```

We now call the CTerrain::LoadTerrain method passing in the TerrainEntity structure that we have filled out. We know that this is the function that will generate the terrain geometry. We also register the CTerrain player and camera callbacks with the player object (used for collision purposes) and our job is done.

```
                        // Load the terrain
                        if ( !pNewTerrain->LoadTerrain( &Terrain ) ) return false;

                        // Add the callbacks for collision with the terrain
                        GetGameApp()->GetPlayer()->AddPlayerCallback(
                                     CTerrain::UpdatePlayer, pNewTerrain );

                        GetGameApp()->GetPlayer()->AddCameraCallback(
                                           CTerrain::UpdateCamera, pNewTerrain );

                    } // End if 'standard' terrain

                    break;
```

The next and final section of this function is executed if the entity being processed is a GILES™ fog entity. The GILES™ fog entity has an entity ID of 0x204 and we set up a define in CScene.h as shown below:

```
#define CUSTOM_ENTITY_FOG       0x204
```

The first thing we do inside the fog case block is test a boolean variable called FogBuilt. If it was already set to true we skip the entity because it is possible that multiple fog entities might exist in the IWF file and we are only interested in finding and using the first one. Once we have processed this fog entity, the boolean will be set to true and any other fog entities will be ignored.

```
                case CUSTOM_ENTITY_FOG:

                    // We only want one fog setup per file please! :)
                    if ( FogBuilt == true ) break;
                    FogBuilt = true;
```

The data area of the fog entity is laid out in exactly the same way as the FogEntity structure we discussed earlier, so we will extract the data straight into this structure. Here is the remaining code to the function.

```
                    // Retrieve the fog entity details.
                    memcpy( &Fog.Flags, pEntityData, sizeof(ULONG) );
                    pEntityData += sizeof(ULONG);

                    memcpy( &Fog.FogColor, pEntityData, sizeof(ULONG) );
                    pEntityData += sizeof(ULONG);

                    memcpy( &Fog.FogTableMode, pEntityData, sizeof(ULONG) );
                    pEntityData += sizeof(ULONG);

                    memcpy( &Fog.FogVertexMode, pEntityData, sizeof(ULONG) );
                    pEntityData += sizeof(ULONG);

                    memcpy( &Fog.FogStart, pEntityData, sizeof(float) );
                    pEntityData += sizeof(float);

                    memcpy( &Fog.FogEnd, pEntityData, sizeof(float) );
                    pEntityData += sizeof(float);

                    memcpy( &Fog.FogDensity, pEntityData, sizeof(float) );
                    pEntityData += sizeof(float);

                    // Process the fog entity (it requires validation etc)
                    if ( !ProcessFog( Fog ) ) return false;

                    break;

                } // End Entity Type Switch

            } // End if custom entities

        } // Next Entity

        // Success!
        return true;
}
```

Notice that after we have extracted the fog information into the FogEntity structure, we call a new member function of CScene called ProcessFog.

CScene::ProcessFog

This function is passed the FogEntity structure that contains all the fog settings loaded from the fog entity. This function has the task of testing the requested fog settings to see if they are supported by the device and modifying any settings that are not.

```
bool CScene::ProcessFog( const FogEntity & Fog )
{
    D3DCAPS9  Caps;
    CGameApp *pApp          = GetGameApp();
    bool      bTableSupport = false, bVertexSupport = false;
    bool      bRangeSupport = false, bWFogSupport   = false;

    // Disable fog here just in case
    m_bFogEnabled = false;

    // Validate requirements
    if ( !m_pD3DDevice || !pApp ) return false;

    // Store fog entity
    m_FogEntity = Fog;

    // Retrieve the card capabilities (on failure, just silently return)
    if ( FAILED( m_pD3DDevice->GetDeviceCaps( &Caps ) ) ) return true;
```

The first section of the function shown above starts by setting CScene::m_bFogEnabled to false. We do this just in case fog is not supported. If this is not set to true at some point in the course of this function the render function for CScene will not set any fog parameters. We also store the passed FogEntity structure in the CScene member variable m_FogEntity since this is the structure the CScene::Render function will use to set up the fog parameters for the DirectX pipeline. Then we call the IDirect3DDevice9::GetDeviceCaps method to get the capabilities of the device.

In the next section of code we query four device capabilities and set four local booleans to true or false based on whether they are supported are not. We need to test support for four fog settings:

1. Is table/pixel fog supported on this device?
2. Is vertex fog supported on this device?
3. If vertex fog is supported does it support the more desirable range based vertex fog (instead of view space Z depth fog)?
4. If table fog is supported does it support the use of the W component in its fog calculations (view space Z) or does it use 0.0-1.0 device coordinates (Z buffer coordinates). W based table fog is more desirable for two reasons. First, the Z buffer coordinates have a very non-linear distribution of depth values causing flaky fog effects for objects in the far distance. Second, it is much nicer when using the linear fog model to specify the fog start and fog end distances using view space Z values instead of using 0.0-1.0 normalized device coordinates.

The next section sets the booleans based on the device capabilities. It returns immediately if the device does not support vertex or table fog. If this is the case, our application will not be able to use fog.

```
    // Retrieve supported modes
    bTableSupport  = (Caps.RasterCaps & D3DPRASTERCAPS_FOGTABLE) != 0;
    bVertexSupport = (Caps.RasterCaps & D3DPRASTERCAPS_FOGVERTEX) != 0;
    bRangeSupport  = (Caps.RasterCaps & D3DPRASTERCAPS_FOGRANGE) != 0;
    bWFogSupport   = (Caps.RasterCaps & D3DPRASTERCAPS_WFOG) != 0;

    // No fog supported at all (silently return)?
    if ( !bTableSupport && !bVertexSupport ) return true;
```

Next we perform a few simple comparisons. If the passed TerrainEntity structure had the FOG_PREFERTABLEFOG flag set but the device does not support table fog, we will un-set this flag.

```
    // Strip table flag if not supported
    if ( !bTableSupport ) m_FogEntity.Flags &= ~FOG_PREFERTABLEFOG;
```

If vertex fog is not supported, then table fog must be supported or we would have returned from the function already. Therefore, we make sure that the FOG_PREFERTABLEFOG flag is set. This flag will only be forcefully set if vertex fog is not supported. If vertex fog is supported and the level creator did not specify the preference for table fog, vertex fog will be used.

```
    // Ensure use of table if vertex not supported
    if ( !bVertexSupport ) m_FogEntity.Flags |= FOG_PREFERTABLEFOG;
```

At this point, we have modified the TerrainEntity structure's Flags member such that we know whether we are going to use table fog or vertex fog. In table fog mode we have something else to worry about. If WFog is not supported, we will need to adjust the Fog Start and Fog End members of the terrain entity structure so that they are specified in normalized device coordinates instead of as view space Z values.

The next section of code is executed if table fog is going to be used.

```
    // Fog mode specific setup
    if ( m_FogEntity.Flags & FOG_PREFERTABLEFOG )
    {
        // Ranged is never supported in table mode, strip it
        m_FogEntity.Flags &= ~FOG_USERANGEFOG;

        // If WFog is not supported, we have to adjust these values
         // to ensure that they
        // are in the 0 - 1.0f range.
        if ( !bWFogSupport )
        {
            float fNear = pApp->GetNearPlaneDistance();
            float fFar  = pApp->GetFarPlaneDistance();

            // Shift into range between near / far plane
            m_FogEntity.FogStart -= fNear;
            m_FogEntity.FogEnd   -= fNear;
            m_FogEntity.FogStart /= fFar;
```

```
            m_FogEntity.FogEnd   /= fFar;

        } // End if no WFog support

    } // End if using table mode
```

If the FOG_USERANGEFOG flag is set in the terrain entity structure we remove it since range fogging is only applicable to vertex fog mode. We then test to see if W fog is supported. If it is, then we have nothing else to do since the Fog Start and Fog End members in the terrain entity structure will already be defined in view space (exactly how we should pass them to the pipeline). If it is not supported, we need to map these values into the [0.0, 1.0] range between the near and far planes. We do this by retrieving the near and far plane values currently being used by the CGameApp class via two of its member functions. We then subtract the near plane from the start and end values and divide them by the far plane value. This results in fog start and end values in the [0.0, 1.0] range that describe depth values between those two planes.

Finally if vertex fog is being used instead of table fog, we test to see if the range fog is supported and if not, we make sure the range fog flag in the terrain entity structure is unset.

```
    else
    {
        // If ranged is not supported, strip it
        if ( !bRangeSupport ) m_FogEntity.Flags &= ~FOG_USERANGEFOG;

    } // End if using vertex mode

    // Enable fog
    m_bFogEnabled = true;

    // Success!
    return true;
}
```

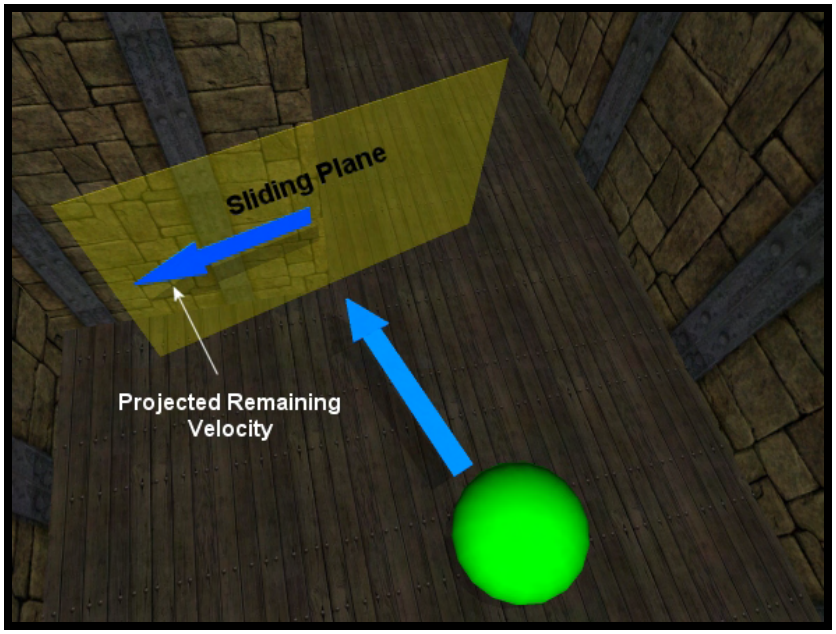
At the end of the function we set the scene's m_bFogEnabled boolean to true so the render function knows to use fog.

Conclusion

A good deal of this workbook has been about consolidating much of what we have learned over the series and upgrading our application framework to support some more advanced constructs. We now have an easy way to describe complex animation sequences for our actor and we have upgraded our code to support multiple terrains, fog, animated actors, trees, and meshes all within the same scene. This is a good place to end the first half of this course because for the remainder of this course, our focus is going to shift almost entirely into the realm of engine design topics. While the goal will not be to design our final game engine just yet (that is our job in Module III), it will be to lay a foundation to do exactly that. We have a lot of extremely important generic game programming topics we need to get through in the coming weeks, so make sure that you feel comfortable with everything we have covered to date.

Chapter Twelve

Collision Detection and Response



Introduction

Since the first lesson in this series we have been implementing visualization applications that permit the camera and other entities to move through solid objects in the game world. But realism in games requires a sense of physical presence and adherence to some simple laws of physics in addition to the visual experience. In the real world, two objects should not be able to simultaneously share the same location. Doing so would indicate that the objects are interpenetrating one another. Since this is not a valid real world state, it cannot be a valid game state either if we want the player to feel as though they inhabit a physical and interactive game space. What our application needs is a means for determining when this situation occurs as well as a means for doing something about it when it does. These two roles fall into the aptly named categories: collision detection and collision response, respectively.

Collision detection and response is actually one of the more heavily researched areas in academic and industrial computer science because there are so many beneficial applications. For example, automobile manufacturers can develop simulations that model various impact phenomena and apply what they learn to improve safety. Of course, as game programmers, we obviously do not have to worry about life and death collision issues in our simulations, and thus our game requirements will be far less demanding. Indeed we will even allow ourselves to occasionally bend or even break the laws of physics and do things that would be virtually impossible in the real world because the results just look better on screen.

More importantly, given the steady increase of geometric complexity in 3D models and environments, it is critical that fast and precise collision determinations and corrections can be made for real-time applications to be able to benefit. Not surprisingly, speed and precision are inversely proportional concepts. The more precise we want our simulation to be, the longer it will take to perform the calculations. Testing every polygon of every object against every polygon of every other object will certainly provide a good amount of precision, but it will be expensive. Modeling proper physics equations in our response engine will generate very precise results, but it will not be as quick as using decent looking (or feeling) approximations. What is required is an appropriate degree of balance between our need for speed and our desire for accuracy.

There are a number of collision systems available to the game developer. Some are free and others are available for purchase and/or licensing. Some systems focus exclusively on the detection portion (SOLID™, I-COLLIDE™, V-COLLIDE™, etc) and require the developer to implement the response phase, while others will include the response side as well (rigid body physics libraries like Havok™ fall into this category and they often include lots of wonderful extra features). The system we will implement in this chapter will include both collision detection and collision response.

This is going to be challenging subject matter, but it is a system that involves concepts that every game programmer should be familiar with. Many of you may even have to implement a system like this at some point in your career. It is probably fair to say that, given the complexity of such systems, many of you may find this chapter to be the most demanding in the training series so far. This is due in large part to a heavy reliance on a significant number of mathematical formulas that must be understood to achieve accurate intersection determination. Rest assured though that we will make every effort in this chapter to try to leave no stone unturned. Hopefully you will find that when all is said and done, it was not so bad after all.

12.1 Our Collision System (Overview)

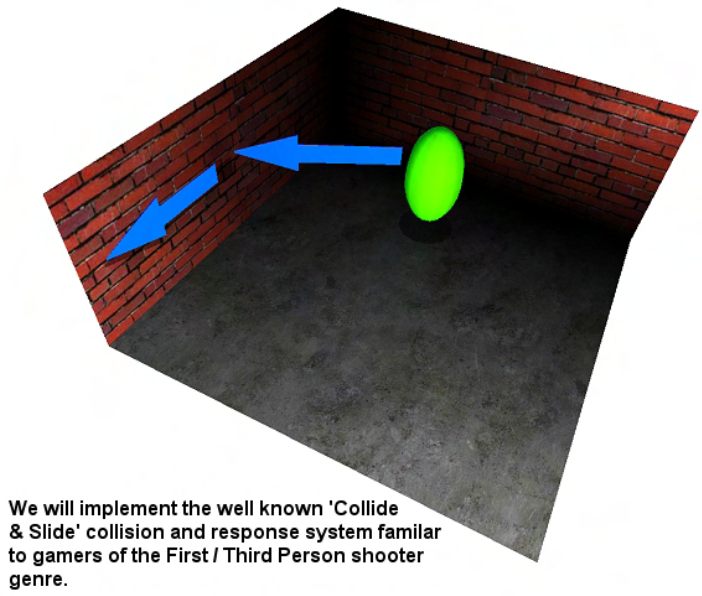
To more accurately model a physical environment, if the user wishes to move in a certain direction at a certain speed, our input code can no longer simply obey this request as it did before. This would allow the player to move through solid objects or embed himself in walls, floors, etc. The same would hold true for other moving objects. Therefore, before any moving entity in our game world can set its final position, it must feed the collision system with information about where it is currently located and where it would like to go. The collision system is tasked with determining whether a clear and unobstructed path is available. If there is a path, then it will let the caller know that it can move the entity to the desired location. If the path is blocked by one or more polygons, then the collision system will calculate and return a final position for the entity that will be different than the requested destination. Suffice to say that the moving entity ultimately ends up deferring to the collision system when it comes to navigating around in the game world. When a clear path is not available, the collision system will essentially say to the entity, "You cannot move where you wanted to move because something was in the way. However, you can move to this other location instead, which has been tested and found to be free from obstruction". Ultimately, the collision detection and response system is responsible for calculating positions that are guaranteed not to be embedded in any solid geometry that comprises the scene.

So our task in this chapter is to figure out a way to prevent moving objects from passing through the polygons that comprise our environment – easier said than done, of course. In Lab Project 12.1 we will use the camera (or more correctly, its attached CPlayer object) as the moving entity we wish to navigate through the level with simulated collision detection and response. We will also have the ability to switch to a third person mode where we will see a skinned character using the collision system in the same way. This will demonstrate that our collision system can be used by any moving entities in the game world to achieve the desired results.

To further clarify the interaction between the moving entity and the collision system we will implement in this chapter, imagine that our moving entity is an ellipsoid and that we wish to move it forward from its current position by 25 units along the world Z axis (velocity vector V = <0, 0, 25>). The entity's current position and its desired velocity vector would be fed into the collision system as a request for a position update. The collision system would then check whether any of the game world polygons would block the displacement of the ellipsoid along this path. For example, let us assume that there is a wall at a distance of 10 units in front of our moving entity. In such a case, our object should only be allowed to move as far as the wall with respect to traveling along its velocity vector (a distance of 10 units).

The collision detection system would initially detect that a collision would occur with the wall. The position that it gives back would be one that corresponded to the entity being just in contact with the wall (i.e., it is moved as far as it can go in the direction described by its velocity vector). Indeed, given this bit of knowledge, we could even say that the collision system *prevents* interpenetration from ever happening. But what about the remaining velocity? We originally wanted to travel 25 units forward, but only managed to travel 10 units before a collision was determined and additional forward movement was prevented. So in a sense, we have an 'energy surplus' that could theoretically carry us for another 15 units of travel. How we handle this remaining velocity is very much a function of the type of collision response system we decide to implement (i.e., our game physics).

In this chapter, the response system we implement will model those that are typically seen in 3D computer games of the 1st/3rd person genre. When a collision is detected, the moving entity will not simply stop at the obstructing polygon and have its excess velocity discarded. Instead, it will slide around such obstructions where possible and use up its remaining velocity. Such a response system will allow us to slide along walls, go up and down stairs and ramps, and smoothly glide over recesses in walls and floors. This is a very common response system in games because it maintains a sense of fluid movement and prevents the player (or other NPCs) from getting stuck on surfaces and edges during fast-paced gameplay.



We will implement the well known 'Collide & Slide' collision and response system familar to gamers of the First / Third Person shooter genre.

Figure 12.1

Our collision system will consist of a *detection phase* and a *response phase*. Both will be called either iteratively or recursively until the energy contained in the initial velocity vector has been completely spent and the entity rests in its final non-penetrating position (more on this later). When a request is made to the collision system to update the position of a moving entity and a collision occurs, the detection phase will determine a position that is flush against the closest colliding polygon (a wall for example). The system response phase will then project any remaining velocity onto what we call the *slide plane*. In the simplest collision cases, the slide plane is simply the plane of the polygon that was collided with (the wall plane, using our current example). There are more complex cases where the moving entity collides with the edge of a polygon (such as on an external corner where two polygons meet or on the edge of a step) where the slide plane will be determined independently from the plane of the collision polygon, and we will discuss such cases later. In the end, this system will allow the moving entity to slide up or down those steps and around such corners.

In Figure 12.1 we see the simple case where the movement of an ellipsoid would cause a collision with a wall. The ellipsoid could only be moved as far as the wall given the information returned by the detection step. Any remaining velocity would be projected onto the slide plane (the wall polygon) in the first iteration of the response step. This results in yet another velocity vector (called the *slide vector*) along which to move the ellipsoid during the next iteration of the system. Moving the ellipsoid along this new velocity vector would result in the appearance of our ellipsoid sliding along the wall.

So we now know that the information returned from the collision step allows us to move the entity into a guaranteed unobstructed position along the velocity vector, and we will spend a lot of time later in this chapter learning how the collision detection phase does this. We also know that the response portion of our system will then project any remaining velocity onto the potential sliding plane to create a new velocity vector along which to slide (starting from the new position determined by the detection phase results). If the detection phase was able to determine that the entity could move to its requested position without a collision occurring, then there will obviously be no remaining velocity for the response phase

to handle. When this is the case, the collision system can simply return immediately and notify the moving entity that it can indeed move into its requested position along the velocity vector. Likewise, even if a collision did occur, if the remaining velocity that is projected onto the sliding plane is so small as to be considered negligible, then we can also return from the collision system with the new position that has been calculated. Remember, the detection phase will always calculate the closest position such that the entity is *not* interpenetrating (or passing through) any geometry. So even if we hit a wall head-on and the projected remaining velocity was zero, we can still return this new position back to the application so that it can update the old position of the entity to this new position (e.g., snug against a wall).

Not surprisingly, the real challenge occurs when the response step successfully projects the remaining velocity vector onto the sliding plane and the result is a slide vector of significant length. In these cases, we find ourselves with an iterative situation. The detection step detects an intersection along the original velocity vector and we calculate a new position such that the entity is moved as far along that vector as possible until the moment the collision occurred. The response step then projects any remaining velocity onto the sliding plane to create a new velocity vector. So in effect, the true position of the entity after the collision should be calculated by adding the new projected velocity (calculated in the response step) to the new position of the entity (calculated by the detection step). Imagine the simple case of an entity hitting a wall at an angle. The collision detection phase would move the entity up as far as the wall and return this new non-intersecting position. The response step would then project any remaining velocity onto the wall to create a new velocity vector pointing along the wall, describing the sliding direction. Therefore, the correct position of the entity after collision processing should be the combination of moving it up to the wall (detection phase) and then sliding it sideways along the wall using its new projected velocity vector (response phase).

> **Note:** It is important to make clear at this point that the terminology and descriptions we are using here are for illustration only. For example, the detection phase does not actually "move" anything. What it does, taking into account the entity's original position, velocity, and bounding volume, is determine the point beyond which the entity cannot go because something in the environment blocks it. It does not physically move the entity, but rather simulates what would happen if we did move the entity according to the requested velocity. However, for the purposes of our current high level discussion, it can be helpful to think of the breakdown of responsibility between the two system phases in the way just described. Later on we will see the precise inner workings of both system components and the details will become clearer to you.

At first, what we just described does not sound like a problem at all. After all, we have the new position and the new projected velocity vector that we have just calculated, so surely we can just do:

Final Position = New Position + New Velocity

In this case, New Position is the guaranteed non-intersecting position of the entity along the original velocity vector calculated during the detection phase and New Velocity is the remainder of the original velocity vector projected onto the sliding plane, starting from New Position.

While this is true, the problem is that we do not know whether the path to this Final Position is free from obstruction. When the collision detection phase was first invoked, it was searching for intersections along the original velocity vector (which it correctly determined and returned a new position for). But

certainly we cannot simply slide the entity along the projected velocity vector calculated by the response step without knowing that this path is also free from obstruction.

As you might have guessed, our solution will need to involve either a recursive or iterative process. If the projection of the remaining velocity vector onto the sliding plane is not zero, we must feed our new position (returned from the detection phase) and our new velocity vector (calculated in the response phase) into the detection phase all over again. The detection phase will then determine any intersections along the new velocity vector and calculate a new position for the entity. This is passed on to the response step and the whole process repeats (potentially many times). It is only when the entity has been successfully moved into a position without any intersections or there is no remaining velocity left to spend beyond the point of intersection, that we can be satisfied that our task is complete. Then we can return a final resting position for our moving entity that we are confident is free from obstruction.

Given the iterative nature of the system, performance is obviously going to be a very real concern. This is especially true when we consider that the detection phase will theoretically need to check every polygon in the scene every time it is invoked in order to accurately determine unobstructed locations. Given the polygon budget for current commercial game environments, testing every scene polygon during every call to the detection phase is not an acceptable design. As a result, commercial collision systems will implement some manner of hierarchical spatial partitioning that encapsulates scene polygons into more manageable datasets for the purpose of faster queries. Indeed, once we have a working collision detection and response system of our own, we will integrate our own spatial partitioning technique (a quad-tree, oct-tree, kD-tree, etc.) to reduce the number polygons that need to be tested for intersection when the detection phase is invoked. We will be examining spatial partitioning techniques and data structures in the next chapter with an eye towards speeding up the detection phase. For now though, we will forego any concerns about optimization and concentrate solely on the core system components and how they work.

Before moving on, let us summarize some of the ideas presented:

1. The collision system will be invoked by the application whenever it wishes to move an object.
2. The collision system inputs will be the current position of the moving entity and a velocity vector describing a direction and distance over which to move the entity. We will also want to input information describing the shape/volume of the entity.
3. The position and velocity are initially passed into the **collision detection phase** of the collision system. This goal of this phase is finding the closest colliding polygon. If no such polygon exists, the system can return the sum of the position and velocity vectors. If a colliding polygon is found along the path of the moving entity:
    a. Calculate and return a new position that it is as far as possible along the input velocity vector, stopping at or before the point where an intersection would occur.
    b. Calculate and return a normal at the point of intersection. In our system, this will act as the normal of a plane that the entity should slide along if there is any velocity remaining beyond the point of intersection.
4. The updated position, the remaining velocity, and the slide plane normal (i.e. intersection normal) are input into the **collision response phase**. The goal in this phase is to apply whatever physics are needed to calculate the contact response of the entity. In our system, we will project the remaining velocity vector onto a sliding plane to generate a new velocity vector that points in

the direction that the entity should slide. We will then pass the updated position and slide velocity vector back into the system to begin the process anew.

Note: Steps 3a and 3b above are not always necessarily going to be tasks assigned to the collision detection phase in every collision system on the market. In fact, most collision detection systems literally just tell you the polygon(s) intersected, and both when and where those intersections occurred. Our detection phase will do a bit more internal housekeeping to make things a little easier to process. Theoretically, these jobs could just as easily have been assigned to the response phase of the system. How you decide to do it in your own implementations is totally up to you.

Later we will learn that the projection of the slide vector will be scaled by the angle between the original velocity vector and the normal of the sliding plane. This way, if we collide with a wall at a very shallow angle, much of the remaining velocity will survive the projection onto the sliding plane and our moving entity will slide along the wall quite quickly. However, if we collide with the wall at a very steep angle (almost perpendicular) then we are hitting the object virtually head-on and the projected velocity vector will be very small, if not zero. In this case we significantly reduce all forward movement and do not slide very much (if at all). This is the response behavior that is implemented in most commercial first-person shooter games.

Figure 12.2 demonstrates the dependency between the projection of the original velocity vector onto the sliding plane and the angle between the original velocity vector and the slide plane normal. In this image, Source is the position of a sphere prior to the update. (We will assume that the sphere is a bounding volume used to describe our moving entity inside the collision system). This current sphere position is one of the initial inputs to the collision system. The red dotted line describes the original velocity vector. This vector tells the collision system both the direction and distance we wish to move the entity. By adding the velocity vector and the Source vector, we get the Original Dest vector which describes the position we wish to move our sphere to (provided that no collisions occur).

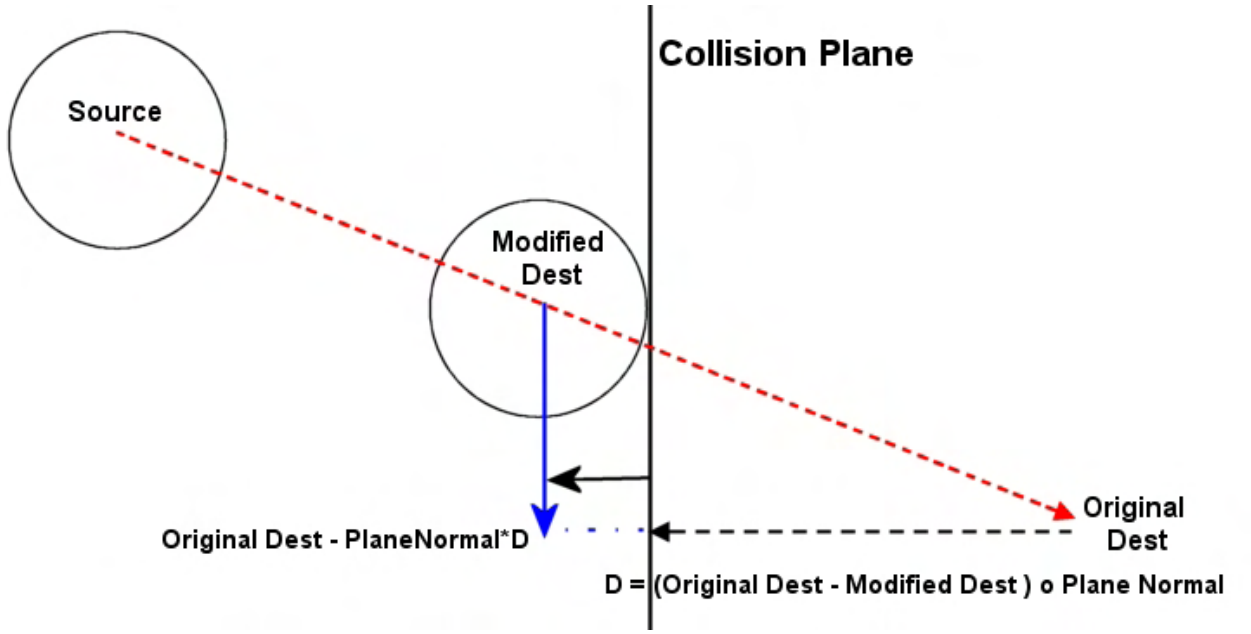


Figure 12.2

We know that the first thing we do is feed this information into the collision detection phase. We are imagining in this instance that a polygon (whose plane is marked as Collision Plane) was found to be blocking the intended path. The detection phase would thus need to return the new sphere position, called Modified Dest, since Original Dest is unreachable. Note that Modified Dest is a sphere position that it is touching, but not intersecting (i.e. does not penetrate), the Collision Plane. We can see clearly that the center of the original sphere only traveled a little less than halfway along the requested velocity vector before hitting the plane, so there is certainly some "leftover" velocity that we can use for sliding. The remaining velocity vector in this example is the vector from Modified Dest (the new center position of the sphere) to Original Dest (the final position of the sphere as originally intended).

When the collision detection phase returns, we have a new sphere position (Modified Dest) and a slide plane normal (the normal of Collision Plane). We can calculate any remaining velocity as:

Remaining Velocity Vector = OriginalDest – Modified Dest

If we perform a dot product between the remaining velocity vector and the unit length plane normal, we get D. D is the length of the adjacent side of a triangle whose hypotenuse is given by the remaining velocity vector (the length of the black dotted line in Figure 12.2). By subtracting D from the Original Dest vector, along the direction of the plane normal, we create the vector shown as the blue arrow in the diagram. This is the projected velocity vector, which forms the opposite side of the triangle. As you can see, this is the direction the sphere should move (i.e., along the plane) to use up the remainder of its velocity. It should also be noted that as the angle of the original velocity vector gets closer to perpendicular with the plane normal, the projected velocity is scaled down more and more until hardly any sliding happens at all (i.e., when the sphere it hitting the plane head-on).

There are times when the slide plane normal returned from the detection routine will not be the same as the normal of the polygon the entity intersected. This is typically the case when the entity collides with a polygon edge (see Figure 12.3).

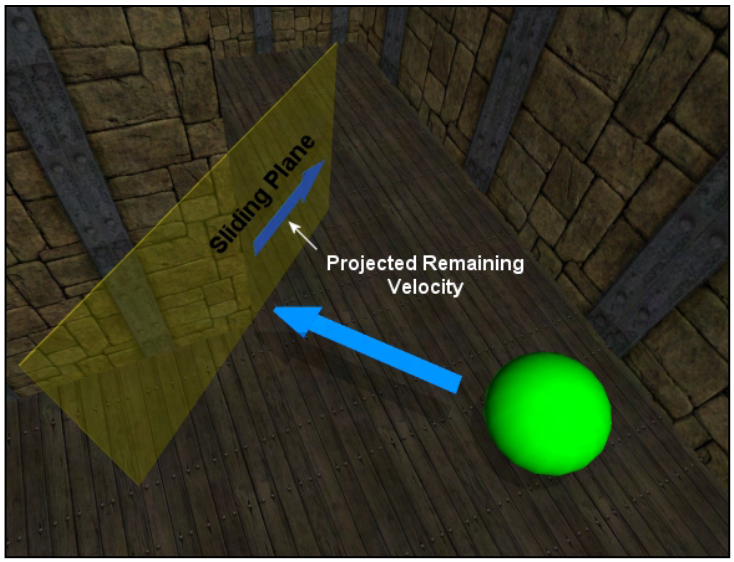

Figure 12.3

In Figure 12.3 we can see that if the green sphere was moved in the direction of the blue arrow, it would collide with the edge where two polygons meet to form an external corner. When this is the case, we want the angle at which the sphere intersects with the edge to determine the orientation of the slide plane. As it happens, this is quite simple to calculate.

When the detection phase calculates the intersection between the edge of a polygon and an entity (a sphere in this example), it will generate the plane normal by building a unit length vector from the intersection point on the edge

to the sphere center point. If you imagine drawing a line from the center of the sphere to the point on the edge where the sphere would hit the corner, you would see that this vector would be perpendicular to the slide plane shown in Figure 12.3. Normalizing this vector gives us the slide plane normal and indeed the slide plane on which to project any remaining velocity that may exist. We can see that in this example, when the sphere hits the edge, it would slide around the corner to the right. Because the slide plane normal returned from an edge intersection is dependant on the position of the entity (the sphere center point in this example), we can see that a different sliding plane would be generated from a collision against the same edge if the sphere used a different angle of approach (see Figures 12.4 and 12.5).

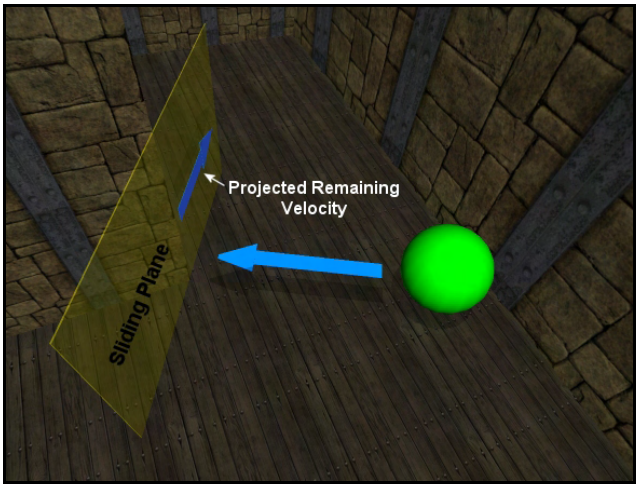

Figure 12.4

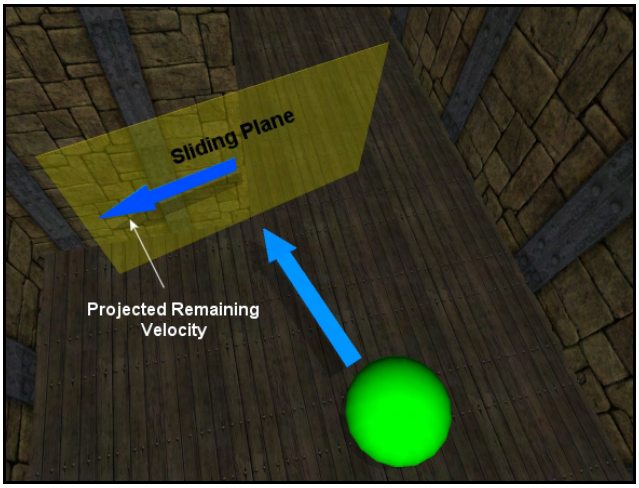

Figure 12.5

It is the sliding plane (and the projection of the remaining velocity vector onto this plane) that also allows the system to automatically handle the navigation of stairs and ramps as well. For example, in Figure 12.6 we see the same sphere attempting to navigate a flight of stairs.

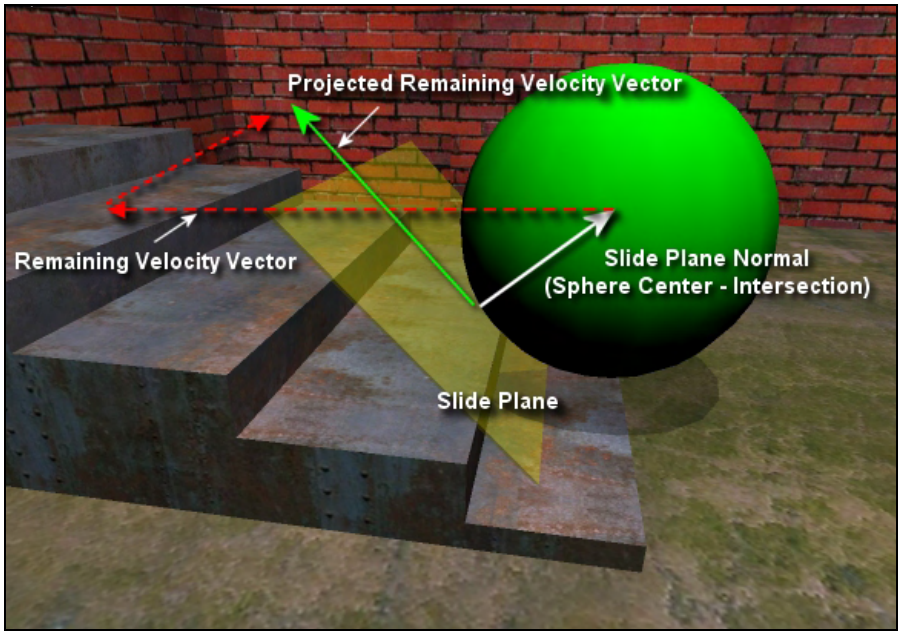

Figure 12.6

In this case, the sphere is already beyond the edge the first step and is trying to travel forward from its current position when it intersects the edge of the second step. The long red dashed line traveling from the sphere center and pointing to the left is the remaining velocity vector after we have first collided with the second step edge.

The small red dashed line shows us the direction of the projection of the remaining velocity vector onto the slide plane.

The collision detection step would determine that somewhere in the bottom left quadrant of the sphere an intersection would happen with the edge of the second step. The slide plane normal would be generated by calculating a vector from this intersection point on the step edge to the sphere center point and normalizing the result. The yellow transparent quad shows the slide plane that would be created for this normal and the plane. This is the plane onto which the response step will project any remaining velocity.

The dot product between the remaining velocity vector (the section of the vector that starts at the new sphere center position calculated by the detection phase) and the slide plane normal creates a new vector tangent to the plane describing the direction in which the sphere should continue to move. This is shown as the green arrow labeled Projected Remaining Velocity Vector. Suffice to say, it is by moving the sphere from its current position (calculated by the detection phase) along this slide vector, that the sphere ends up in its correct final position for the update. We will have moved the sphere as much as possible in the original direction and then diverted all remaining velocity in the slide direction.

As mentioned previously however, the response step cannot simply assume that it can add the slide vector to the position of the new sphere center without testing for obstruction. That is why the response phase must invoke the detection phase again, using the new slide vector as the input velocity vector to the system. This in turn invokes another response phase, and so on. Only when the remaining velocity vector has zero (or near zero) magnitude, do we consider the sphere to be in its final position. Of course, this is always the case as soon as the detection phase determines that it can move the entity along its input vector (which may be the slide vector calculated in a previous response step) without obstruction, since there will be no remaining velocity vector in this instance when the detection phase returns.

Note as well that the height of the step with respect to the entity is very important. The shallower the step, the shallower the slide plane generated. Therefore, any remaining velocity vector will be more strongly preserved when projected onto the sliding plane. For example, in Figure 12.7 we can see the same sphere bounding volume trying to climb a much steeper flight of steps with larger step sizes. The point of intersection with the step is much higher up on the surface of the sphere than before. As such, the slide plane normal calculated from the intersection point to the sphere center position is almost horizontal. In this case, the slide plane is so steep that when any remaining velocity vector is projected onto it, it is almost scaled away to nothing. Depending on your implementation what you might see in

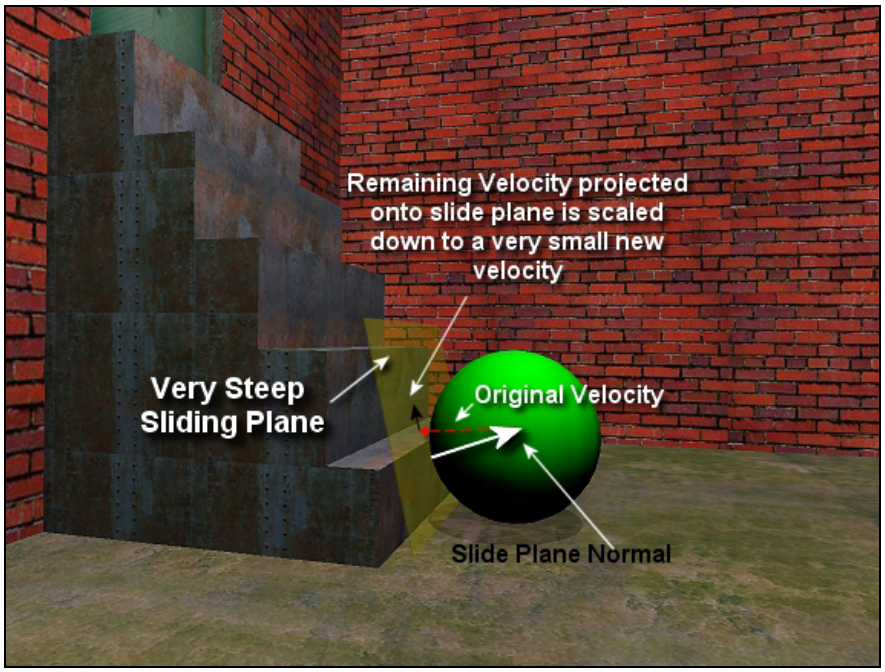

Figure 12.7

this situation is the sphere unsuccessfully attempting to mount the step. Perhaps you would even see a small upwards movement before the sphere came back down again.

Note that this is generally going to be the correct response for this situation. If we imagine the sphere in Figure 12.7 to be the bounding primitive for a character, one step alone would be about half the character's height. We would not expect a character in our game to simply slide over such large obstructions without having to perform some special maneuver (e.g. jumping or climbing). This is an extremely useful side effect of using the sliding plane style of collision response. Indeed it makes the system almost totally self-contained; it will correctly slide over small obstructions (such as steps and debris) and automatically generate very steep sliding planes for larger obstructions, where intersections with the sphere happen a fair way up from its base. Again, the taller the obstruction, the higher the intersection point between the sphere and the polygon will be. As such, the slide plane normal generated by subtracting the intersection point from the sphere center will be almost, if not totally, horizontal. As we have seen, very steep sliding planes zero out any remaining velocity during projection. Therefore, assuming the bounding volume is suitably tall to be consistent with the scale of the geometry, the response step will automatically create shallow sliding planes for collisions against small obstructions like stairs but stop the entity in its tracks when it collides head-on with taller obstructions.

You may wish to verify this behavior now by running Lab Project 12.1. Notice how the camera smoothly glides up stairs and ramps and, with the integration of gravity with the velocity vector, how it falls to the ground when the character walks off a steep ledge. In truth, the gravity vector is not really part of the collision system (it is implemented as part of the CPlayer class movement physics). Every time the position of the CPlayer (which the camera is attached to) is updated, it adds a gravity vector to its current velocity vector. Gravity acts as a constant force, accelerating the entity downwards along the negative world space Y axis during every frame. Since this velocity vector is an input to the collision system (technically, gravity is an acceleration, but we integrate it into a velocity vector for our physics calculations), the entity will automatically fall downwards when there is not a polygon underneath blocking the way. Without the floor of the level for it to collide against, the moving entity would continue to fall forever. While we will talk about this in much more detail later, it demonstrates that from the perspective of the collision system, even the floor of our level is just another polygon to collide and slide against.

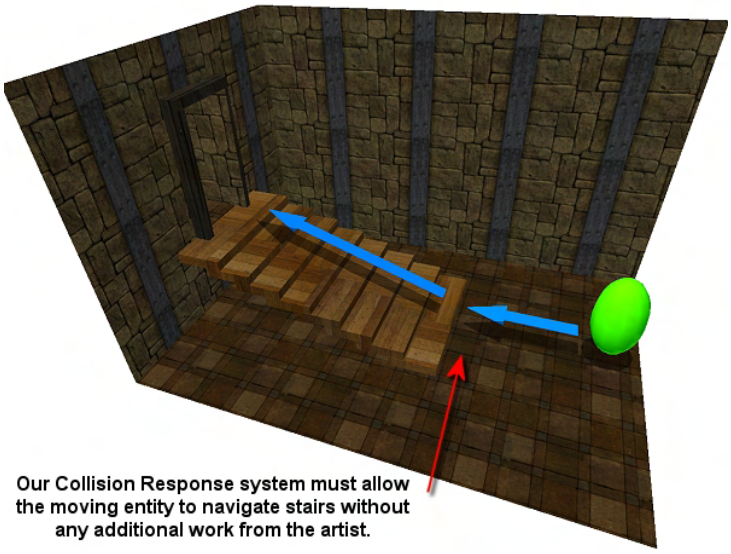

Figure 12.8

As mentioned, stairs and ramps are not the only obstructions that the sliding plane response can handle. It also allows us to slide over small obstructions placed in the game world using the same logic. We certainly would not want the player to be killed in the middle of an intense firefight because his character got stuck while running over a 2-inch thick wood plank. Indeed we want our artists to be able to populate the floor space of our game worlds with lots of interesting details like cracks, dips, splits and

piles of debris; we just do not want these geometric details to prevent us from navigating across the floor (unless they have been designed specifically to be large enough for that task). Our collision system will automatically handle such small obstructions (see Figure 12.9) using the sliding plane response mechanism.

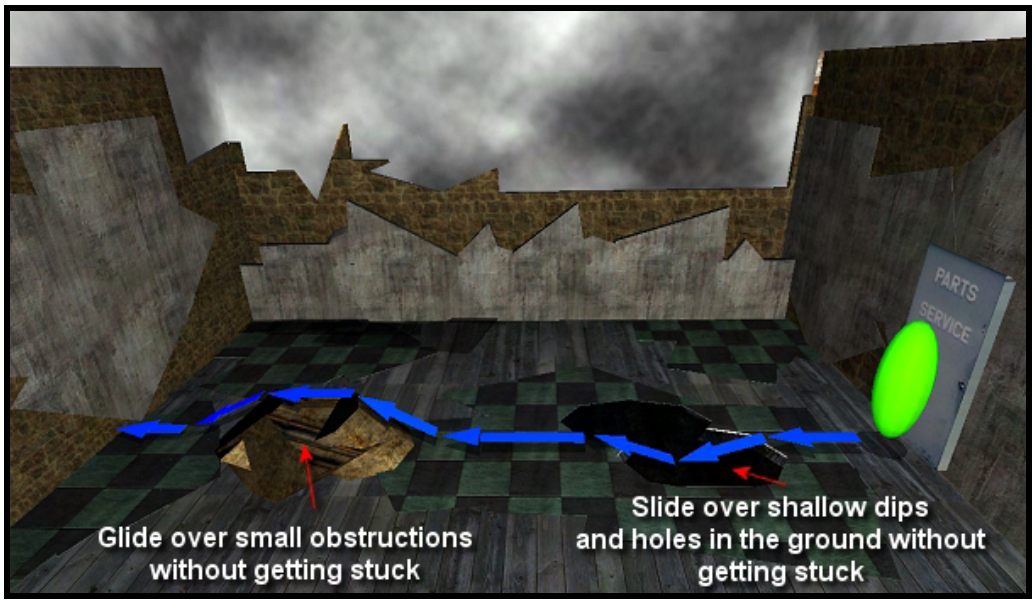

Figure 12.9

The sliding plane response concept will be familiar to gamers who enjoy titles in the first and third person game genres, but it is worth noting that this behavior is easily replaced or augmented according to application requirements. For example, you could replace the response system so that instead of projecting any remaining velocity, you calculate a reflection vector with respect to the collision plane. This would cause the objects to bounce off the polygons in the environment and might be a useful response system when implementing an outer space themed game. Alternatively, the response phase could be simplified so that the position returned from the first iteration of the detection phase of the collision system is used 'as is'. This would mean that when objects collide with the environment, they stop moving. This would feel a little bit like navigating around a world where all polygons are coated with a strong adhesive. While not very useful in most games, it would at least provide a sense of physical presence to your polygons. The larger point here is that your response physics can be as simple or as complicated as you want them to be. As long as you maintain separate detection and response sub-systems, you can configure your results as needed.

In actual practice, the (sliding) response phase we use in our collision system, which features most of the behavior we have discussed so far, can be implemented using only a few lines of code. It involves nothing more than projecting (using a dot product) the remaining velocity vector onto the sliding plane returned from the detection phase and then re-calling the detection phase with new input parameters. Technically, there are a few additional tests we will do in the response phase to reduce certain artifacts. For example, a jittering effect can occur when forcing an entity into an area where two polygons form an internal corner. This jittering results from trying to solve multi-polygon collisions one at a time rather than simultaneously (which is much more computationally expensive). Fortunately, jittering artifacts can be mostly eliminated with another dot product. This will make sure that during any iteration, the

response step does not try to slide the entity in the direction opposite the initial input velocity vector for a given position update. We will cover all of this in detail when we discuss the full implementation later in the chapter. For now, just know that the response phase is quite straightforward and will not require significant effort to implement.

The detection phase is much more complex. If all we had to do was detect was whether or not an entity's bounding volume currently intersects polygons in our scene database, then that would be fairly easy to do (relatively speaking – there is still a good amount of math involved, as we will see later). However, the objects we are concerned with are not standing still, so we have to detect whether the bounding volume will intersect any geometry in the scene *at any time* along its movement vector, before we actually move it. The mathematics for this are a little more involved. Our collision detection phase will also be responsible for returning a new position describing the furthest point the entity can move along that vector before the intersection occurred.

Before we begin our detailed examination of the detection phase and look at the various intersection routines we must implement that make it all possible, we will discuss our high level objectives for the system design and talk about some of the key components that will be necessary for the final system to come together. Note that this chapter is going to be a little different from previous ones in that we will actually be including a good amount of discussion of the lab project source code here in the textbook rather than leaving it all for the workbook. Looking at the source code should help cement a lot of the theory we will be introducing, so keep this in mind as you move forward.

12.2 The Collision System Design

As stated, our primary goal in this chapter is the implementation of a robust and reusable collision system. Along the way, we will progress through the development of a set of class code (CCollision) that can be used by moving entities in our game world to provide accurate collision detection and response. This collision system will be able to be plugged into all of our future applications and can be easily modified and extended to provide different response behaviors.

The collision detection phase will incorporate several static intersection routines. These routines will be included in the system's namespace. Because they are static, these intersection routines can also be called from any module outside the collision system. This will provide future applications with a useful library of intersection functions that can be used with or without the main collision system

> **NOTE:** Because our intersection routines are static and rely on no member variables of the CCollision class, they may be invoked using the CCollision namespace even if a CCollision object has not been instantiated.

Finally, the collision system we develop will place no burden on the project artists to create their geometry in a particular way to make it 'collision compliant'. A primary goal is for the system to work with arbitrarily arranged polygons and meshes (i.e., a polygon soup). This is not to say that you might not want to include artist-placed collidable geometry for particular game purposes (or to solve minor artifact problems should they occur), but that on the whole, the system should be able to work with anything we can throw at it.

12.2.1 Core Components

Our collision system will contain four main components:

Component 1: The Collision Geometry Database

Many tests will need to be made against the geometry of the environment to determine a clear path for a moving entity. Often, the triangles comprising the game world will reside somewhere that would make them either inefficient or impossible to access for collision testing. For example, the vertex data may reside in either local or non-local video memory, or it may have been compressed into a proprietary format that only the driver understands. Having to lock such vertex buffers will cause stalls in the pipeline if the geometry has to be un-swizzled into a format the application can read back and work with. If the buffer is located in video memory, we know that reading back data from an aliased pointer to video memory will result in very serious performance degradation.

Of course, we could create managed vertex buffers (i.e., a resident system memory copy maintained by the D3D memory management system) and lock this buffer with a read-only flag. This would allow our collision system to lock and read back that data without causing a pipeline stall or a possible re-compression step. But this is still far from ideal. When an entity moves, we do not want to have to lock vertex and index buffers and determine which indices in the index buffer and vertices in the vertex buffer form the triangles the entity must collide with. Large scenes would potentially require locking and unlocking many vertex and index buffers, and would prove to be terribly inefficient.

Thus, it is usually the case that a collision system will maintain its own copy of the scene geometry. That data can be stored in an application-friendly format in system memory, making it very efficient for the CPU to access. This is very important because the collision detection will be done by the host CPU and not by the graphics hardware.

Our CCollision class will expose a series of functions that will allow an application to register geometry with the collision system. Therefore our CCollision class will maintain its own **geometry database**. An application loading geometry for scene rendering can just pass the same triangle data into the collision system's geometry registration methods. As our collision system will allow us to pass triangle data to its geometry database as a triangle list, this makes it very convenient to use. Both X files and IWF files export triangle lists, so when our application loads them in, we can simply pass the triangle lists directly into the collision system so that it can store an internal copy for its own use. For convenience, the collision system we develop in this chapter will also allow us to pass in an ID3DXMesh or even a CActor object. It will handle registration of the triangle data contained with these object types automatically. Thus our application could load a single X file containing the main game level (using D3DXLoadMeshFromX for example) and just pass it into the CCollision geometry registration function. The collision system would then have its own copy of the scene geometry and all the information it needs about the environment.

So we will accept that the triangle data used for rendering and the data used for the collision system, while related, are totally independent from one another. While this obviously increases our memory requirements, the collision geometry need not be an exact copy of the triangle data used to render the game world. For starters, we can reduce memory footprint by eliminating unnecessary vertex components like normals and texture coordinates. Additionally, our geometry can be defined at a much coarser resolution to speed up collision queries and to conserve memory. For example, instead of our moving entity having to test collisions with a 2000 triangle sphere, the collision detection geometry version of this sphere may be made up of only 100 polygons approximating a rougher bounding volume around the original geometry. This allows us to speed up collision detection by reducing the number of triangles that need to be tested and it lowers the memory overhead caused by maintaining of an additional copy of the original scene data. If you consider that a wall in your game world might have been highly tessellated by the artist to facilitate some fancy lighting or texturing technique, the collision system's version of that wall could be just a simple quad (eliminating pointless testing). Therefore, while not required by the collision system, the game artists may decide to develop lower polygon versions of the game environment for collision purposes or you may elect to use a mesh simplification algorithm to accomplish the same objective.

One additional benefit can be derived from the separation of rendering and collision geometry: the collision database can contain geometry that the actual renderable scene does not. For example, we can insert invisible walls or ramps in our level simply by adding new polygons only to the collision data. We have all seen this technique employed in games in the past, where the player suddenly hits an invisible wall to stop him wandering out of the action zone.

Component 2: Broad Phase Collision Detection (Bulk Rejection)

The collision detection portion of most systems will distribute the intersection determination load over two stages or phases: a broad phase and a narrow phase. The goal of the **broad phase** is to reduce the number of *potentially* collidable triangles to as few as possible. The goal of the subsequent narrow phase (discussed next) is to test those triangles for intersection and return the results to the response handler.

We simply do not have enough processing power to spare on today's machines to test every polygon in the collision database. While this is obviously true for very large levels, it is also important for small levels (there is no point in wasting CPU cycles unnecessarily). Before intensive calculations are performed at the per-triangle level to determine whether our entity intersects the scene geometry, the broad phase will attempt to (hopefully) eliminate 95% or more of the geometry from consideration. It will accomplish this through the use of any number of different techniques -- hierarchical scene bounding volumes and/or spatial partitioning are the most common solutions. These techniques divide the collision geometry database into some given number of volumes (or 'regions' or 'zones'). We know that if our moving entity has an origin and a destination in only one region, then all other regions (and the polygons stored in those regions) cannot possibly be intersecting our entity along its desired path and require no further testing in the main collision detection phase.

The output of broad phase testing is (hopefully) a very small list of triangles which *might* block the path of the entity, because they essentially 'live in the same neighborhood'. This list is often called the *potential colliders* list as we have been unable to definitively rule out whether or not any of these

triangles are blocking the path of the entity. These triangles (i.e., the potential colliders) become the inputs to the narrow phase where the more time consuming intersection tests are done between the moving entity and each triangle (one triangle at a time).

This component of the system is often separate from the detection and response steps that comprise the core of the collision system discussed earlier in the chapter. In fact, the broad phase may not even be present in a collision system. Although this is the first functional phase in the collision process that is executed whenever a moving entity requires a position update, and indeed it is the one that is most crucial to the performance of our own collision system, this is the phase that we will be adding to our collision system last. In Lab Project 12.1, the broad phase will be absent from our collision system. In fact, it will not be added until the next chapter.

Of course, we would not make such a design decision without good reason. The broad phase we will add to our system in the next chapter will be optionally a quad-tree, an oct-tree, or a kD-tree. These data structures will subdivide space such that the collision geometry database is partitioned into a hierarchy of bounding boxes. Each box is called a *leaf* and will contain some small number of polygons. Because of their hierarchical nature, these trees make per-polygon queries (such as intersection tests) very fast since they allow us to quickly and efficiently reject polygons that could not possibly be intersecting our entity along its desired path.

The broad phase can also be implemented using less complex schemes that rely purely on mesh bounding volume testing (e.g. sphere/sphere, sphere/box, etc.). But even in this case, some manner of hierarchy is preferable. We talked a little bit about such a system design towards the end of Chapter Nine, but we will not give any serious attention on this type of scheme until we examine scene graphs in Module III of this series. Instead we will focus on the highly efficient and very important spatial partition trees just mentioned. Because spatial partitioning is a significant topic all by itself (which needs to be studied in great depth by all game programmers), we have dedicated an entire chapter to it in this course. So we will leave broad phase testing out of the equation for now so as not to lose our focus on the core collision detection and response handling routines.

Component 3: Narrow Phase Collision Detection (Per-Polygon Tests)

In the **narrow phase** of the collision detection step, we will determine the actual intersections with our scene geometry. In our particular system, during the narrow phase we will also attempt to calculate a new non-intersecting position for the entity.

> **NOTE:** It is very important to emphasize that our narrow phase will always return a position that is non-intersecting. This is not always the case in every collision system, but it common enough that we decided to do it in our system as well.

This phase is ultimately responsible for determining if the requested movement along the velocity vector can be achieved without an environment collision taking place. If a collision will occur at some point along the path described by the velocity vector, the narrow phase will determine the maximum position the entity can achieve along that vector before a penetration occurs. It will then return this new position along with the normal at the point of intersection on the polygon (treated as, a sliding plane normal in

our case) to the response phase of the system. This data will be used by the response phase to calculate a slide vector which will be fed in once again to the collision detection system to test for obstruction along the path of the slide vector, and so on. Only when the detection phase is executed without a collision occurring (or if the response phase considers the remaining velocity vector to be of insignificant length) is the iteration stopped and the position returned from the last execution of the detection phase. We can then set the final position of the entity to this new location.

Component 4: Collision Response

The responsibility of our system's **collision response** component is the generation of a new velocity vector (a slide vector) if a collision occurred in the detection phase. This slide vector is computed by projecting any remaining velocity from the previous velocity vector onto a sliding plane returned to the response step by the narrow phase collision detection step. If the projection of the remaining velocity from a previous intersection results in a vector magnitude of insignificant length, then the response step will simply return the position generated during the detection phase back to the application. If a collision occurred in the detection phase and the remaining velocity vector produces a vector of significant length when projected onto the slide plane, the response phase will call the detection phase again with the new position and the slide vector acting as the new velocity vector. The response step will continue this pattern of calling back into the detection phase until no collision occurs or until the length of a projected slide vector is considered insignificant.

The possibility exists with certain types of complex geometry and a large enough initial velocity vector that an expensive series of deep recursions (a slide loop) could occur. In such rare cases, the detection phase would initially detect a collision, the response phase would calculate a new slide vector and pass it to the detection phase, which would detect another collision, and so on. We run the risk of getting mired in a very time consuming recursion waiting for the velocity vector to be completely whittled away. Therefore, our system will put a maximum limit on the number of times the response phase can call the detection phase. If we still have remaining velocity after a maximum number of calls to the detection phase, we will simply discard any remaining velocity and return the non-intersecting position returned from the last detection step. This will all be revisited later when we examine the response step from a coding perspective.

12.2.2 Bounding Volume Selection

In most real-time collision systems, entities are represented using simple bounding volumes like boxes, spheres, cylinders, etc. During broad phase tests, this means that we typically wind up computing very quick volume/volume intersections to reject large areas of our geometry database. Narrow phase collision detection is also often reduced to relatively inexpensive testing for intersections between a bounding volume and a triangle, making this phase suitably efficient for real-time applications.

> **Note:** Many collision detection systems (especially those used in academia) will compute polygon-polygon collisions. These tests are more accurate and thus more expensive. For our purposes, we will generally not require such detailed collision information. Volume-polygon testing is typically all that is

needed for most real-time game development projects, although this is obviously determined by application design requirements.

While there are many different bounding volumes a collision system can use to represent its moving entities, the system we will develop in this course uses ellipsoids as the primary bounding volume. All of our moving entities, regardless of type (a character, a motor car, a bouncing ball), will be assigned a bounding ellipsoid which encompasses the object. When our collision system is asked to calculate the new position of an entity, its ellipsoid will be tested for intersection with the geometry database and used to calculate a new position for that entity. Our decision to use ellipsoids was based on their simplicity of construction and use and their ability to produce a decent fitting bounding volume around the most common types of moving objects we will encounter.

An ellipsoid is the three-dimensional version of an ellipse. It can have three uniquely specified radii along its X, Y and Z extents. Ellipsoids tend to look like stretched or elongated spheres when their radii are not equal. Indeed in the study of quadric surfaces (a family of surfaces to which spheres, cylinders and ellipsoids belong), we find that the sphere is classified as a special form of ellipsoid – one in which the radii along the X, Y and Z extents are equal, giving a single uniform radius about the center point for every point on the sphere's surface.

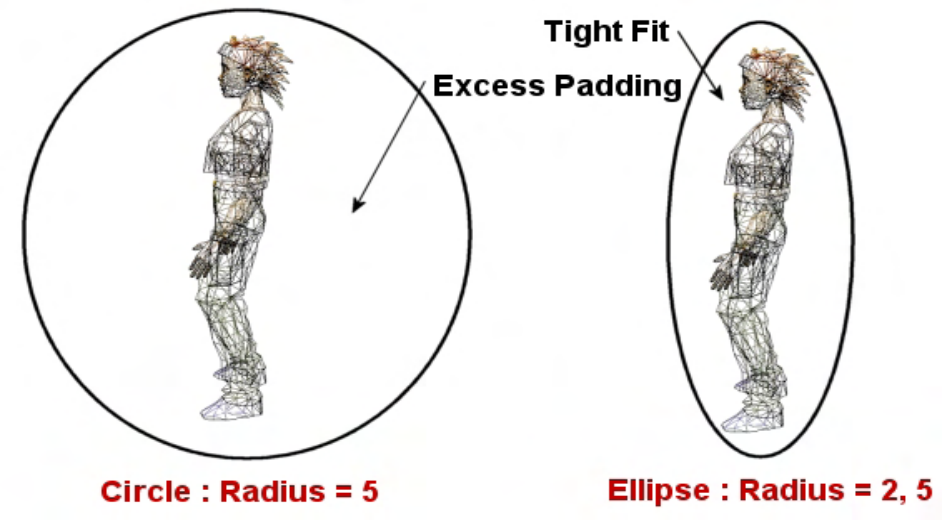

Figure 12.10

We will see later that our collision detection routines will work with unit spheres (spheres with a radius of 1) rather than ellipsoids. Intersection testing is simpler mathematically and more computationally efficient when working with spheres.

However, spheres are not a very friendly bounding volume for most shapes (although they would be a great choice for a beach ball!). If we consider a humanoid character (see Figure 12.10), we can see that if we use a sphere to bound the character, we will get a very loose fit both in front and behind (as well as left and right in the 3D case). This is due to the fact that the sphere's radius has to be sufficiently large to contain the full height of the humanoid form. However, humanoids are generally taller than they are wide, which results in the excess empty space we see depicted. If we imagine the bounding sphere in Figure 12.10 being used by our collision detection system, we would expect that even when the front of the character is quite far away from a polygon (a wall for example), its bounding sphere's surface would intersect it. The character would be prevented from getting any closer to the wall even though it would be clear that adequate room to maneuver exists. The situation is even more problematic when the character wants to walk through a standard sized doorway. The sphere would simply be too wide to accommodate this movement, even when it is clear that the character should easily fit through the opening.

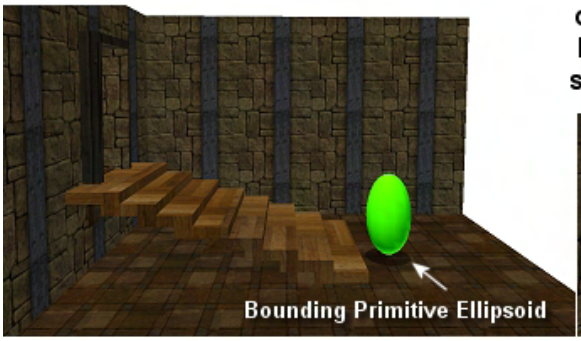
In Figure 12.10 we see that because the height radius can be different than the width/depth radii, we can use an ellipsoid to describe a stretched sphere that better bounds the volume of the entity we are trying to approximate. In this example, the ellipse (2D here for ease of demonstration) has a width radius of 2 and a height radius of 5. An ellipsoid can also be used to tightly bound an animal form (a quadruped) by making the ellipsoid width/depth radii larger than its vertical radius. For example, if you look again at the ellipse shown in figure 12.10 and imagine that the radii were switched so that the ellipse had a width of 5 and a height of 2, we would have a sphere that has been stretched horizontally instead of vertically. This is ideal for bounding a quadruped or even some types of vehicles and aircraft.

So it would seem that from our application's perspective, using the more flexible ellipsoidal bounding primitive for our moving entities is preferable to the use of generic spheres. However, as mentioned, the detection phase would rather use spheres as the bounding primitive to keep the intersection testing mathematics as simple and efficient as possible.

As it happens, we can have the best of both worlds. We can use ellipsoids as the bounding primitives for our collision system's moving entities and, by performing a minor transformation on the scene geometry prior to execution of the detection routines, we can allow our detection routines to use unit sphere mathematics. How does this work?

Figure 12.11 shows a small scene and the position of a bounding ellipsoid. In this example, we will assume that the vertices of the geometry and the ellipsoid position are both specified in world space. When we describe the position of the ellipsoid in world space, we are actually describing the world space position of the ellipsoid's center point. In Figure 12.11 we will assume that the ellipsoid has width and depth radii of 1.0 and a height radius of 4.0. Thus, in contrast to a sphere whose radius can be defined by a single value, the extents of the ellipsoid are described by three values (X, Y, and Z radii). They are usually stored in a 3D vector referred to as the radius vector. In our example, the radius vector for the ellipsoid in Figure 12.11 would be:

Radius Vector = (1.0 , 4.0 , 1.0)



Original World Space Geometry

12.2.3 Inputs/Outputs

The collision system is activated by the application when it wishes to move an object in the scene. This is done with a call to the function shown next. This is the only CCollision method our application will need to call when it wishes to update the position of a moving object.

> **Note:** It should be noted that the *actual* CollideEllipsoid function exposed by our collision system takes a few extra parameters beyond the prototype shown here. These additional parameters will be described later in the chapter when the timing is more appropriate.

```
bool CCollision::CollideEllipsoid (   const D3DXVECTOR3& Center,
                                      const D3DXVECTOR3& Radius,
                                      const D3DXVECTOR3& Velocity,
                                      D3DXVECTOR3& NewCenter,
                                      D3DXVECTOR3& IntegrationVelocity )
```

The function is passed the position of the center of the ellipsoid, the ellipsoid radius vector (describing its three radii) and a velocity vector describing the direction we wish to travel. All three are given in world space units. The length of the velocity vector describes the distance we wish to travel, so we can think of the velocity vector parameter as having both a direction of movement and a desired distance for this particular frame update. The next parameter is a 3D vector which, on function return, will contain the updated position for the ellipsoid. This position will be used to update the position of the entity represented by the ellipsoid. Our final parameter is a 3D vector output parameter called IntegrationVelocity which will contain the 'new' velocity of the object on function return. This final parameter requires a little more explanation.

As discussed, we will pass into the function a velocity that describes the direction and distance we wish to move the object. Our collision system will then repeatedly iterate to move the ellipsoid along this velocity vector until it winds up in a position where no more collisions occur and no velocity remains. We also mentioned earlier that every time the detection phase returns true for an intersection, the remaining velocity (the portion of the velocity vector beyond the point of intersection) is projected onto the slide plane and used to call the detection phase again. This continues until we have spent all the energy in the original velocity vector. It is here that we encounter a problem.

The application will be controlling the velocity of the object using some manner of physics calculations. In our Lab Project for example, when the player presses a movement key, a force is applied to the player. In the player update function, this force is combined with air resistance, drag, and friction to ultimately produce an acceleration which is in turn, integrated into a new velocity vector. This is useful because it means we can apply a large initial force when the user presses a movement key, which results in a vector which can be decelerated to zero over a number of frames (as gravity, drag, etc. operate on the object's mass). When the user releases the movement key, the player will smoothly slow to a halt rather than abruptly stop in their tracks. So what does this have to do with our collision system?

Each time the velocity is calculated in the player's update function, it is later fed into a collision system which whittles it away to nothing during execution. Remember that the system will only return once that velocity has been totally spent. The problem is that our collision system should really not alter the speed

of our player in this way. For example, imagine we were making a space combat simulation where our object (a spaceship) was supposed to be moving through a vacuum. Once the player pressed a key to apply a force/thrust to the ship, even if that key was only pressed for a short time, the object would continue to move at that velocity forever. This is because in a vacuum there are no environmental forces (like resistance and drag) that act to decelerate the object over time. So we know in this case that as soon as the force was applied and the velocity vector was determined to be of a certain magnitude, it should remain at that magnitude for all future frame updates. But if we let our collision system whittle away our actual velocity, every time we called the CollideEllipsoid method for our spaceship, the final velocity would be zero (even if no intersections occur). Since the application needs to apply velocity during every frame update (assuming no forces counteract it) and a zero velocity would clearly have no effect, this is not very helpful.

Now you might think that the obvious solution to the problem is to let the collision system work with a temporary velocity vector and let the object maintain its own copy that is never tampered with by the collision system. But that only works if our object never hits anything. The problem with this approach is that while the collision system should not tamper unnecessarily with the object's speed, it absolutely needs to be able to modify the direction of the velocity vector according to collision events.

Imagine that the player collides with a wall and the collision response step projects the remaining velocity onto the wall and we eventually move the sphere into its final position. At this point the velocity vector will be spent and the collision system can return. However, the collision system needs to let the application know that the object is now traveling in a completely different direction. When the collision system was invoked, the player's velocity vector had a direction that carried it straight into the wall. The system detected this and the response step ultimately modified the direction of travel. Indeed, if several intersections occur in a single movement update, the direction might have to be changed many times before the object comes to rest in its final position. Our collision system will need to return this new direction vector back to the application so that it can use it to overwrite the previous velocity vector and integrate it into physics calculations during future updates. Our collision system will also try to maintain as much of the original input velocity's magnitude as possible. It is this integration velocity vector that is returned from CollideEllipsoid and it represents the new velocity vector for the object.

Calculating the integration velocity is easy enough as it is done in nearly the same way that we project the remaining velocity onto the slide plane. Every time a collision occurs, the response phase receives a slide plane and an intersection point. It uses this information to project the remaining velocity onto the slide plane to generate a new velocity vector as input to the next detection call. All we have to do now is repeat this process during iteration to generate the integration velocity. There is one big difference however. When the integration velocity is projected onto the slide plane, we use the *entire* vector and not just the portion of the vector that lies behind the slide plane. We can think of both the slide plane and the integration velocity as being located at the origin of the coordinate system. A simple direction change is achieved by projection onto the new plane to create a new integration velocity for the next iteration. When the collision detection phase finally returns false (meaning no more responses have to computed), we will have the final integration velocity to return to the application. Note that the continual projection of the integration velocity onto different planes during the iterative process will mean that its length (i.e., speed) will still degrade by some amount. However, when only a few shallow collisions occur (e.g. clipping a corner or sliding into a wall at a small angle), most of the object's original speed will be maintained.

From the application's perspective, using our collision system could not be easier. We just tell it where we are currently situated (Center), how big we are in the world (Radius) and the direction and distance we wish to move from our current position (Velocity). On function return, we will have stored in the parameter (NewCenter) the new position we should move our entity to. Of course, this may be quite different from the position we intended to move to if a collision or multiple collisions occurred. We may have requested a movement forward by 10 units but the detection phase may have detected a collision against a wall. The response phase may have then calculated that it needs to slide to the right by 5 units and called the detection phase again to test that the slide vector path is clear. The detection phase may have discovered another intersection along the slide vector and therefore the position of the ellipsoid may have only been moved partially along the first slide vector. Any un-spent velocity of the slide vector will then be handed back to the response system which will use the remaining velocity of the previous slide vector to calculate a new slide vector from this new polygon that has been hit during the first sliding step. The response system would then call the detection phase again passing in this new (2^{nd}) slide vector and so on until the collision detection finally slides the entity into a position which does not cause an intersection.

12.2.4 Using Collision Ellipsoids

In the last section we learned that our application passes an ellipsoid radius vector into the collision system when it wishes to update the position of an entity in the game world. We know that the detection step will initially use both a broad and narrow phase to determine triangles which may cause obstructions along the path of the velocity vector. Once done, a new step will need to be taken. The narrow phase will transform each triangle it intends to test for intersection into something called *ellipsoid space*.

In ellipsoid space, the ellipsoid is essentially 'squashed' into a unit sphere and the surrounding triangles that are to be tested for intersection are also 'squashed' by that same amount. Therefore, after we have scaled any potentially colliding triangles into ellipsoid space, they now have the same size/ratio relationship with the unit sphere as they did with the ellipsoid before it was transformed. In this manner, our collision system can now perform intersection tests between a unit sphere and the transformed ellipsoid space geometry to efficiently find intersections. Once an intersection is found, the new unit sphere position can be transformed back into world space and returned to the application for final update of the moving entity's position.

To understand this concept of ellipsoid space, take another look at Figure 12.11. We stated earlier that the ellipsoid in this image was assumed to have a radius vector of (1.0, 4.0, 1.0). If we wished to convert this ellipsoid into a unit sphere (a sphere with a radius of 1.0) we would simply divide each component of its radius vector by itself:

$$\textbf{Unit Sphere Radius} = \left(\frac{X}{X}, \frac{Y}{Y}, \frac{Z}{Z}\right)$$

$$= \left(\frac{1.0}{1.0}, \frac{4.0}{4.0}, \frac{1.0}{1.0}\right)$$

$$= (1.0, 1.0, 1.0)$$

$$= 1.0 \text{ Radius}$$

Now this may seem quite obvious because if we divide any number by itself we always get 1.0. However, as can be seen in Figure 12.12, if we scale the X, Y, and Z components of a triangle's vertices by the (reciprocal) components of the ellipsoid's radius vector as well, we essentially squash that triangle into the same space. This is a simple scaling transformation, just like any scaling transform we have encountered in the past. By applying the scale, we wind up bringing both the triangle and ellipsoid into a new shared space (coordinate system).

Note that as far as position and orientation are concerned, we do not consider the ellipsoid center to be the origin of the coordinate system or its radii to be the axes of the system. While it would certainly be possible to transform everything into the local space of the ellipsoid (i.e., use the ellipsoid as a standard frame of reference) it turns out to be an unnecessary step. The world origin and axes can continue to serve as the origin/orientation in this new space, but we will scale everything in that space by the same amount, thus preserving the initial (world) spatial relationships between the ellipsoid and the triangles. In that sense, all we have done here is scale the world coordinate axes using the (reciprocal) ellipsoid radii as our scaling factor. So, ellipsoid space is ultimately just a scaled world space.

In Figure 12.12 we can see that we have scaled the ellipsoid by a factor of 1.0 / 4.0 (its Y radius) along the Y axis and we have also scaled the surrounding geometry (the potential colliders) by the same amount. We can now safely perform intersection tests against the surrounding triangles with a unit sphere since both the triangles and the ellipsoid have been transformed into ellipsoid space. For example, imagine a quad comprising the front of a step that had a height of 6 (its top two vertices had a world space position of 6). We would simply divide the Y components of the vertices of the quad by 4, scaling the height of the step by the same factor that we scaled the height of the ellipsoid to turn it into a sphere. The height of the transformed step quad in ellipsoid space remains just as high proportionally to the unit sphere as the untransformed step quad was to the original ellipsoid.

Therefore, all our collision system will have to do before performing intersection tests between a given triangle and the unit sphere, is divide the components of each of the three triangle vertices by the components of the ellipsoid's radius vector:

```
Ellipsoid Space Position.x =  Center.x / Ellipsoid Radius.x;
Ellipsoid Space Position.y =  Center.y / Ellipsoid Radius.y;
Ellipsoid Space Position.z =  Center.z / Ellipsoid Radius.z;

Ellipsoid Space Velocity.x = Velocity.x / Ellipsoid Radius.x;
Ellipsoid Space Velocity.y = Velocity.y / Ellipsoid Radius.y;
Ellipsoid Space Velocity.z = Velocity.z / Ellipsoid Radius.z;

For ( each vertex in triangle )
{
        Ellipsoid Space Vertex.x = World Space Vertex.x / Ellipsoid Radius.x;
        Ellipsoid Space Vertex.y = World Space Vertex.y / Ellipsoid Radius.y;
        Ellipsoid Space Vertex.z = World Space Vertex.z / Ellipsoid Radius.z;
}
```

> **NOTE:** In practice, we would likely calculate the reciprocal of the ellipsoid radii as a first step and then change all of the divisions into multiplications.

As can be seen in the above pseudo-code, it is very important that the center position of the ellipsoid and the velocity vector passed in by the application be transformed into ellipsoid space using the same method. We need to make sure that all of the positional information about to be used for the intersection testing (entity position, velocity and triangle vertex coordinates), exist in the same space. If we do not do this, the system will not function properly and we will generate incorrect results.

So, when our collision system is invoked by the application to update the position of a moving object, it will transform the input position and velocity vectors into ellipsoid space (from here on in called eSpace). This must take place prior to performing any per-polygon intersection testing. It is worth noting that the system will not use eSpace during the broad phase. Collection of potential triangle colliders will remain a world space operation (we will see this in the next chapter). However, once we have assembled the list of possible colliders, all of them will need their vertex positions transformed into eSpace. We do this by dividing the X, Y and Z components of each vertex by the corresponding radius component of the ellipsoid. The collision system will examine every triangle in the list and test for intersections with a unit sphere at the eSpace input position moving with the eSpace input velocity. Actual intersection positions are recorded along with a parametric distance along the velocity vector indicating when the intersection took place.

> **NOTE:** The collision system cannot simply return after finding the first colliding triangle because the velocity vector may pass through multiple triangles if it is sufficiently long. The detection phase must test all potential colliders and only calculate the new position of the sphere after it has found the *closest intersecting triangle* (if one exists) along the velocity vector. This will be the first triangle that the sphere will hit and must be prevented from passing through.

This should give you some indication as to why the broad phase is so critical to the overall performance of the system. Without some means for quickly rejecting triangles which could not possibly be intersecting the ellipsoid along the velocity vector, our detection routine will have no choice but to test every single triangle in the environment. This will include the added cost of transforming all triangle vertices into eSpace prior to the intersection tests.

Finally, once the collision system is satisfied that it has found the new position, this position will need to be transformed from eSpace back into world space before being returned to the application for entity position update. The transformation of a position vector from eSpace back into world space can be done by simply reversing the transformation we performed earlier. Since dividing the components of a world space vector by the corresponding components of the ellipsoids radius vector transformed it into eSpace, multiplying the components of an eSpace position vector by the components of the ellipsoid's radius vector will transform it from eSpace to world space.

12.2.5 System Summary

We now have a good idea about the type of collision system components we are going to implement and the end results we should expect them to generate. As discussed, the performance enhancing broad phase component will be deferred until the next chapter so that we can focus on the core collision system in our first implementation.

The geometry database component of our CCollision class will be simple in our first implementation and will not require detailed discussion. The CCollision object will maintain an STL vector of triangle structures containing the three triangle indices, the triangle normal, and the material used by the triangle. A material in this case does not refer to a rendering material, but rather to a set of physical properties so that concepts like friction can be calculated. There will also be an STL vector of vertices. This will just be an array of the <X, Y, Z> position components since the collision geometry database has no use for additional vertex components like color or texture coordinates. Our system will provide a simple API for the purposes of adding triangle data to these arrays. The collision detection system will work exclusively with the geometry stored in these vectors, so the application must register any polygons it considers to be 'collidable' before collision testing begins (e.g., when the scene is created/loaded). Please refer to the workbook for details about the functions that add triangles to the collision database.

12.3 Collision Response

The response phase of the collision system is going to be very simple for us to implement; it requires only a few lines of code in its basic form. The collision detection step is where most of our work will occur and it is where we will find ourselves getting into some mathematics that we have not discussed before in this course series. Fortunately, you have likely already encountered most of this math in high school, so it should not be too difficult to follow. Our collision detection routines will do a fair amount of algebraic manipulation and will utilize the quadratic equation quite extensively. Students who may be a little rusty with these concepts need not worry. We have included a very detailed discussion of quadratics and will walk through the algebra one step at a time.

The collision detection phase is where we will focus most of our energies in this first section of the textbook. But before covering the detection phase code in detail, it will be useful to first look at the context in which it is used. We said earlier that the application need only call a single method of the CCollision object in order to update the position of any moving entity. This method is called

CollideEllipsoid. For now, just know that this single function is the heart of our collision system, called by the application to update the position of an entity in the scene. This function iteratively calls the detection phase and executes the response phase until a final position is resolved. We will have a look at this function in a moment and get a real feel for the flow of our system.

The code to the CollideEllipsoid method is quite simple to follow. The caller passes the position vector, radius vector and the velocity of the ellipsoid that is to have its position updated. It then calls a single collision detection function which completely wraps the detection phase of the collision system. This function will return either true on false indicating whether an intersection has happened along the path described by the velocity vector. If no collision has taken place, the CollideEllipsoid function will immediately return the new position to the application. This new position will be Position + Velocity, where both Position and Velocity are the vectors input to the routine by the application.

If an intersection does occur, then the collision detection function (called CCollision::EllipsoidIntersectScene) will return the new position for the object (in a non-intersecting location) and an intersection (slide plane) normal. CollideEllipsoid will then perform the response step and project any remaining velocity onto the slide plane before calling the EllipsoidIntersectScene function again to invoke another detection pass.

Before we look at the code to the CollideEllipsoid function, let us first examine the parameter list to the EllipsoidIntersectScene. Although we will not yet know how the detection phase works, as long as we know the parameters it takes and the values it should return, we will be able to look at the code to the rest of the collision system and understand what is happening.

The collision detection component of our system may sound like a complicated beast, but from a high level it is just a single method that is called by the collision system when a position update is requested. The prototype for the parent function that wraps the entire detection phase is shown below. This function is called by CCollision::CollideEllipsoid (our collision system interface) to determine if the path of the ellipsoid is clear. If not, it returns the furthest position that the ellipsoid can be moved to along the velocity vector such that it is not intersecting any geometry. If this function returns false then no intersection occurred and the entity can be safely moved to the position that was originally requested by the calling application (NewPos = Center + Velocity).

```
bool  CCollision::EllipsoidIntersectScene  (const D3DXVECTOR3& Center,
                                            const D3DXVECTOR3& Radius,
                                            const D3DXVECTOR3& Velocity,
                                            CollIntersect Intersections[],
                                            ULONG & IntersectionCount,
                                            bool bInputEllipsoidSpace = false,
                                            bool bReturnEllipsoidSpace = false );
```

We have quite a lot of work to do before we find out how this function (and the functions it calls) works, but a good place to start is by examining the parameter list and the way that it is used by the collision system in general.

const D3DXVECTOR3& Center
const D3DXVECTOR3& Radius
const D3DXVECTOR3& Velocity
These three parameters tell the detection phase the position of the center point of the ellipsoid we wish to move, its radius vector, and the magnitude and direction in which we wish to move it. The application passes this information into the parent function of the collision system (CCollision::CollideEllipsoid) which passes it straight through to the detection function (EllipsoidIntersectScene) via these parameters.

CollIntersect Intersections[]
The collision system passes in an array of CollIntersect structures. The CollIntersect structure is defined in CCollision.h and is contained in the CCollision namespace. It is the structure that the collision detection phase uses to transport intersection information back to the main collision system (for use in the response phase for example). This information will only be available if a collision occurred. The CollIntersect structure describes the intersection information for a single colliding triangle and is defined as:

```
struct CollIntersect
{
   D3DXVECTOR3 NewCenter;
   D3DXVECTOR3 IntersectPoint;
   D3DXVECTOR3 IntersectNormal;
   float       Interval;
   ULONG       TriangleIndex;
};
```

This structure's members are explained below.

D3DXVECTOR3 NewCenter
This member will contain the new position that the ellipsoid can be moved to without intersecting the triangle. This position can be used in the response phase or it can be passed back to the application (depending on your system's design needs) to update the position of the moving entity which the ellipsoid is approximating. In our system, we will not just return this new position back to the application if there is significant velocity left over beyond the point of intersection. In such cases, the response phase will create a new velocity vector from the remaining velocity by projecting it onto the sliding plane. The response phase will then call the EllipsoidIntersectScene function again to re-run the detection phase and test that the path described by the slide vector is also clear. This variable (NewCenter) will be the new position input as the first parameter in that next iteration of the detection phase. It essentially describes how far we managed to move along the velocity vector fed into the previous invocation of the detection phase.

D3DXVECTOR3 IntersectPoint
This vector will contain the actual point of intersection on the surface of the triangle. This will obviously also be a point on the surface of the ellipsoid (since they are in contact at the same physical point in space), so we now exactly what part of the ellipsoid skin is currently resting against the triangle we intersected with.

D3DXVECTOR3 IntersectNormal

This vector describes the normal at the point of intersection (described above). If the collision detection function determines that the ellipsoid collided somewhere in the interior of the triangle, this vector will simply store the normal of the triangle that was hit. If the ellipsoid collided with the edge of a triangle, then this will be a normal describing the direction to the center of the ellipsoid from the intersection point (returned above). Either way, this is the normal that describes to the response phase the orientation of the plane we wish to slide along if there is any left over velocity beyond the point of intersection. We will treat the IntersectPoint and the IntersectNormal as describing a sliding plane onto which the response phase will project any remaining velocity.

float Interval

This floating point member stores the *t* value for intersection along the velocity vector passed into the detection phase. As you will see in a moment when we start covering the mathematics of intersection, the *t* value describes the time (or distance, depending on context) along the velocity vector when the intersection occurred. The *t* value is in the range [0.0, 1.0] where a value of 0.0 would describe an intersection at the very start of the velocity vector and a value of 1.0 describes an intersection at the very end of the velocity vector. A value of 0.5 describes the collision as happening exactly halfway along the velocity vector. In effect, it describes the time of collision as a parametric percentage value. The point of intersection returned in the IntersectPoint member described above, is calculated as:

```
IntersectPoint = Center + (Velocity * Interval)
```

As our collision detection function does this calculation for us and conveniently returns the intersection point in a separate variable, there is no need for us to do this. But this is how we would do it if we were required to calculate the intersection point ourselves.

ULONG TriangleIndex

This value will store the index of the triangle in the collision system's triangle array (STL vector) that the collision has occurred with. This is often a useful piece of information to return to the caller, so we will include it in our structure.

ULONG & IntersectionCount

You will notice that our collision system passes an array of CollIntersect structures into the EllipsoidIntersectScene function to be filled with intersection information. This is because it is possible that when the new position is calculated, it is actually touching two or more triangles. This may seem strange at first when we consider that we are only interested in finding the first (i.e., closest) intersection time along the velocity vector, and indeed, our collision detection function will only return collision information for the closest impact. Ordinarily this is going to be a single triangle and only the first element in the passed CollIntersect array (Intersections[0]) will contain meaningful values on function return. However, it is possible that the ellipsoid could come into contact with multiple triangles at exactly the same time (see Figure 12.13).

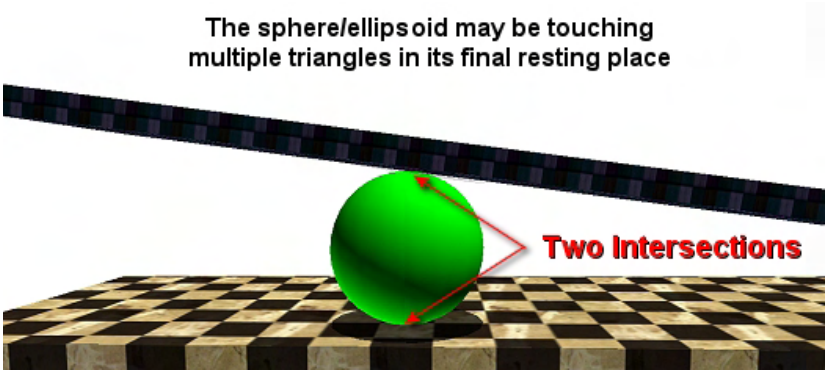

Figure 12.13

As you can see in this image, the sphere is being moved into a wedge shaped geometry arrangement and as such, will intersect with both the floor and ceiling at exactly the same time. In such a case, the detection function would return two pieces of intersection information which have exactly the same time interval. That is, collision information will be stored in the first two elements of the array (Intersections[0] and Intersections[1]) describing the information discussed previously (triangle index, intersection point, etc.). Remember, this will only happen when both intersections happen at exactly the same time along the velocity vector since our collision detection function is only interested in returning collision information for the first time of impact.

The IntersectionCount parameter will contain the number of simultaneous intersections that have occurred. This describes the number of triangles that the detection phase has determined the ellipsoid will be touching in its final position. It obviously also describes the number of elements in the Intersections array that was passed into the detection function.

One thing might be concerning you at this point. When we discussed the CollIntersect structure, we said that it contains a variable called NewCenter which describes to the response step (and possibly the application) the new non-intersecting position of the ellipsoid along the velocity vector. If we have multiple CollIntersect structures returned, which one's NewCenter member should we use to update the position of the entity? As it happens, it does not matter, because our detection function will only return information for the closest intersection. If that intersection involves multiple triangles, the NewCenter vector in each structure will be exactly the same. If you take a look at Figure 12.13 you can see that whether the collision information for the floor or the ceiling is stored first in the intersection array, the same center position for the sphere will be contained in both items. This is still the furthest the sphere can move in the desired direction before the intersections occur. Therefore, it is the only position that can be returned for all intersections that may be happening at that first point(s) of contact along the velocity vector. So while the intersection points and normals will obviously be different, the sphere center position will always be the same amongst simultaneous colliders.

Thus, when the detection phase returns, we can always use the new position stored in the first intersection structure in the array for our response step. The detection phase returns the array of intersection information mostly out of courtesy. Our particular system implementation only needs the new position, so we need not return information about all intersections. However, this might be useful if you intend to extend the collision system later on. After all, we can certainly imagine a situation when it might be useful to know not only if a collision occurred, but have a list of the actual triangles that were hit (perhaps to apply a damage texture to them for example).

Now that we know what the EllipsoidIntersectScene function will expect as input and return as output, we can now examine the code to a CCollision::CollideEllipsoid function that implements the system we have discussed thus far. Remember, this is the only function that needs to be called by the application in

order to update the position of a moving entity. It is also the function that contains all the code for the response step. The only code we will not see just yet is the code to the detection phase. This is tucked away inside the EllipsoidIntersectScene function whose parameter list we have just discussed. Understanding this function will require some study, but now we know how the detection function is expected to work with the rest of the system, so we can understand how everything else in the system works.

The CCollision::CollideEllipsoid function is shown below. This is a slightly more basic version than the one we will finally implement in the workbook. It has had all application specific tweaks removed so that we can concentrate on the core system. The function we are about to examine is really the entire collision system. We should understand everything about our system after studying this code except for how the actual detection phase determines intersections along the velocity vector. This will be discussed in a lot of detail later on in the chapter.

In this first section of code we are reminded that this function is called by the application and passed the position of the ellipsoid that is to be moved, the radius vector, and the velocity vector describing both the direction and distance of movement we desire. At the moment, all three use world space units. For the final parameters, the application passes a reference to two 3D vectors which on function return will contain the new position the application should move the entity to and its new velocity.

```
bool CCollision::CollideEllipsoid ( const D3DXVECTOR3& Center,
                                    const D3DXVECTOR3& Radius,
                                    const D3DXVECTOR3& Velocity,
                                    D3DXVECTOR3& NewCenter,
                                    D3DXVECTOR3& IntegrationVelocity )
{
    D3DXVECTOR3 vecOutputPos, vecOutputVelocity, InvRadius, vecNormal
    D3DXVECTOR3 eVelocity, eInputVelocity, eFrom, eTo;
    ULONG       IntersectionCount, i;
    float       fDistance;
    bool        bHit = false;

    vecOutputPos       = Center + Velocity;
    vecOutputVelocity  = Velocity;

    // Store ellipsoid transformation values
    InvRadius = D3DXVECTOR3( 1.0f / Radius.x, 1.0f / Radius.y, 1.0f / Radius.z );
```

The first thing we do is add the velocity vector to the position passed in and store the result in the vecOutputPos local variable. If no intersections occur then this describes the new position that should be returned to the application. We calculate it here so that if no intersections occur we can simply return it without any additional work. If intersections do occur then this value will be overwritten with the final position determined by the detection and response steps. We also copy the input velocity vector into the local variable eOutputVelocity. This vector will be used to store the integration velocity that will be returned to the application.

Next we create a vector called InvRadius where each component equals the reciprocal of the matching component in the ellipsoid's radius vector. We will need to convert the information (Center, Velocity,

etc.) into eSpace by dividing each vector component by the matching component in the radius vector. Because we will need to do this quite a bit (especially in the detection phase where it will be done for each triangle vertex), we create a vector that when component multiplied with another vector will perform this division. Remember, A / B = A * (1 / B) and therefore, if we create a vector that has the components, 1/Radius.x, 1/Radius.y, and 1/Radius.z, we have a vector that scales by the radius of the ellipsoid to transform points into eSpace.

In the next section of code we will see this transformation being done. As discussed, the detection phase wants to work in eSpace so we must send it the ellipsoid position and its velocity in eSpace, not world space. We accomplish this by multiplying the world space vectors (Velocity and Center) by the inverse radius vector we just computed:

```
    // Calculate values in ellipsoid space
    eVelocity = Vec3VecScale( Velocity, InvRadius );
    eFrom     = Vec3VecScale( Center, InvRadius );
    eTo       = eFrom + eVelocity;

    // Store the input velocity for jump testing
    eInputVelocity = eVelocity;
```

Notice that we store the eSpace velocity vector in eVelocity and the starting position of the ellipsoid in eSpace in the eFrom vector. We also calculate the eSpace position we would like to move the sphere to by adding eVelocity to the eFrom point. If no collisions occur, this is exactly where we would like our sphere to end up in eSpace after travelling the full extent of the velocity vector. We need to know this position in order to calculate any left over velocity in the event of an intersection. This remaining velocity can then be projected onto the slide plane as will be seen in a moment. A copy of the initial velocity vector (in eSpace) is stored in the eInputVelocity local variable. You will see in a moment how this will be used if a satisfactory position cannot be found by the system in the requested number of slide iterations. When this is the case, we will call the detection phase one final time, passing in the initial velocity and simply return the position generated to the application. We need a backup of the initial velocity vector passed into the function in order to do this since the eVelocity vector will be continually overwritten in the response step with a new slide vector (to pass it back into the detection function in the next iteration).

In the above code, we use a helper function called Vec3VecScale which performs a per-component multiply between two vectors. Its code is a CCollision method and implemented inline as shown below.

```
inline static D3DXVECTOR3 Vec3VecScale (const D3DXVECTOR3&v1,const D3DXVECTOR3&v2 )
            { return D3DXVECTOR3( v1.x * v2.x, v1.y * v2.y, v1.z * v2.z ); }
```

In the next section of code we enter the actual collision detection and response phase. As discussed previously, there are times when the ellipsoid could get stuck in a sliding loop before the velocity vector is projected away to nothing. We control the maximum number of times the response phase will call the detection phase using a member variable called m_nMaxIterations. In virtually all cases, the new position of the ellipsoid will be found after only a few iterations (a few slides) at most. However, by putting this limit on the number of iterations the collision system will run, we can control the case where the ellipsoid is sliding repeatedly back and forth between two or more surfaces.

As you can see in the next code snippet, the maximum number of iterations is governed by a for loop. Inside this loop, the detection and response phases will be executed per iteration. If, during any iteration, the final position of the ellipsoid is determined (i.e., there is no remaining velocity vector), we can exit the loop and return this position back to the caller. If the loop finishes all iterations, it means a position could not be determined in the maximum number of iterations such that there was no remaining velocity. In this (rare) case an additional step will have to be taken that we will see at the end of the function. Let us have a look at the first section of the loop:

```
    // Keep testing until we hit our max iteration limit
    for ( i = 0; i < m_nMaxIterations; ++i )
    {
        // Break out if our velocity is too small
        if ( D3DXVec3Length( &eVelocity ) < 1e-5f ) break;

        // Attempt scene intersection
        // Note : We are working totally in ellipsoid space at this point
        if ( EllipsoidIntersectScene( eFrom, Radius, eVelocity,
                                      m_pIntersections, IntersectionCount) )
        {
```

Inside the loop we first test to see if the currently length of eVelocity is zero (with tolerance). If so, we do not have to move the ellipsoid any further and we can exit from the loop. We know at this point that the eTo local variable will contain the current position the entity should be moved to and can be returned to the caller. If this is the first iteration of the loop, then eVelocity will contain the initial velocity vector passed in by the application (in eSpace) and eTo will contain the desired destination position as calculated above (eFrom + eVelocity). However, if this is not the first iteration of the loop then eVelocity will contain the slide vector that was calculated in the last response step (performed at the bottom of this loop). If this is zero, then the response step projected the remaining velocity from a previous detection step onto the sliding plane and created a new eVelocity vector with such insignificant length that it can be ignored. In this case, we can still exit from the loop since the eTo local variable will contain the eSpace position of the ellipsoid returned from the previous call to the detection function.

Next, in the above code, we feed the eSpace position and velocity into the collision detection function EllipsoidIntersectScene. Notice that we also pass in the radius vector of our ellipsoid which was passed in by the caller. Why do we need to do this if we are already passing in the position and velocity vectors in eSpace (where the ellipsoid is a bounding sphere)? Remember that the detection function will need to transform the vertices of each triangle it tests for intersection into eSpace also, and for that, it will need to divide the components of each vertex of each triangle by the radius of the ellipsoid. The detection function is also passed in an array of CollIntersect structures (this array is allocated in the CCollision constructor to a maximum size of 100) which on function return will contain the intersection information for the closest collision between the unit sphere and the environment (in eSpace). The variable passed by reference as the final parameter will contain the number of triangles that have been simultaneously intersected and thus, the number of elements in the m_pIntersections array that contain meaningful information.

The next few sections of code demonstrate what happens when the EllipsoidIntersectScene function returns true (i.e., an intersection has been determined at some point along the velocity vector). This means the response phase needs to be executed. Since we talked about the response phase as being a

separate component of the collision system, you might have assumed it would be a large and complex function. But in fact, the code executed in this next block comprises the entire response phase of the system we have discussed thus far.

```
            // Retrieve the first collision intersections
            CollIntersect & FirstIntersect = m_pIntersections[0];

            // Set the sphere position to the collision position
            // for the next iteration of testing
            eFrom = FirstIntersect.NewCenter;

            // Project the end of the velocity vector onto the collision plane
            // (at the sphere centre)
            fDistance = D3DXVec3Dot( &( eTo - FirstIntersect.NewCenter ),
                                     &FirstIntersect.IntersectNormal );

            eTo -= FirstIntersect.IntersectNormal * fDistance;
```

In the above code we alias the first element in the returned m_pIntersections array with the local variable FirstIntersect for ease of access. Although multiple elements may exist in this array containing the information for several triangles that may have been intersected, all of these triangles will have been intersected at the same time along the velocity vector and as such, each element in this array will contain the same eSpace sphere position in its NewCenter member. Remember, this is the furthest position the detection phase could theoretically move the sphere along the velocity vector before it intersects one or more triangles. Since we are only interested in getting the new sphere position, we can just extract this information from the first element in the array.

Notice how we copy the new position of the sphere into the eFrom vector, which previously described the position we wish to move our sphere from prior to the detection function being called. However, because the response step is about to be executed, this position is going to be the new 'from' position when the detection function is called again in the next iteration of the loop. The velocity vector eVelocity will also be overwritten with the new slide vector that will be generated. Therefore, it is as if we are saying, "Let us now run the collision detection function again, starting from this new position. We will test to see if we can slide along the new velocity vector (the slide vector) the next time an iteration of this loop is executed."

In the next line of code (shown above) we project any remaining velocity onto the sliding plane. eTo currently describes the position we wanted to reach before the detection function was called. The NewCenter member of the first CollIntersect structure contains the position we are able to move to along the velocity vector. If we subtract the new position vector from the intended destination, we get the remaining velocity vector for the sphere. If we perform a dot product between this vector and the slide plane normal (returned from the detection phase also), we get the distance from the original eTo position (Original Dest in Figure 12.14) that we wanted to travel to, to the center of the sphere along the plane normal (D in Figure 12.14). That is, if the remaining velocity vector forms the hypotenuse of a right angled triangle and the new position of the sphere describes the point at which the hypotenuse and the opposite side of the triangle meet, dotting the vector **eTo - NewCenter** (Original Dest – Modified Dest in Figure 12.14) with the intersection plane normal, describes the length of the adjacent side of the triangle. As you can see in the final line of the code shown above, once we have calculated this distance, we can simply move eTo back along the plane normal (negative direction) so that it describes the

position where the opposite side meets the adjacent side (the blue arrow in Figure 12.14). This is a vector that is situated in the direction tangent to the slide plane that our sphere should slide along. Therefore, if we subtract this new eTo position from the new position of our sphere returned by the detection function, we have a new velocity vector describing the direction and magnitude we wish to slide along the plane when the collision detection phase is called in the next iteration of the loop.

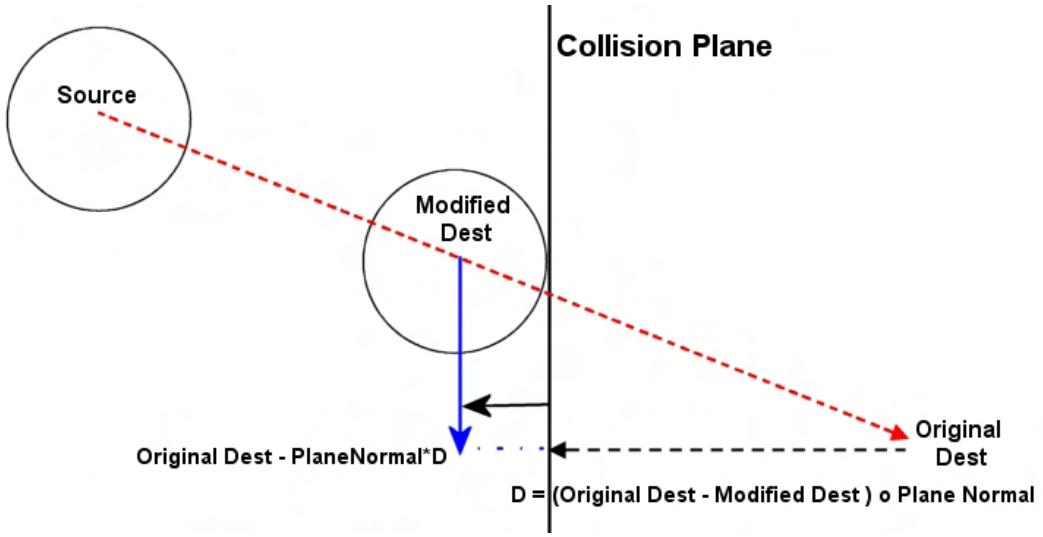

Figure 12.14

In the next section of code you will see how we calculate the eVelocity vector for the next iteration of the detection phase by doing what we just described -- subtracting the new position of the sphere from the projection of the remaining velocity vector onto the slide plane.

```
             // Update the velocity value
            eVelocity = eTo - eFrom;

            // Calculate new integration velocity
            fDistance = D3DXVec3Dot( &vecOutputVelocity,
                                     &FirstIntersect.IntersectNormal );
            vecOutputVelocity -= FirstIntersect.IntersectNormal * fDistance;

            // We hit something
            bHit = true;
```

In the above code we also project the current integration velocity (which in the first iteration will just be the input velocity) onto the slide plane. Notice that this is done in almost an identical way to the previous projection except that we project the whole velocity vector and not just the remaining portion behind the point of intersection. That is, we imagine that vecOutputVelocity describes a point relative to the origin of the coordinate system, and the slide plane normal passes through the origin. The dot product will produce fDistance which is the distance from that point to the plane along the plane normal. We then move the point (vecOutputVelocity) onto the plane by moving it towards the direction of the plane for a distance that places that point on the plane. This is our new integration velocity unless it gets changed in the next iteration. As you can see, this vector is continually projected onto the new slide plane in its entirety to preserve as much of the original velocity vector's length as possible.

Notice that in the above code we also set the local Boolean variable bHit to true so that we can tell, at the bottom of the function, whether at least one collision occurred. We will see how this is used in a moment.

Take a moment to study what we have done above. To reiterate, we have recalculated the eVelocity vector to store the slide vector, the eFrom vector now contains the new modified position of the sphere butted up against the colliding polygon. We have also updated the eTo vector describing the position we wish to travel to in the next iteration of the loop. We have essentially overwritten all the inputs that will be fed into the next iteration of the detection function. As far as the detection function is concerned, in the next iteration, these values could have been passed in by the application. They have of course been calculated by the response step to force a new movement into another location along the slide vector. The integration velocity is calculated using the same projection, but the entire vector is projected, not just the remaining velocity. Remember, this is the new velocity vector that will be returned to the caller, so we do not want this to be whittled away to zero.

We have essentially just covered the entire response step. There is just one additional line we put in to help reduce jittering that might occur when the player is trying to force the entity into an internal corner as shown in Figure 12.15.

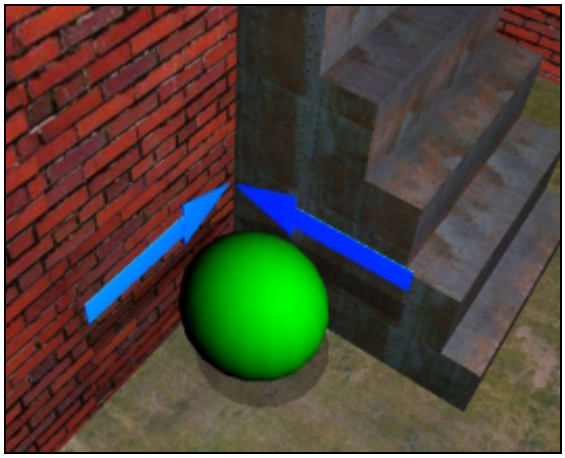

Figure 12.15

If the entity is forced into an internal corner or lip where polygons meet at an angle of 90 degrees or less (see Figure 12.15) a vibration artifact can occur until the initial velocity vector is completely spent. We might imagine that the sphere in Figure 12.15 first hits the wall in the corner which the response step slides into the corner and then into the side of the steps. When the sphere intersects with the side of the steps in the next detection step, it gets slid back into the wall it just slid along causing it to slide back in the opposite direction. When the sphere hits the wall again in the next detection phase, the response phase once again generates the original slide vector pushing it back into the side of the steps again, and so on. The sphere would seem to bounce between the two faces that form the corner in a cyclical pattern producing an unattractive vibration. To help resolve this, the response step can test if the slide vector (now stored in eVelocity ready for the next iteration) is pointing in the opposite direction to the original velocity vector that was passed in. That is, we can detect whether we are generating a slide vector that forms an angle greater than 90 degrees with respect to the original velocity vector that was first input by the application. If so, then we know that we are trying to move the sphere in a direction opposite of what was originally intended and have successfully detected where such a pattern of bouncing might be about to be carried out. When this is the case, we can simply use the current sphere position (returned from the last call of the detection function) as the final resting place of the sphere and exit the loop. The final line of code for the response step is shown below and performs this test.

```
            // Filter 'Impulse' jumps
            if ( D3DXVec3Dot( &eVelocity, &eInputVelocity ) < 0 )
                { eTo = eFrom; break; }
```

```
        } // End if we got some intersections
        else
        {
            // We found no collisions, so break out of the loop
            break;
        } // End if no collision

    } // Next Iteration
```

Studying the above code you can now see why we originally made a backup of the original velocity vector in eSpace (eInputVelocity) at the start of the function -- so we can filter out any vibration artifacts. And that is basically all there is to our main collision detection and response loop.

In the above code we also show the ‘else’ code block. This is executed when no collisions between the velocity vector and the scene are detected (i.e., EllipsoidIntersectScene returns false). In such a case, we break from the loop immediately since we already have the final resting place of the sphere in eSpace in the eTo variable. Either way, eTo will always contain the final resting place of the sphere in eSpace when this loop is exited. Notice that when we detect a looping pattern in the bottom of the response step in the above code, we copy the current position stored in eFrom to the eTo variable. Remember that this variable contains the new sphere position that was returned from the previous call to the detection function. Since we have discovered a looping pattern, we will decide to stop doing any further response processing and set this as the final resting place of the sphere.

At this point we have exited the loop and one of two conditions will be true; we will have exited the loop prematurely (the usual case) and we have the final resting position of the sphere in eSpace stored in the eTo variable, or the loop will have exited naturally after its full number of iterations. The second case is bad news since it means a very rare case has arisen where we were unable to spend the entire velocity in the maximum number of iterations to resolve a final resting place for the sphere. As discussed earlier, this can happen very infrequently when the geometry forms an angle that causes the sphere to repeatedly slide between opposing surfaces without significantly diminishing the velocity vector each time it is projected onto the sliding plane. If the maximum number of iterations was executed, then we have decided we no longer wish to spend any more processing time sliding this sphere around.

In the first case, we have our final position in eTo, so all we have to do is transform it back into world space. Just as we transform a position vector into eSpace by dividing its components by the radius vector of the ellipse, we transform an eSpace vector back into world space by multiplying its vector components by the radius vector of the ellipse (see below). This code is only executed if the loop variable is smaller than the maximum number of iterations (i.e., a final resting place for the sphere was resolved in the given number of loops and the loop exited prematurely). The final world space position for the ellipsoid is stored in the local variable vecOutputPos.

```
    // Did we register any intersection at all?
    if ( bHit )
    {
        // Did we finish neatly or not?
        if ( i < m_nMaxIterations )
        {
            // Return our final position in world space
```

```
            vecOutputPos = Vec3VecScale( eTo, Radius );

        } // End if in clear space
```

When this is not the case and we have executed the maximum number of iterations of the loop, we have to 'hack' around the problem. We will simply ignore everything we have done thus far and simply call the collision detection routine one more time with the original eSpace values. We will then take the position returned by the detection function (first point of impact along the original velocity vector) and return that as the final position of the sphere.

```
        else
        {
            // Just find the closest intersection
            eFrom = Vec3VecScale( Center, InvRadius );

            // Attempt to intersect the scene
            IntersectionCount = 0;
            EllipsoidIntersectScene( eFrom, Radius, eInputVelocity,
                                     m_pIntersections, IntersectionCount )
            vecOutputPos = Vec3VecScale( m_pIntersections[0].NewCenter, Radius );

        } // End if bad situation
    } // End if intersection found
```

As you can see in the above code, we reset the eFrom vector to be the eSpace version of the original position vector passed into the function and run the detection routine again. We then transform the intersection position into world space before storing it in vecOutputPos.

Our job is now done. Whatever the outcome, we now have the position the ellipsoid should be moved to stored in the local variable vecOutputPos and the new integration velocity vector stored in vecOutputVelocity. As a final step we will copy these values into the NewCenter and IntegrationVelocity variables which were passed by reference by the caller. The application will now have access to this new position and velocity and can use it to update the position of the entity which the ellipsoid is approximating. We then return either 'true' or 'false' to indicate whether any intersection and path correction took place.

```
    // Store the resulting output values
    NewCenter            = vecOutputPos;
    IntegrationVelocity  = vecOutputVelocity;

    // Return hit code
    return bHit;
}
```

And there we have it. With the exception of our examination of the EllipsoidIntersectScene method which actually calculates the new non-intersecting position of the unit sphere, we have walked through the entire collision system. Hopefully you will find this to be relatively straightforward, especially the response step which, while very effective, was actually quite small.

> **Note**: If you are comparing the code described above with the version in Lab Project 12.1's source code, you will likely notice that the version in the source code looks much more complicated and quite different in places. This is because the version supplied with Lab Project 12.1 has had a lot of extras added, such as the ability to provide collision detection and response against moving meshes in the environment (lifts, automated doors, etc). At the moment, we are just concentrating on the core system that deals with a static collision environment. As we progress through this chapter and the more advanced features are added to our collision system, you will see the code snippets start to look more like those in the accompanying lab project.

Of course, there is still a large portion of the collision system that requires explanation. We have not yet discussed how the EllipsoidIntersectScene function determines intersections with the sphere along its velocity vector and how it returns the new position of the sphere at the point of intersection. Moving forward, we will begin to focus on the implementation of the collision detection phase (i.e., EllipsoidIntersectScene and its helper functions).

12.4 Collision Detection

Our collision detection phase will be responsible for testing the movement of a sphere along a velocity vector and determining the distance that the sphere can travel along that vector before an intersection occurs between the surface of the sphere and the environment. The collision detection phase will comprise several intersection tests between rays and various geometric primitive types. While it might not be obvious why this is the case at the moment, we will need to cover how to intersect a ray with a triangle, a cylinder, and a sphere. These intersections tests will be performed one after another to determine whether the path is clear. Only when all intersection tests fail for every potential collider do we know that the velocity vector is clear to move the sphere along.

Also, several of the intersection tests may return different collision times along the velocity vector for a given triangle. This is because each uses a different technique to test the different parts of a triangle with the sphere. The edges, the vertices, and the interior of each triangle will all need to be tested separately to make sure they do not intersect the sphere at some point along its velocity vector. If several of the tests return different intersection positions along the velocity vector for a single triangle, our collision system will only be interesting in recording the intersection information with the smallest *t* value (the first collision along the path). In other words, we are only interesting in finding the furthest point the center of the sphere can move to along the velocity vector until its first impact with the environment occurs.

The detection process is complex because our sphere is (theoretically) moving along the velocity vector. Simple tests that could be performed with a static sphere cannot be used here because our entity is assumed to be in motion. We cannot perform a sphere/triangle test at both the start and end points of the velocity vector since that would ignore collisions that might have happened between the endpoints. We can easily imagine a situation where a sphere starts off in front of a triangle and is not intersecting it. Assume that we wish to move to a position (given a velocity vector) completely behind the triangle, which we know is also non-intersecting. Intuitively we see that in order for the sphere to get from one side of the triangle to the other, it must pass right through the triangle and thus must collide with it at some point along that path. Simply testing the start and end positions of the sphere would prove negative

for intersection, which might lead us to believe the sphere can indeed be moved across the full extent of the velocity vector to its desired destination.

Solving this problem requires that we account for the time aspect of the velocity vector. We will use a technique referred to as swept sphere collision detection, which accounts for the full travel path, including endpoints. A swept sphere is shown in Figure 12.16 and as you can see, it is like we have stretched (i.e., swept) the sphere along its velocity vector to create a capsule shape. Source describes the initial center position of the sphere and Dest describes the desired destination for the center of the sphere (Center + Velocity). In between, we see a solid area representing the integration of the sphere at each moment in time in which the sphere is traveling from origin to destination.

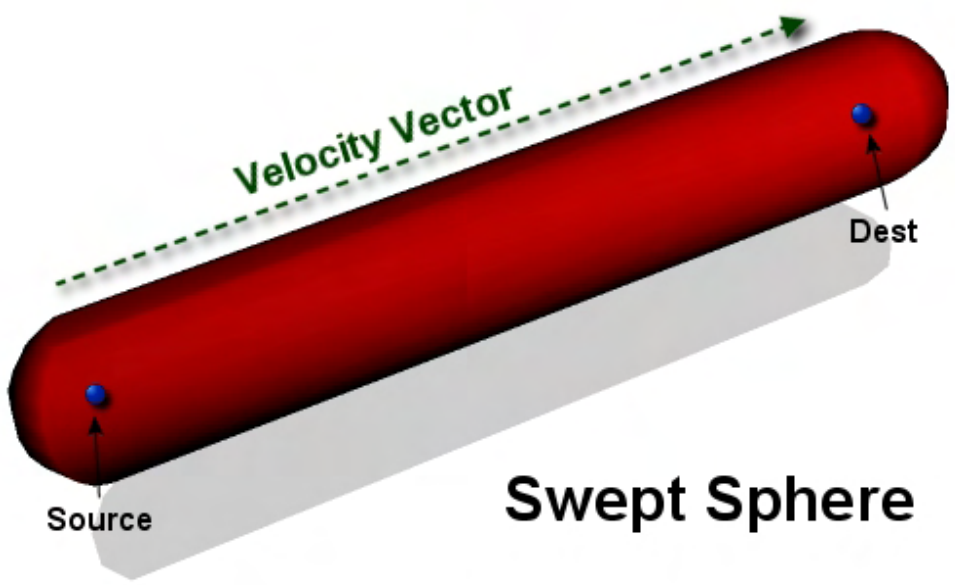

Figure 12.16

We know that if any geometry intersects the swept sphere then it must intersect the sphere at some point along the velocity vector. It is as if we have thickened the velocity vector ray by the radius of the sphere and are now testing this against the scene instead of the sphere itself. It covers all the space in the environment that the sphere will touch when moving along the velocity vector.

When we visualize the swept sphere as a primitive (as shown above) we can see that it bounds all the space that will be touched by the sphere on its path along the velocity vector. While this is vaguely interesting we still have not covered how to intersect such a shape with the environment. As you will see in a moment, we can greatly simplify this process by performing a transformation on any triangle that is to be tested against the swept sphere. Instead of creating a capsule shape as shown in Figure 12.6 describing the velocity vector thickened by the sphere radius, we can approach this problem from the other angle. We will see later that if we instead ‘inflate’ the geometry of our environment by the radius of the sphere, we can treat the sphere’s movement along the velocity vector, not as a capsule, but as a simple ray. We can test for intersections between this ray and the ‘inflated’ environment to determine the point at which the sphere surface intersects the environment. This technique will be used for testing the sphere’s path against the center of the polygon, the polygon edges, and the polygon vertices. It should be clear then that our collision detection techniques will essentially be a collection of methods

that intersect a ray with other geometric primitive types. Therefore, before we try to understand the collision detection system as a whole, let us spend some time defining what a ray is and look at some of the various intersection techniques we can perform with rays. Once we understand how to intersect a ray with several different primitive types, we will then see how these intersection techniques can be assembled to create our core collision detection system.

12.4.1 Rays

In this section we will discuss rays and how they can be represented and used to perform intersection tests. It is important that we initially get our terminology right because in classical geometry there is a distinct difference between a line, a line segment, and a ray.

- A **Line** has no start and end point and is assumed to extend infinitely in both directions along a given slope.
- A **Line Segment** is a finite portion of a line in that it has a start and an end position in the world. To visualize a line segment we would draw a mental line between the two position vectors describing the start and end points. Thus, it is quite common for a line segment to be represented by two positional vectors.
- A **Ray** has a starting position (an origin) and a direction. It is assumed to extend infinitely in the direction it is pointing. We can think of a Ray as being one half of a line. Whereas a line would extend infinitely from the starting position of the ray in both the positive and negative directions, a Ray will start at some origin and extend infinitely in one direction only -- the direction the ray is pointing.

Figure 12.17 demonstrates the differences between these three geometric primitives.

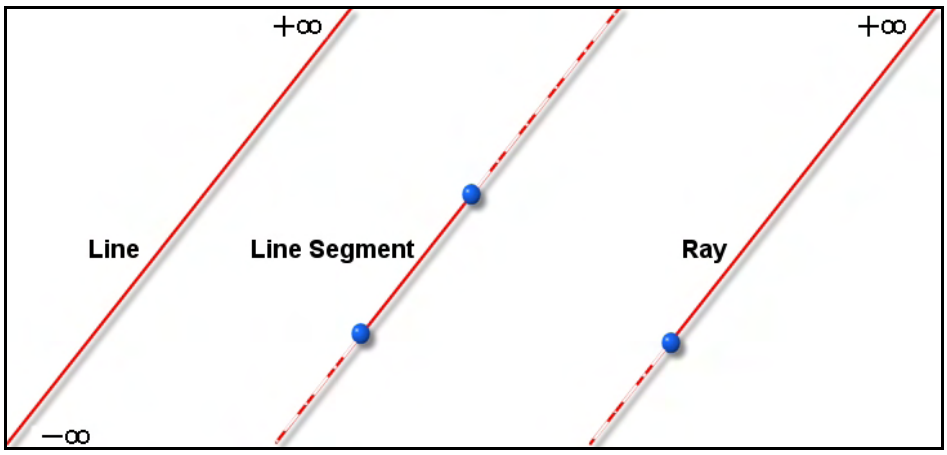

Figure 12.17 : A Line, A Line Segment and a Ray

In computer science, we will sometimes take some liberties with these definitions, and this is especially true in the case of a ray. While it is often useful to think of a ray has having a starting position and a direction in which the ray extends infinitely, it is also useful to use a ray definition that allows for a finite length from the origin. If we think about the velocity vector passed into our collision routines, we

can think of this as being a ray of finite length when coupled with the center position of the sphere. The sphere center point describes the origin of the ray and the velocity vector describes the direction of the ray and its magnitude. This is the ray representation we will be using most in this chapter and throughout our ray intersection routines. Since we can add the ray's direction vector to its origin to get the end point of the ray, we can see that our ray is really just a directed line segment. In other words, it is a line segment that is described not as two position vectors, but as a single position vector (the ray origin) and a vector describing the direction the ray is traveling from the origin and the distance it travels in that direction. Therefore, in our discussions we will use the following definition:

A **Ray** is a directed line segment.

Let us now take a look at how we will define our ray. A 3D ray is often specified in its parametric form as shown below using three functions.

Parametric Form of a Ray (3D)

$$x(t) = x_o + t\Delta x$$
$$y(t) = y_o + t\Delta y$$
$$z(t) = z_o + t\Delta z$$

where

$(x_o \;\; y_o \;\; z_o)$ = **Ray Origin (Start Position)**

$(\Delta x \;\; \Delta y \;\; \Delta z)$ = **Direction (Delta) Vector**

The parameter to each of these functions is *t*, where *t* = [0.0, 1.0]. The combined results of each function will form a vector that describes a position somewhere along the ray where *t* is between 0.0 and 1.0. Note that *t* is the same input to each function. Each function shown above is simply describing a movement along the direction vector (Δi) from the ray origin (i_o) for each component x, y, and z. The result of each component calculated can then be linearly combined into the final position vector (x, y, z) describing the point along the ray given by *t*. It is often nicer to represent a 3D ray parametrically using its more compact vector form:

$$p(t) = p_o + td$$

where

p_o = A 3D vector describing the position of the start of the ray (the origin)

d = A non-unit length 3D vector (or a unit length vector if you wish the length of the ray to be 1.0) describing the direction and length of the ray.

We can describe any position on that ray by specifying a function input value of *t* between 0.0 and 1.0. For example, imagine that the ray origin **p** is a vector describing a ray origin <100, 100, 100>. Also imagine that the direction and magnitude of the ray described in vector **d** sets the end of the ray at a position offset 10 units along the X, Y and Z axes from the ray origin. That is, <10, 10, 10>. To calculate a position exactly halfway along that ray we can use a *t* value of 0.5, as shown below.

Position = (100, 100, 100) + t (10, 10, 10)
= (100, 100, 100) + 0.5 (10, 10, 10)
= (100, 100, 100) + (5, 5, 5)
= (105, 105, 105)

Using a *t* parameter of 0.5, we have correctly calculated that the exact position of a point situated exactly halfway along the ray is (105, 105, 105).

In Figure 12.8 we see the same ray and the calculation of other points along the ray. We can see for example that a *t* value of 0.25 gives us a position situated ¼ of the way along the ray from the ray origin. We can also see that using a *t* value of 0.75 provides us with a position situated exactly ¾ of the length of the ray from the origin. Finally, we can see that the end point of the ray can be calculated using a *t* value of 1.0. As the function for calculating the end position (*t* = 1) will simply scale the ray direction vector by 1.0, we can omit the *t* value altogether when we wish to calculate the end of the ray by simply adding the direction vector to the ray origin:

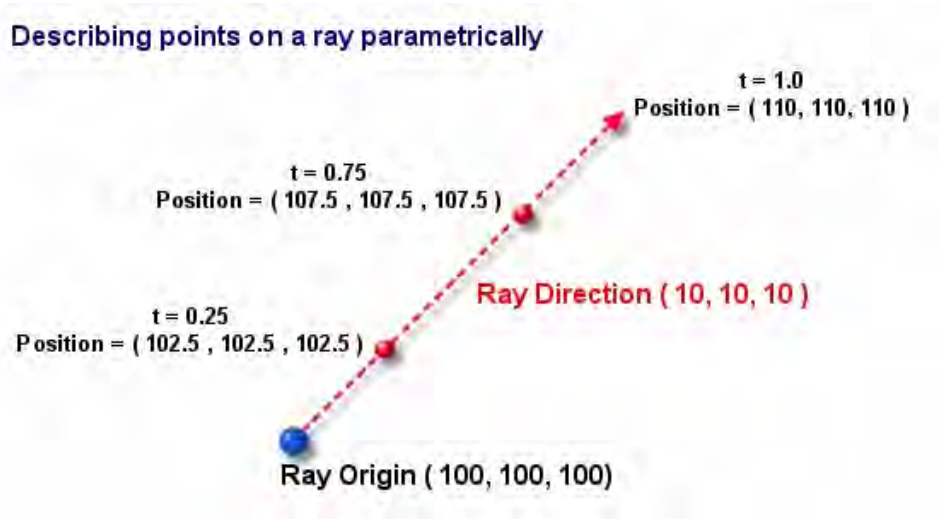

Figure 12.18

Position = (100, 100, 100) + 1.0 (10, 10, 10)
= (100, 100, 100) + (10, 10, 10)
= (110, 110, 110)

Alternatively, we can think of *t* as describing how many units we would like to move along the ray measured in units of 'ray length'. A value of 1.0 means we would like to travel one whole ray length and a value of 0.5 would describe us as wanting to move along the ray ½ of the ray length. Even when representing a ray in its classical geometry form, this same relationship holds true, although it may not be immediately obvious. The classical geometry representation of a ray is that it has a position and a

direction and an infinite length. Such a ray definition can be represented in the same parametric vector form we have been using thus far:

$$p(t) = p_o + td$$

The only difference between this representation and the one we have been using is that it is implied that ***d*** is a unit length vector. It describes a direction only, but no magnitude since the length of the ray is infinite (controlled by *t* which in this case has an infinite range). When using such a definition we will usually have some other variable that determines legal values for points along the ray. For example, we might have a variable *k* that contains the length of the ray. Positional vectors on the ray that have a distance from the origin that is larger than *k* are considered to be beyond the legal end point of the ray.

When using the classical representation of a ray, the *t* value still essentially means the same thing -- it describes the number of units (in vector length) we would like to move along the ray from the origin. However, with the classical definition, the *t* value will not be restricted between 0.0 and 1.0, but rather between 0.0 and *k*, where *k* is some arbitrary value used to describe the length of the ray. Using the classical definition we would use a *t* value to describe a position exactly *t* units along the infinite ray. A value of $t = 7$ for example would describe a point along the ray seven units away from the origin, when in the case of the classical definition, the units of measurement are the units of the coordinate system for which it is defined (e.g., world space). Obviously, this seems quite different from the ray definition we have been using thus far, where units are based on 'ray length'. However, if we think about the classical ray representation where a unit length direction vector is used, we could hold the view that instead of the ray being infinite, it has a length of 1 (because the direction vector ***d*** is unit length). In this case, we can see that a value of $t = 7$ does indeed still describe a position along the ray measured in units of 'ray length'. In the classical case, ray length is 1.0, so the mapping between the ray length and the units of the coordinate system for which it is defined is 1:1.

Although we will be using the definition of a ray which involves a delta vector, that does not mean that we cannot create a ray in this form from information stored in another form. Very often we may not have the delta vector at hand and may have only the start and end points that we would like the build the ray between (i.e. the line segment). That is not a problem since we can create the delta value by subtracting the start position from the end position. The resulting vector ***d*** will describe the direction from the first vector to the second and will have the length of that ray encoded as its magnitude. The example below shows how easy it is to calculate the delta vector for our ray when the initial information is in the form of two positional vectors:

RayStart = (100, 100, 100)
RayEnd = (110, 110, 100)
d = RayEnd – RayStart = (10, 10, 10)

Exactly the same technique can be used to create the unit length direction vector for the classical geometry representation of the ray. An additional step is required to normalize vector ***d***. The following example shows how we could create a ray in classical form and then use an additional variable *k* to describe the length of the ray. Any *t* value larger than *k* would be considered past the end of the ray.

RayStart = (100, 100, 100)
RayEnd = (110, 110, 100)

d = RayEnd - RayStart = (10, 10, 10)
d = Normalized (d)

k = $\sqrt{10^2 + 10^2 + 10^2}$ = **17.3205**

We now know what a ray is and how we can represent one using two vectors (a ray origin and a direction). Because we will be using the non-classical geometry definition of a ray, our direction vector will also have magnitude and will be referred to as a delta vector. When using delta vectors, points on the ray can be described parametrically using *t* values between 0.0 and 1.0. Any *t* value that is smaller than zero is said to exist on the same line as the ray, but exists before the ray origin. Any *t* values that are larger than 1.0 describe points that exist on the same line as the ray but after the ray end point.

With the description of a ray behind us, let us now move on and look at some intersection tests that can be performed using rays. This will help us uncover why rays are so useful in 3D computer graphics (and in particular, in our collision detection system).

12.4.2 Ray / Plane Intersection Testing

It only takes a small amount of experience to realize that the dot product is the veritable Swiss Army Knife of 3D graphics programming. It is used to perform so many common tasks in 3D graphics programming that it would be impossible to make a 3D game without it. The dot product comes to the rescue again when trying to determine whether a ray intersects a plane. The process is remarkably simple as long as you understand how the dot product operation works.

We have discussed several times in the past (see Graphics Programming Module I) the properties of the dot product and we even examined ray intersections with a plane in our workbooks. We approached the understanding of this technique by analyzing the geometry and applying the properties of the dot product to solve the problem. But this method is not always ideal when handling more complex intersections since drawing diagrams to show geometric solutions can become a very ungainly process.

It is generally much simpler to come up with a pure mathematical solution. That is, we can find solutions by substituting the ray equation into the equation for the primitive we are testing against and then perform some algebraic manipulation to solve for *t* (the interval along the ray where the ray intersects the primitive). This is a technique we managed to steer clear of in the past because other solutions were available. We did not have to worry about your ability to solve equations using algebra. But we can put this off no longer. So we will start with the ray/plane intersection technique as a refresher for the math we (hopefully) learned in high school. We will start with the more familiar geometry perspective and then will solve the same problem algebraically to get us warmed up for what is to come later in the chapter. Do not fear if your algebra skills are a little rusty. We will review everything in detail and you will quickly see just how easy it can be once you get the hang of it again.

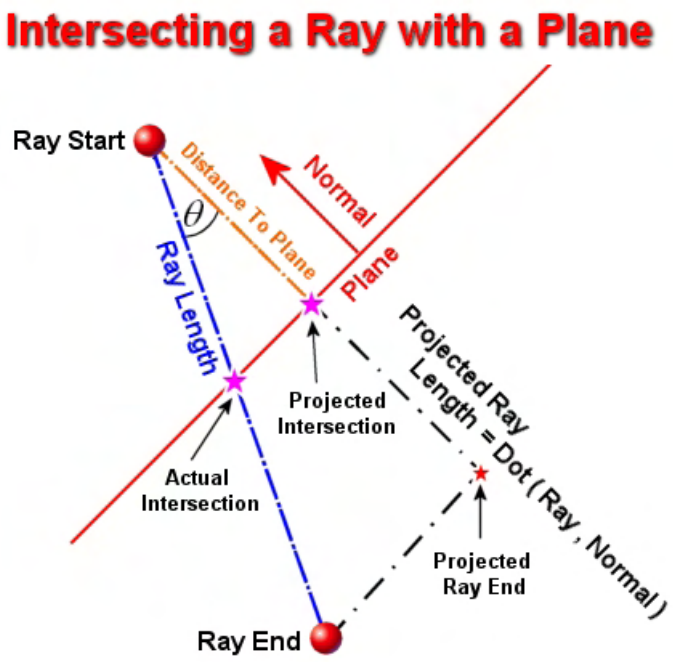

Figure 12.19

Study the diagram in Figure 12.19. Ray Start describes the position of the ray origin and the blue dashed line describes the delta vector. We can see that if we add the delta vector to the ray origin we would get the ray end position. We wish to find the position along the ray where intersection with the plane occurs. This can be done quite simply by applying the properties of the dot product and projecting the ray delta vector along the plane normal.

Our first task is to calculate the distance from the ray origin to the plane. Recall that the plane equation is:

$$ax + by + cz + d = 0$$

In the plane equation **a**, **b,** and **c** are the x, y and z components of the plane normal and **d** is the signed distance from the origin of the coordinate system to the plane along the plane normal. The **x**, **y**, and **z** variables in the plane equation describe the 3D components of the point on the plane. For the equation to be satisfied, the point (x,y,z) must lay on the plane described by (a,b,c,d). As both the position of the point and the plane normal are 3D vectors, we can write the plane equation as a dot product between the point and the plane normal with the addition of the plane distance. The plane equation in its more compact vector form looks like this:

$$P \bullet N + d = 0$$

where **P** is the point on the plane and **N** is the plane normal. It should also be noted that you could store the plane coefficients in a 4D vector and represent the point on the plane as an homogeneous 4D coordinate with w=1. The classification of the point against the plane is then simplified to a 4D dot product. As can be seen, the plane equation will return the distance from the point to the plane (which will be zero for any point on the plane). Therefore, if the plane equation is satisfied, the point **P** is located on plane. For any point not on the plane, the result will be the signed distance to the plane.

While it is most common for a plane to be stored in **a**, **b**, **c**, **d** format, it is also fairly common to find a plane represented using the plane normal and a point known to be on the plane. When this is the case, the **d** plane coefficient can be calculated by taking the negative dot product of the plane normal and the point on the plane. This can be seen by looking at the plane equation. To solve for **d** we have to leave **d** on its own on the left hand side of the equation. We can do this by subtracting $P \bullet N$ from the left and right side of the equation. Remember that anything we do to one side of the equation must be done to the other, so that the equation remains balanced. So we start with:

$$(P \bullet N) + d = 0$$

If P is our point on the plane, then we wish to subtract $P \bullet N$ from both sides of the equation. Subtracting it from the LHS (left hand side of the equals sign) leaves us with just **d** and we have successfully isolated **d**. We then have to perform the same operation to the RHS of the equation to keep it balanced. Subtracting $P \bullet N$ from zero gives us:

$$d = -(P \bullet N)$$

This can also be written as:

$$d = -N \bullet P$$

This is commonly how you will see **d** calculated.

Sometimes people will use the plane equation in the form:

$$ax + bx + cz - d = 0$$

In this case the vector form is obviously:

$$(P \bullet N) - d = 0$$

When using this form of the equation to solve for a distance, the **d** coefficient must be calculated slightly differently. Let us manipulate this form of the plane equation to see how **d** must be calculated. To isolate **d** we add **d** to both sides of the equation. This will cancel out **d** on the LHS and introduce it to the RHS.

$$P \bullet N = d$$

or in the more familiar form:

$$d = P \bullet N$$

So as you can see, if we intend to use the ax+by+cz+d version of the equation, d must be calculated by negating the result of the dot product between the plane normal and the point on the plane. If we intend to use the ax+by+cz-d version of the equation, d must be calculated by taking the dot product of the plane normal and the point on plane and not negating the result. This subtle difference in the calculation of d is what makes both forms of the equation essentially the same. Please refer back to Module I in this series for more detailed discussion on the positive and negative versions of the equation if you need more in depth coverage.

Getting back to our problem, we first must calculate the distance from the ray origin (Ray Start) to the plane. We do this as follows:

PlaneDist = $RayStart \bullet Normal + D$

This gives us the distance from the ray origin to the plane along the direction of the plane normal. This is shown as the orange dashed line in Figure 12.19 labelled Distance To Plane. We can also calculate the distance to the plane from the origin in another way. We can simply dot the plane normal with a vector formed from a point known to be on the plane to the ray origin. You will see us using this technique many times in our code.

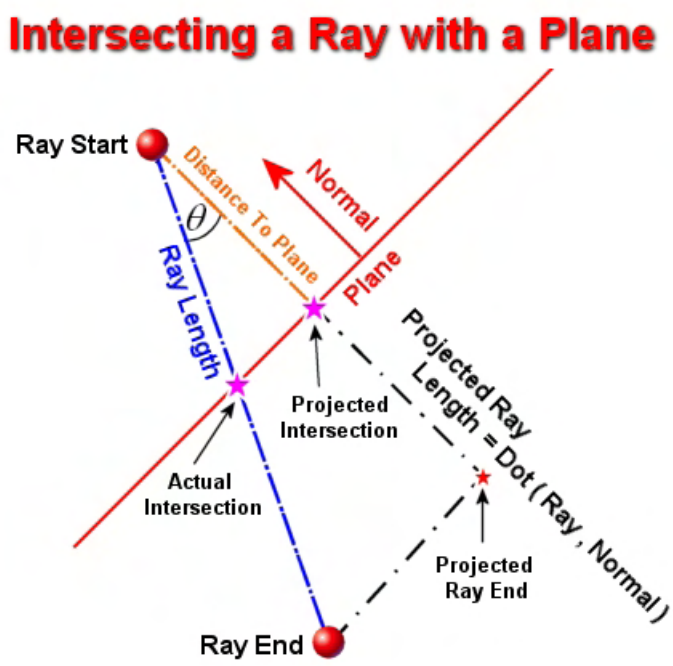

Figure 12.19 (again for convenience)

Our next task is to make sure we have the ray delta vector. Our intersection routines will use the ray in the form of an origin and a delta vector, so if the only information at hand is the start and end positions (as can sometimes be the case) we can calculate the delta vector by subtracting the ray start position from the ray end position. If we imagine that the line labelled Distance To Plane is our ray (instead of the actual ray) we would instantly know the distance to the intersection -- it is simply the distance to the plane from the start point which we have already calculated. However, our ray is travelling in an arbitrary direction and we need to know the time of intersection along this ray, not along the direction of the plane normal. But if we take the dot product of the negated plane normal and the ray delta vector ***d*** to get them both facing the same way (see the blue dashed line in Figure 12.19), we will get the length of the delta vector projected onto the plane normal. This describes the length of the ray delta vector as if it had been rotated around the ray origin and aligned with the plane normal.

Projected Line Length = $d \bullet -Normal$

Remember that the plane normal is a unit length vector but the ray delta vector is not. The result of a dot product between a unit length vector and a non unit length vector is:

$$\cos(\theta)|Ray| = d \bullet -Normal$$

In other words, the result is the length of the non unit length vector (the ray delta vector) scaled by the cosine of the angle between them. If you look at the image, we can see that this would give us the length of a vector from the ray origin to the Projected Ray End point along the direction of the negated plane normal. If we imagine the ray delta vector to be the hypotenuse of a right angled triangle, the result describes the length by which we would need to scale the unit length normal vector such that it correctly described the adjacent side of the same right angled triangle. If we were to scale the negated normal of the plane by this result, we would get the projected ray end point shown in the diagram. If we were to

draw a straight line from the actual ray end point to the projected ray end point we can see that this would form the opposite side of a right angled triangle also. So, by dotting the ray delta vector with the negated normal, we end up with the length of the ray projected along the plane normal.

So what does this tell us? Quite a lot, actually. With the projected ray length, we can measure the intersection between the projected ray and the plane much more easily. We know from looking at the diagram that the point at which the projected ray intersects the plane in this new projected direction is simply the distance to the plane from the ray start point. This is the orange line in the diagram labelled Distance to Plane, which we have already calculated.

We know the length of the projected ray and the distance at which the plane intersects the projected ray because now they both share the same orientation. The intersection point is simply the distance to the plane from the ray origin. If we divide the distance to the plane (the distance to the intersection along the projected ray direction) by the length of the projected ray, we get back a float *t* that represents the intersection along the projected ray as a percentage between 0.0 and 1.0. It essentially describes the distance to the intersection in units of overall ray length. So a *t* value of 0.5 would mean the intersection is exactly halfway along the ray's delta vector.

You may see versions of the calculation of the *t* value that negate the sign of the Distance to Plane when performing such a calculation. It depends on whether you calculate your distance to plane value as a positive or negative value when a point is in front of the plane. You may also see versions of this calculation where the Projected Ray Length is negated before the divide. This boils down to whether it was projected by performing $d \bullet -Normal$ as we have, or by using $d \bullet Normal$. In the second case, the dot product will return a negative value for the projected line length because the delta vector ***d*** and the non-negated plane normal are facing in opposite directions. All that is happening is that the negation is not being applied to the normal; it is being applied later to the result. However, for the time being, we are assuming that we have calculated the distance to the plane and the projected ray length as positive values by flipping the plane normals where applicable.

t = Distance To Plane / Projected Ray Length

If Projected Ray length ($d \bullet -Normal$) equals zero then it means no intersection occurs because there is a 90 degree angle formed between the plane normal and the ray delta vector. This means the ray is parallel with the plane and cannot possibly intersect it. If the distance to the plane from the ray origin is a negative value, it means the ray origin is already behind the plane. You may or may not want to consider intersections with the back of a plane depending on your application's needs, so you may or may not wish to return false immediately when this is the case. If $t < 0$ then the ray origin is situated behind the plane and will never intersect the back of it. If $t > 1$ then the intersection with the plane happens past the end point of the ray and is not considered to be a valid intersection. A *t* value in the range of 0.0 to 1.0 describes the intersection with the plane along the projected ray and the intersection along the actual ray parametrically. Thus, if we wanted our Ray/Plane intersection method to return the position of intersection (and not just the *t* value) we could easily calculate it as follows:

Intersection Point = Ray Origin + (Ray Delta * t)

As you can see, we are just scaling the ray delta vector by the *t* value to reduce the delta vector's length such that it correctly describes the length of a vector from the ray origin to the intersection with the plane. We then add this to the ray origin to get the actual position of the intersection with the plane.

Taking what we have just learned, we can now implement a function that will calculate ray/plane intersections. It will take a ray origin, a ray delta vector, a plane normal, and a point on that plane as input parameters. We also have two output parameters: a 3D vector which will store the intersection point (if one occurs) and a float to store the *t* value of intersection.

```
bool RayIntersectPlane( const D3DXVECTOR3& Origin,
                        const D3DXVECTOR3& Direction,
                        const D3DXVECTOR3& PlaneNormal,
                        const D3DXVECTOR3& PlanePoint,
                        float& t,
                        D3DXVECTOR3& IntersectionPoint )
{
    // Calculate Distance To plane
    float PlaneDistance = D3DXVec3Dot( &(Origin - PlanePoint), &PlaneNormal );

    // Calculate Projected Ray Length
    float ProjRayLength = D3DXVec3Dot( &Direction, &-PlaneNormal );

    // If smaller then zero then it is either running parallel to the plane
    // or intersects the back of the plane. We choose to ignore in this version.
    if ( ProjRayLength < 1e-5f ) return false;

    // Calculate t
    t = PlaneDistance / ProjRayLength;

    // Plane is either before the start of the ray or past the end of the ray so
    // not intersection
    if ( t < 0.0f || t > 1.0f ) return false;

    // Calculate the intersection point
    IntersectionPoint = Origin + ( Direction * t );

    // We're intersecting
    return true;
}
```

In this version of the function we calculate the distance to the plane from the ray origin by projecting a vector from the point on the plane to the ray origin along the plane normal. This step would not be necessary if the function was passed all the plane coefficients and not just the normal.

Next we see another version of the function that does the same thing, only this time, the distance to the plane from the ray origin can be calculated using ax+by+cz+d. In this version, we pass the plane in as a single parameter (instead of a normal and a point) stored inside a D3DXPLANE structure. This is a structure with four float values labeled a, b, c, and d as expected.

```
bool RayIntersectPlane( const D3DXVECTOR3& Origin,
                        const D3DXVECTOR3& Direction,
                        const D3DXPLANE& Plane,
```

```
                          float& t,
                          D3DXVECTOR3& IntersectionPoint )
{
    // The D3DXPlaneDotCoord function performs the plane equation calculation.
    // It could be written manually as :
    // Plane Distance = Plane.a * Origin.x + Plane.b * Origin.y +
    //                  Plane.c * Origin.Z + Plane.d
    float PlaneDistance = D3DXPlaneDotCoord( &Plane , &Origin );

    // Calculate Projected Ray Length using the D3DXPlaneDotVector function
    // It performs ax + by + cz. A simple dot product between the plane normal
    // and the passed vector
    float ProjRayLength = D3DXPlaneDotVector( &Plane, &Direction );

    // if smaller then zero then it is either running parallel to the plane
    // or intersects the back of the plane we choose to ignore in this version.
    if ( ProjRayLength > -1e-5f ) return false;

    // Sign must be negated because Plane Normal was not inverted
    // prior to dot product above
    t = - ( PlaneDistance / ProjRayLength );

    // Plane is either before the start of the ray or past the end of the ray so
    // not intersection
    if ( t < 0.0f || t > 1.0f ) return false;

    // Calculate the intersection point
    IntersectionPoint = Origin + ( Direction * t );

    // We're intersecting
    return true;
}
```

This version of the function will probably appeal more to the math purists. This will make some sense when we try to arrive at an algebraic solution in a moment. Here we are using the standard plane equation **ax + by + cz + d** to calculate the distance to the plane from the ray origin. This is performed inside the function D3DXPlaneDotCoord. It essentially performs a 4D dot product between the plane coefficients and a 3D vector with an assumed *w* coordinate of 1.0 (1**d*).

We then calculate the projected line length by doing a dot product between the plane normal and the ray delta vector. We use the D3DXPlaneDotVector function for this which performs a 3D dot product between the a, b, and c components of the plane (the normal) and the x, y and z components of the input vector. You will recall that in the previous version of the function we negated the plane normal before we performed this dot product so that both the ray delta vector and the plane normal were facing the same way. In this version we have not done this (i.e., negating the a, b, and c coefficients of the plane prior) so the projected line length returned will be a negative value. Dividing the plane distance by this value will also generate a negative *t* value, which is not desirable. Notice how we take care of this later in the function simply by negating the result the of the *t* value calculation. This nicely demonstrates what was said earlier about the *t* value calculation potentially needing to have its result negated depending on the sign of the inputs to its equation.

The Algebraic Solution

In the last section we analyzed ray / plane intersection from a geometric perspective and arrived at our final *t* value calculation. As we proceed through this chapter however, we will have to be ready to find algebraic solutions since the problems we will attempt to solve will become more challenging and less easily represented from a geometric perspective. In order to refresh ourselves in the subject of algebra, we will start by finding a solution for Ray / Plane intersection using algebraic manipulation.

When using the standard plane equation in the last section, we discovered that to determine the value of *t*, the calculation was:

$$t = -\frac{\text{Distance To Plane}}{\text{Projected Ray Length}}$$

Let us see if we come up with the same equation using an algebraic approach.

Our ray **R** is defined parametrically and has an origin vector **O** and a delta vector **V**. *t* values in the range of 0.0 to 1.0 represent points on the ray.

$$R(t) = O + tV$$

Our plane is represented using the standard form of the plane equation:

$$ax + by + cz + d = 0$$

In vector form this can be written as the dot product between a point **P** (x,y,z), a plane normal **N** (a,b,c) and the addition of the d coefficient (the distance to the plane from the origin of the coordinate system).

$$P \bullet N + d = 0$$

Substituting the Ray into the Plane Equation

In the vector form of the plane equation, **P** represents a point on the plane if the equation is true. However, we wish to find a point on the ray which intersects the plane. Of course, if the ray intersects the plane, the point where it intersects is obviously on the plane. Thus, we are going to want to find the *t* value for our ray which would produce a point which makes the plane equation true. So we substitute **P** in the plane equation with our ray definition and we get:

$$(O + tV) \bullet N + d = 0$$

As the term (**O** + *t***V**) is dotted by **N**, this is equivalent to dotting both vectors (**O** and *t***V**) contained inside the brackets by **N** individually (the dot product is distributive). This means we can instead write **O** dot **N** + *t***V** dot **N** allowing us to expand out the brackets:

$$O \bullet N + tV \bullet N + d = 0$$

In order to find the point on the ray which intersects the plane, we have to find *t*. If we solve for *t* in the above equation, then we are finding the point on the ray which returns a distance of zero (look at the = 0 on the RHS) from the plane.

Solving such equations is actually quite simple. We just have to figure out a way to move everything we do not want to know about over to the right hand side of the equals sign, leaving us with the variable we do want to know about isolated on the left hand side of the equals sign (or vice versa). At this point, we will have solved the equation and will know how to calculate *t*.

Looking at the above equation we can see that the first thing we can get rid of on the LHS is '+*d*'. If we subtract *d* from the LHS of the equation it will cancel it out. We must also make sure that anything we do to the LHS must be done to the RHS to keep the equation balanced. If we subtract *d* from both sides of the equation, our equation now looks like this :

$$O \bullet N + tV \bullet N = -d$$

We also see that *t* is multiplied by ($V \bullet N$) on the LHS. If we divide the LHS by $V \bullet N$ we can cancel that out from the LHS. Of course, we must also divide the RHS by $V \bullet N$ as well to keep the equation balanced. Performing this step gives us the following:

$$\frac{O \bullet N}{V \bullet N} + t = \frac{-d}{V \bullet N}$$

t is very nearly isolated on the LHS now. All that is happening to *t* now on the LHS is that it is having $O \bullet N$ added to it. Therefore, we can completely isolate *t* on the LHS by subtracting $O \bullet N$ from both sides of the equation. This leaves us with the final solution for *t* as shown below:

$$t = \frac{-d - O \bullet N}{V \bullet N}$$

Of course, this can also be written by placing the numerator in brackets and distributing a -1 multiplication:

$$t = \frac{-(O \bullet N + d)}{V \bullet N}$$

This is the equivalent of the more common form:

$$t = -\frac{O \bullet N + d}{V \bullet N}$$

And here we see the final solution for *t*. Note that is it exactly how the last version of the RayIntersectPlane function calculated its *t* value:

```
t = - ( PlaneDistance / ProjRayLength );
```

Looking at our final equation, we know that $O \bullet N + d$ calculates the distance to the plane from the ray origin **O**. We also know that $V \bullet N$ computes the length of the ray projected onto the normal. However, because the normal **N** and the delta vector **V** are pointing in opposite directions, this will produce a negative length value. When the positive plane distance is divided by a negative projected length, we will get back a negative *t* value. This is why we negate the final result. As you can see, this is exactly what we have in the equation for *t*.

The solution for *t* could also be written by negating $V \bullet N$ before the divide like so.

$$t = \frac{O \bullet N + d}{-V \bullet N}$$

These are all identical ways of calculating the final positive *t* value with a negative projected length. You may see us using any of the forms to solve for *t* in our code from time to time. They all are equivalent.

12.4.3 Ray / Polygon Intersection Testing

Determining whether or not a ray intersects a plane is very a useful technique. It is used in polygon clipping for example, where each edge of the polygon can be used as a ray which is then intersected with the clip plane. We will cover polygon clipping in the next chapter when we discuss spatial partitioning techniques and you will see this all taking place. Ray/Plane intersection testing is also used when determining whether or not a ray is intersecting a polygon. This is important because ray/polygon intersections will be used by our collision detection system and by a host of other techniques we will employ later in this training program.

We will see one application of Ray/Polygon intersection testing later in this course when writing a Lightmap Compiler tool. A Lightmap Compiler is an application that will calculate and store lighting information in texture maps which can later be applied to polygons to achieve excellent per-texel lighting results. In such an application, a ray is used to represent a beam of light between each light source in the scene and the texels of each polygon's texture. If the light source ray reaches the polygon currently being tested then the lighting information is added to the light map texture. If the ray is

intersected by other polygons in the environment on its way to the polygon currently having its lightmap computed, then the polygon is said to be at least partially in shadow with respect to that light source and the light source does not contribute lighting information to that particular texture element. We will look at how to build our Lightmap Compiler later in the course. In fact, Ray/Polygon intersection tests will be used in all manner of lighting techniques and not just light mapping.

Another application of Ray/Polygon intersection is a technique called picking. When writing an application such as GILES™, we want the user to be able to select a polygon in the scene using the mouse as an input device. To accomplish this, the screen coordinates of the mouse can be converted into world space coordinates and then used to create a ray that extends into the scene from the camera position. The polygon intersection producing the smallest *t* value is assumed to be the first polygon that is hit by the ray and is the polygon that is selected. This is pretty much the same technique that is used by simple ray tracing renderers as well. In a simple ray tracer, the near view plane is essentially carved up into a pixel grid and rays are cast from the eye point (located some distance behind the plane) through each pixel location into the scene to find the point of closest intersection. The lighting information at that point is then computed and stored in the image pixel.

As you are no doubt convinced by now, the need to be able intersect rays with polygons is of paramount importance in 3D computer graphics.

Testing whether a ray intersects a polygon is a two step process. First we can perform a ray/plane intersection test to see whether the ray intersects the infinite plane that the polygon is on. The ray/plane test is done first because testing for a ray/plane intersection is computationally inexpensive. If a ray does not intersect the plane that a polygon lies on, it cannot possibly intersect the polygon itself. Therefore, performing the ray/plane intersection test first provides an early out mechanism for many of the polygons that we need to test which are not going to be intersecting the ray.

If a polygon passes the initial ray/plane test, the next test looks to see if the ray intersects the actual polygon itself. Since planes are infinite, even if the ray does intersect the plane of the polygon, the intersection with the plane may have happened well outside the borders of the polygon. So our second test will need to determine if the plane intersection point returned from the ray/plane intersection test is within all the edges of the polygon. If this is the case, then the point is indeed inside the polygon and we will have successfully determined that the ray has intersected the polygon. Since polygons can take on arbitrary shapes it might appear that a generic solution would be very hard to create. However, with our trusty dot product and cross product operations (see Module I), the task is mostly trivial.

Once a plane intersection point has been found, our job is to see whether the intersection point actually resides within the interior of the polygon. Since a polygon is just a subset of its parent plane, the testing process is really nothing more than finding out whether the intersection point is contained within all edges of the polygon. So how do we test this? Usually, your polygons will store their plane normals, but if this is not the case, you can refer back to Module I to see how to generate a polygon normal by performing the cross product on two of its edge vectors and normalizing the result. We will assume for the sake of this discussion that the polygon you wish to test for intersection also contains a polygon normal.

The “Point in Polygon” testing process is broken down into a set of simple tests (one for each edge of the polygon). For each edge we create an edge normal by performing a cross product between the edge vector and the polygon normal. For this test, the edge normal does not need to be normalized. This will return to us the normal of the edge and since we know that any vertex in the edge will suffice for a point that lay on the plane described by this edge normal, we have ourselves a complete description of the plane for that edge. We then simply classify the plane intersection point against the edge plane.

In the example shown in Figure 12.20, the edge planes are created with their normals facing outwards from the center of the polygon. Therefore, if the point is found to be in front of **any** edge plane, it is outside the polygon and we can return false immediately. If the point is behind the edge currently being tested, then we must continue to test the other edges. Only when the intersection point is contained behind all edge planes is the intersection point considered to be inside the polygon.

Figure 12.20 shows this process by demonstrating two example intersection points (P0 and P1) which are being tested for “Point in Poly” compliance. P0 is clearly inside the polygon because it lies behind all the planes formed by the edges of the polygon. P1 is not inside because it does not lay behind all edge planes (although it does lay behind some). We will use this diagram to step through the testing process using these two example intersection points.

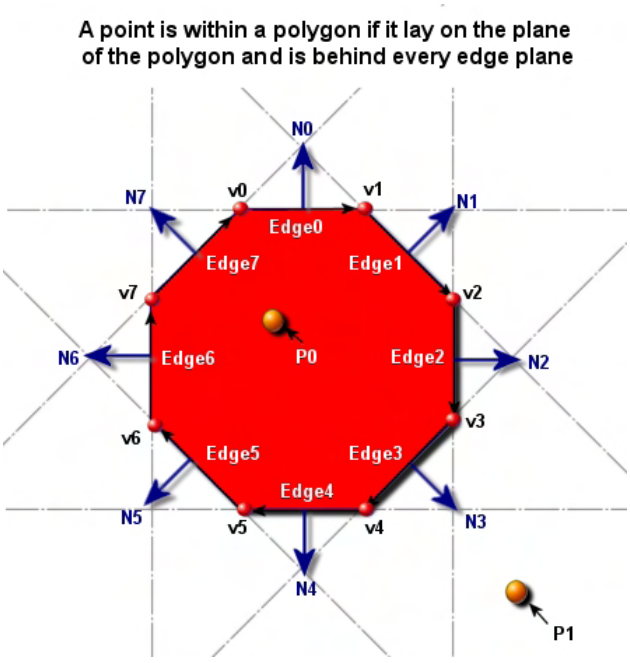

Figure 12.20

In the first example we will start with intersection point P0 which has been found to be on the plane of the polygon by a prior ray/plane intersection test. The polygon being tested for intersection is an octagon with 8 vertices labelled v0 through v7. We start by entering a loop that will iterate through each of the eight edges of the polygon. In the first iteration of this loop, we test the first edge formed by the first two vertices v0 and v1. We can create an edge vector by subtracting v0 from v1 which give us the black arrow running along the first edge in the diagram from left to right connecting those two vertices:

```
EdgeVector = v1 – v0
```

Now, while the polygon normal is not illustrated in the diagram because it is directly facing us (coming out of the page), we can imagine it is sticking out from the polygon in our direction such that it is perpendicular to the polygon. So we have an edge vector and a polygon normal at our disposal with which to generate the plane normal for the first edge (N0 in the diagram).

We know that performing the cross product between two vectors will return a third vector which is orthogonal to the two input vectors. The edge vector and the polygon normal are already perpendicular to each other, so crossing these two vectors will return vector N0 forming an orthogonal set of vectors (like a coordinate system axis). Vector N0 will be the normal to the plane for that edge. Looking at Figure 12.20 and at edge 0 in particular, we can see that the normal N0 generated by the cross product is the normal to an infinite plane aligned with the edge and shown as the gray dashed line running horizontally through that edge. We can imagine this plane to continue infinitely both to the left and right of the edge and can further imagine the plane continuing infinitely both into and out of the page on which you are viewing the diagram. Remember, these edge planes are perpendicular to the plane of the actual polygon.

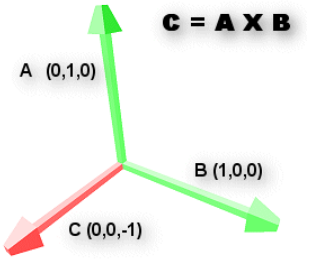

Figure 12.21

Once we have the edge plane normal for the edge we are testing, we simply classify the point P0 against that plane. If the point is in front of the edge plane, then it is clearly outside the polygon. In this example however, we can see that intersection point P0 is behind the first edge plane and we must continue through to the next iteration of the loop and check the next edge in the polygon. So, as P0 has now passed the test for edge 0, we move on to the second iteration of the edge loop where we test edge 1. Once again, we create an edge vector from the vertices of that edge (v1 and v2) like so:

```
EdgeVector =  v2 – v1
```

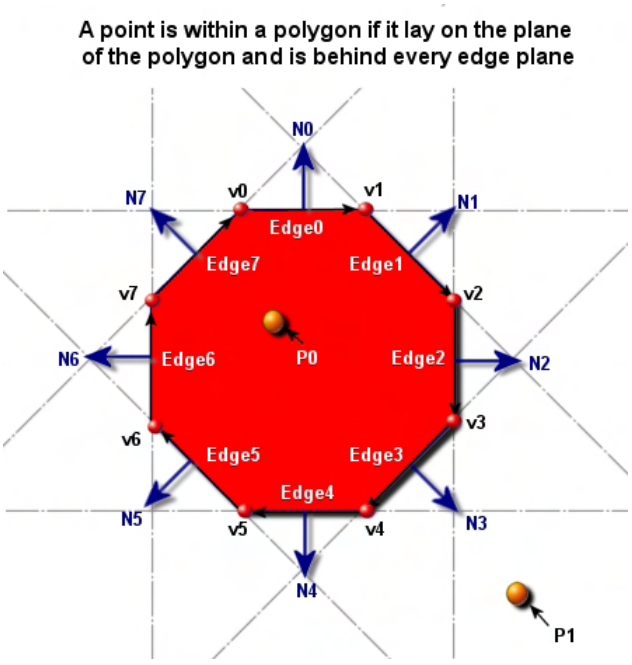

Figure 12.20 (again for convenience)

We then perform the cross product with the polygon normal and edge 1 to generate the normal N1 (the normal of the second edge). We classify the intersection point P0 against this plane and once again find it to lay behind the plane for this edge. If it lay in front of this plane we could return false from the function and skip the edge tests which have not yet been performed. In this case however, the point has passed the test for edge 1 also so we must continue to the third iteration of the loop and test the third edge.

You should be able to see by looking at the diagram that for any point that is actually inside the polygon, each edge will need to be tested and the point P0 would be found to lay behind all of the polygon's edge planes. If we reach the end of the process and have not yet returned false, it means the point is situated behind all edge planes and is therefore inside the polygon. Thus, the ray for which the intersection point with the plane was generated does indeed impact the polygon also.

Let us now see how intersection point P1 fares using this technique. We can clearly see by looking at it that it is not within the bounds of the polygon, but let us quickly walk through the testing process to see at which point it gets rejected and the process returns false.

First we create the plane for edge 0 (N0) and see that intersection point P1 is behind the plane and cannot be rejected at this point. As far as we are concerned right now, P1 may very well be inside the polygon, so we continue on to edge 1. Once again, we can see that when we test P1 against the second edge plane (edge 1), P1 is also found to be behind edge plane N1 and therefore, at this point may still be inside the polygon. When testing edge2 however, we can see that when we create the plane for this edge and classify P1 against it, P1 is found to be in front of the plane described by normal N2. As such, we can immediately return false from this procedure eliminating the need to test any more edges.

So this process does indeed correctly tell us if the point is inside the polygon, provided that we know beforehand that the point being tested is on the plane of the polygon. This all works out quite nicely because the point in polygon test is much more expensive than the ray/plane intersection test. We only have to perform the point in polygon test for a given polygon when the ray/plane intersection test was successful. When performing ray/polygon intersection tests on a large number of polygons, most of those polygons will be rejected by the cheaper ray/plane test first. This avoids the need to carry out the point in polygon test for polygons which cannot possibly intersect the ray. Once we have reduced our polygon list to a list of potential intersecting polygons, we can move to the second step and perform point in polygon tests on this subset. Note that usually only a few, at most, of the potential intersecting polygons will actually be intersected by the ray. So it is only for those polygons that every edge will need to be tested. But even the majority of these polygons tested will exit from the process early as soon as the first edge plane is found that contains the intersection point in its front space.

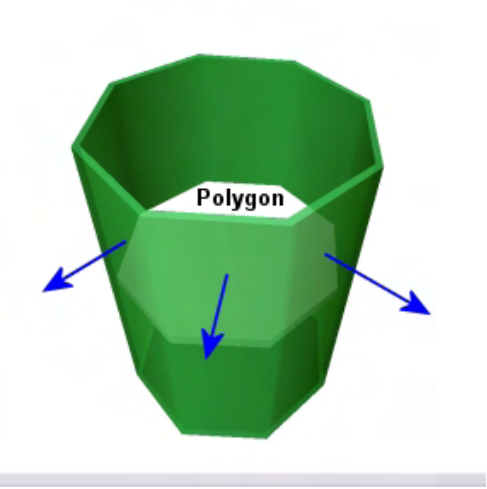

Figure 12.22

It is sometimes difficult to picture the orientations of the edge planes given the 2D image we saw earlier. But we can imagine the planes in the above example forming an infinitely long 3D cylinder based on our octagon polygon. Figure 12.22, while showing the planes as having finite length (for the sake of illustration), hopefully demonstrates this concept. The green cylinder surrounding the polygon in this example shows the planes of each edge. These planes would be infinitely tall in reality. The polygon is at the center of these planes. As we see in the diagram, the plane normals face outwards. Any point found to be behind every plane is by definition inside the space of the cylinder formed by these planes. Since we already know that the point we are testing shares the same plane as the polygon (determined by the ray/plane intersection test) we know that the point is actually on the polygon itself.

Let us now look at how we might implement a “Point in Polygon” function. We will return true if the positional vector passed in is found to be contained inside the polygon and false otherwise. Remember, this function should be used in conjunction with a ray/plane intersection test. Whenever it is called, we are always passing in a vector that describes a position on the plane of the polygon being tested. This

will be the intersection point returned from the ray/plane intersection test in a prior step. If the ray/plane test returned false for a given polygon, then there is no need to call this next function.

This simple version of the function assumes that the polygon being tested is an N-gon where all points are assumed to lay on the same plane in a clockwise winding order.

```
BOOL PointInPoly ( D3DXVECTOR3 * Point , CPolygon * pPoly)
{
   D3DXVECTOR3 EdgeNormal, Direction, Edge;
   D3DXVECTOR3 FirstVertex, SecondVertex;

   // Loop through each vertex ( edge ) in the polygon
   for ( int a = 0; a < VertexCount; a++ )
   {
       // Get First vertex in edge
       FirstVertex      = pPoly->m_vecVertices[a];

       // Get second vertex in edge  ( with wrap around)
       SecondVertex = pPoly->m_vecVertices[ (a+1)%VertexCount ] ;

        // Create edge vector
        Edge            = SecondVertex - FirstVertex;

        // Generate plane normal
        D3DXVec3Cross   ( &EdgeNormal, &pPoly->m_vecNormal, &EdgeNormal );

        //Create vector from point to  vertex ( point on plane )
        Direction       = FirstVertex-*Point;

        float d = D3DXVec3Dot( &Direction, &EdgeNormal );

        if ( d < 0 ) return FALSE;

    } // Next Edge

    return TRUE;
}
```

The code sets up a loop to test each edge (each pair of vertices). Notice how we use the modulus operator to make sure that the second vertex of the final edge wraps back around again to index the first vertex in the polygon's vertex list. We then create Edge, the edge vector of the current edge being tested.

After generating the edge vector, we create the normal for the edge plane by performing a cross product between the edge vector we just calculated and the polygon normal. In this example, we are assuming that the polygon data is represented as a CPolygon structure which contains the normal. If the normal is not present then you will have to generate it by crossing two edge vectors.

At this point we have the normal for the edge currently being tested and we also know a point that exists on that plane (i.e., either vertex in the edge). We use the first vertex in the edge, but it could be the second also, as long as the point is on the edge plane. We then calculate a vector (Direction) from the point being tested to the point on the plane (the first edge vertex) and take the dot product of this vector with the edge normal. If the angle between these two vectors is greater than 90 degrees (i.e., the result is

larger than zero) then the point is in front of the plane. As soon as this happens for any edge we know the point is not contained inside the polygon and we can exit.

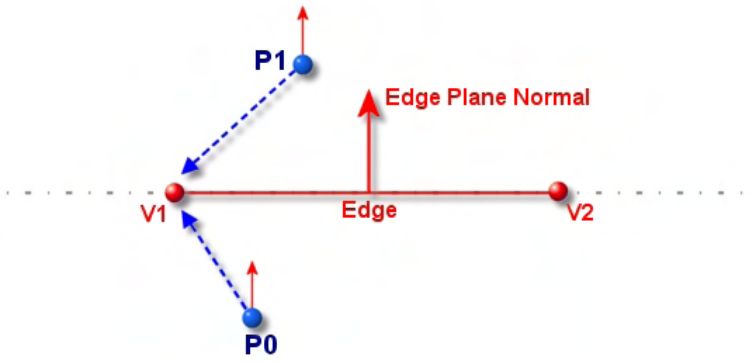

Figure 12.23

Figure 12.23 demonstrates testing to see if a point is in front or behind the edge plane. In this diagram we show two example points (P0 and P1) and perform the test on a single edge (v2 – v1). Starting with P0 we can see that creating a vector from P0 to V1 (called Direction in the above code) forms an angle with the plane normal that is less than 90 degrees. Remember that we bring vector origins together when we perform the dot product. Therefore, the dot product will return a positive result indicating that the point is behind the edge and cannot be removed from consideration without checking the other edges. The point should be tested against other edge planes as it may be inside the polygon. However, when we perform the same edge test on point P1, we can see that the vector created from P1 to V1 forms an angle with the edge normal that is larger than 90 degrees, returning a negative dot product result. When this happens, we know that the point is in front of the edge plane and cannot possibly be contained inside the bounds of the polygon. We can return false immediately and refrain from performing any more edge tests.

Bringing together everything we have learned, a function could be written to test for the intersection between a ray and a polygon by combining the ray/plane intersection test and the point in polygon test. In the following code we implement a function called RayIntersectPolygon which does just this. This function is assumed to understand the data type CPolygon which is expected to contain a polygon normal. You should be able to substitute this for your own custom polygon structures. This version of the function will return the intersection point and the intersection *t* value if the ray hits the polygon.

```
bool RayIntersectPolygon( const D3DXVECTOR3& Origin,
                          const D3DXVECTOR3& Direction,
                          const CPolygon  &Polygon,
                          float& t,
                          D3DXVECTOR3& IntersectionPoint )
{
    D3DXVECTOR3 EdgeNormal, Direction, Edge;
    D3DXVECTOR3 FirstVertex, SecondVertex;

    // Phase One : Test if Ray intersects polygon's plane
    // Calculate Distance to polygons plane using first vertex as point on plane
    float PlaneDistance = D3DXVec3Dot( &(Origin – Polygon.VertexList[0]),
                                       &Polygon.Normal );

    // Calculate Projected Ray Length onto polygons plane normal
    float ProjRayLength = D3DXVec3Dot( &Direction, &-Polygon.Normal );

    // if smaller then zero then it is either running parallel to the plane
    // or intersects the back of the plane we choose to ignore in this version.
    if ( ProjRayLength < 1e-5f ) return false;
```

```
    // Calculate t
    t = PlaneDistance / ProjRayLength ;

    // Plane is either before the start of the ray or past the end of the ray so
    // not intersection
    if ( t < 0.0f || t > 1.0f ) return false;

    // Calculate the intersection point
    IntersectionPoint = Origin + ( Direction * t );

    // Phase Two : Point in Poly
    // Loop through each vertex ( edge ) in the polygon
    for ( int a = 0; a < VertexCount; a++ )
    {
        // Get First vertex in edge
        FirstVertex     = pPoly->m_vecVertices[a];

        // Get second vertex in edge  ( with wrap around)
        SecondVertex = pPoly->m_vecVertices[ (a+1)%VertexCount ] ;

        // Create edge vector
        Edge            = SecondVertex - FirstVertex;

        // Generate plane normal
        D3DXVec3Cross   ( &EdgeNormal, &EdgeVector , &pPoly->m_vecNormal);

        //Create vector from point to  vertex ( point on plane )
        Direction       = FirstVertex-IntersectionPoint;

        float d = D3DXVec3Dot( &Direction, &EdgeNormal );

        if ( d < 0 ) return FALSE;

    } // Next Edge

    return TRUE; // Yes it must intersect the polygon

}
```

Most often in 3D graphics we are dealing with triangles and not with N-gons. The point in polygon test can be optimized somewhat when being used specifically for “Point in Triangle” tests because we can unwind the loop and lose a bit of overhead. The following snippet of code shows how we might write a function called PointInTriangle whose code could also be substituted into the function shown above to create a RayIntersectTriangle method.

A triangle will always have three vertices, so we will pass these in along with the normal for the triangle.

```
bool PointInTriangle(const D3DXVECTOR3& Point,  const D3DXVECTOR3& v1,
                     const D3DXVECTOR3& v2,     const D3DXVECTOR3& v3,
                     const D3DXVECTOR3& TriNormal )
{
    D3DXVECTOR3 Edge, EdgeNormal, Direction;
```

```
    // First edge
    Edge      = v2 – v1;
    Direction = v1 - Point;
    D3DXVec3Cross( &EdgeNormal, &EdgeNormal , TriNormal );

    // In front of edge?
    if ( D3DXVec3Dot( &Direction, &Edge ) < 0.0f ) return false;

    // Second edge
    Edge      = v3 – v2;
    Direction = v2 – Point;
    D3DXVec3Cross( &EdgeNormal, &Edge, &TriNormal );

    // In front of edge?
    if ( D3DXVec3Dot( &Direction, &EdgeNormal ) < 0.0f ) return false;

    // Third edge
    Edge      = v1 – v3;
    Direction = v3 - Point;
    D3DXVec3Cross( &EdgeNormal, &Edge, &TriNormal);

    // In front of edge?
    if ( D3DXVec3Dot( &Direction, &EdgeNormal ) < 0.0f ) return false;

    // We are behind all planes
    return true;
}
```

The cross product is not commutative so you have to make sure to feed the Edge and Plane normal vectors into the cross product in the order shown above if your edge normals point outwards. If the normals are generated so that they point inwards, then the sign of the dot product should also be changed to match. With inward facing normals, a point is considered inside the triangle if the angle formed by the vector from that point to the vertex in the edge and the edge normal is greater than 90 degrees (greater than 0.0). Alternatively, you could flip the direction of the vector from the point to the vertex and use (Point – Vertex) instead of (Vertex – Point). In that case, both vectors will have been flipped for the comparison and point into the same halfspace, so we can go back to the < 0.0 case for failure.

You will completely invalidate your results if you calculate your vectors to point in opposite directions and forget to change the sign of the dot product test. This is worth remembering since you will see instances of this in our source code from time to time.

12.4.4 Swept Sphere / Plane Intersection Testing

As discussed earlier, an application that uses our collision system will call the CollideEllipsoid method to request a position update for a moving entity. When examining a simplified version of this function, we saw the invocation of the detection phase via EllipsoidIntersectScene. We will get to study the code to this function a bit later in the chapter, but first we will concentrate on understanding the separate intersection tests which must be performed by this function in order to determine a new position for the ellipsoid.

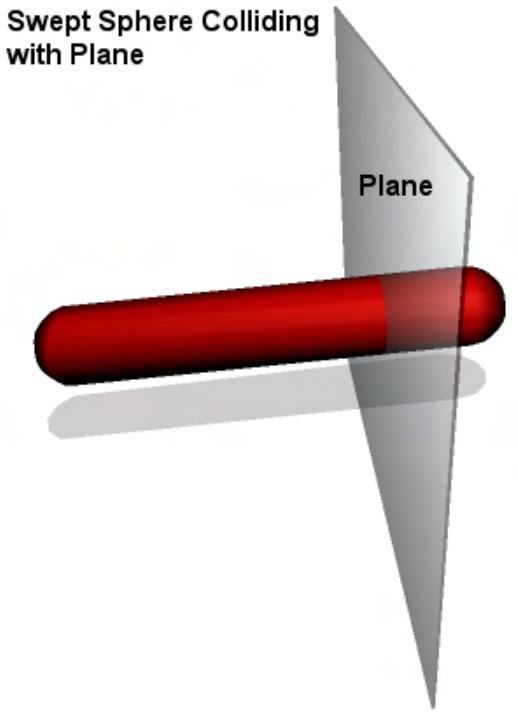

Figure 12.24

EllipsoidIntersectScene is passed the velocity vector and the ellipsoid center position in eSpace so that it can determine scene geometry intersections using unit sphere tests. The function will have to test the swept sphere against each potential colliding triangle to see if an intersection occurs. It will then return a final eSpace position based on the closest intersecting triangle (if one exists).

In order to use our unit swept sphere for intersections, this function must transform the vertices of each triangle it tests into eSpace prior to performing the intersection test. This is absolutely essential since we must have our ellipsoid and our triangles in the same space in order for the intersection results to have meaning. Over the next several sections of the lesson we will discuss the core intersection techniques that will be used by this function to determine intersections between the swept sphere and a triangle. These intersection tests will have to be executed for every triangle that is considered a potential candidate for intersection. As we currently have no broad phase in our system, this will be every triangle registered with the collision geometry database. Once we have covered the various components of the detection phase we will finally see how they are used in combination by looking at source code to the EllipsoidIntersectScene function.

When covering ray/triangle (ray/polygon) intersection, the first test we performed was ray/plane. If the ray did not intersect the plane, then it could not intersect the triangle and we can skipped any further tests. This was beneficial because this is an inexpensive test that allows us to reject most triangles very early on in the process. For the same reasons, when determining whether a swept sphere intersects a triangle, our first test is also going to be determining if the swept sphere intersects the plane of the triangle. If this is not the case then it cannot possibly intersect the actual triangle and we can bail out early from the test. Intersecting a swept sphere with a plane is going to be the cheapest intersection test we will have to perform for each triangle, so the benefit is the same for spheres as it was for rays (i.e., many of the potential colliders will be removed from consideration with very little computational overhead). Figure 12.24 demonstrates the intersection of a swept sphere and a plane. As can be seen, the sphere does indeed intersect the plane at some point along its velocity vector and we must write a function that will return that time *t* of intersection.

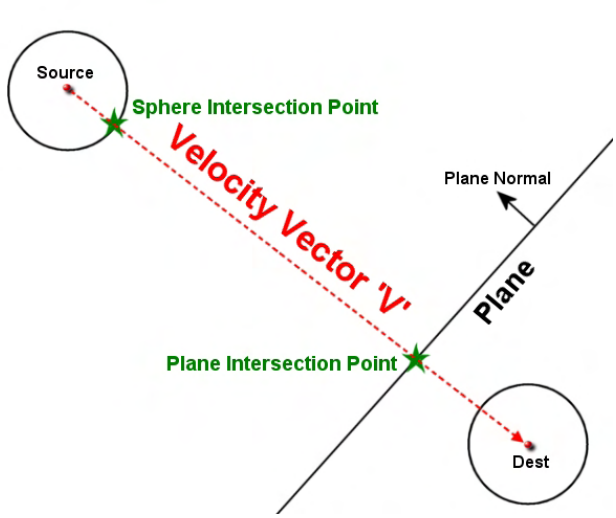

Figure 12.25

In Figure 12.25 you see the intersection we ultimately wish to find marked off. Source shows the center of the sphere in its starting position and Dest shows the sphere in its desired final position. The red dashed line is the velocity vector V describing the path we intend to move the sphere along during this update.

We want to find the *t* value for the time when the surface of the sphere first intersects the plane. The diagram shows both the intersection point on the plane and the matching point on the sphere surface that will intersect the plane first.

Unfortunately, we are not interested in finding the *t* value for the moment when the center of the sphere (Source) intersects the plane. If we were, this could be achieved by performing a simple ray/plane intersection test. You should be able to see in this diagram that if the center of the sphere Source was assumed to be the origin of a ray and the velocity vector V was the ray's delta vector, performing a ray/plane intersection test would give us the *t* value for the time when the center of the sphere would intersect the plane along the velocity vector. But this information is not helpful to us as is, because when this *t* value is later used to create the new center position of the sphere, the sphere would already be halfway embedded in the plane (and thus the triangle, assuming one exists at that location on the plane).

But as it happens, analyzing this problem sheds some light on a relationship that exists between the plane normal, the sphere radius and the intersection point on the sphere surface. By exploiting this relationship we will be able to rearrange the problem into one that allows us to use a simple ray/plane intersection test again.

In Figure 12.26 we see another example of a sphere of radius R intersecting the plane. We also see the sphere in its desired final resting place on the plane (Modified Dest). It is this center position we are attempting to find.

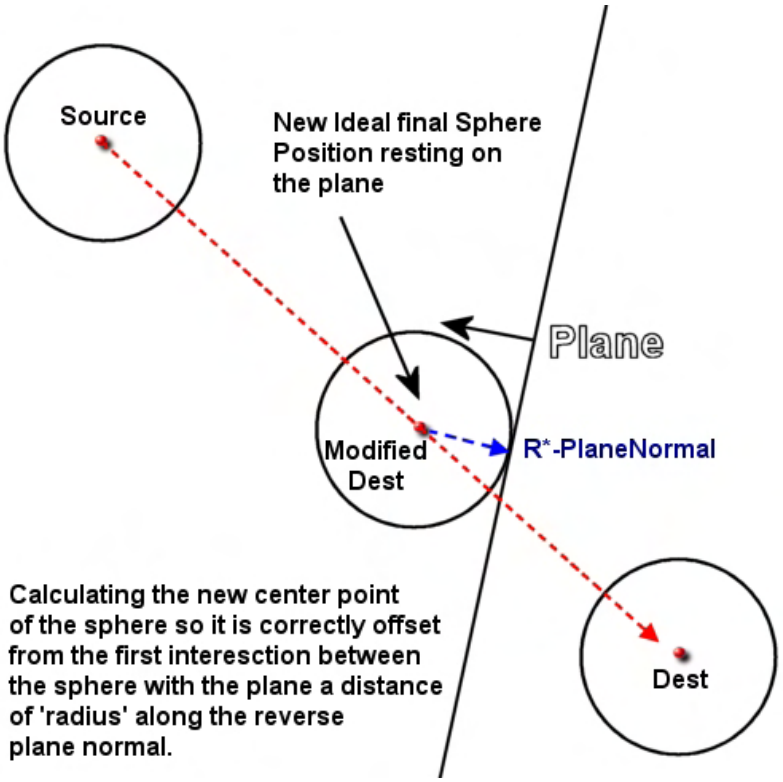

Figure 12.26

Notice that if we study the center point of the sphere resting against the plane (Modified Dest), it is offset from the plane by a distance equal to its radius. That is, it is offset along the plane normal by a distance R. Notice also how the intersection point on the surface of the sphere is found by traveling out from the center of the sphere Modified Dest by a distance of R along the negated plane normal. This is very important because it just so happens that regardless of the orientation of the plane and the orientation of the velocity vector V, if an intersection happens, the first point of intersection on the surface of the sphere will *always* be the point that is offset from the center of the sphere by a distance of R along the negated plane normal.

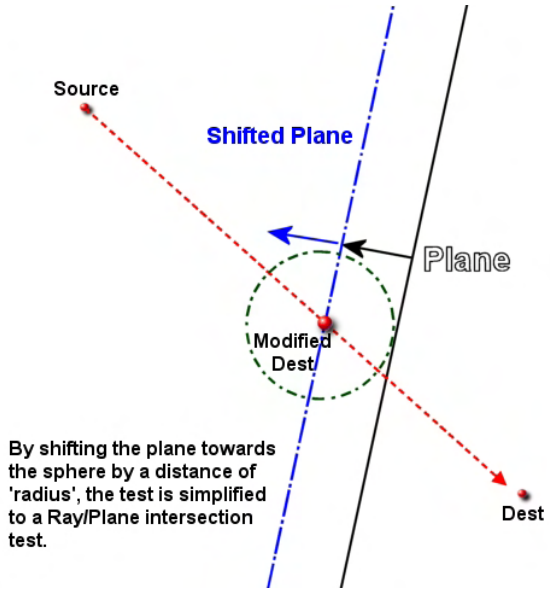

Figure 12.27

While this might not sound like a great discovery by itself, study Figure 12.26 again and imagine that you could pick up the plane and move it along the plane normal by a distance of R units. You would have essentially shifted the plane along the plane normal by a distance of –R such that the shifted plane now passes straight through the center of the sphere in its new position (Modified Dest). This is clearly shown in Figure 12.27.

As mentioned, it is the new center position of the sphere resting up against the plane we are searching for. If we shift the plane along its normal by a distance of -R, we get a plane that the center point of the sphere will intersect at exactly the same time that the surface of the sphere intersects the actual (unshifted) plane. This means we can find the new center position of the sphere by simply performing a ray/plane intersection test using the shifted plane. The ray will have the initial sphere center point

Source as its origin and it will have velocity vector V as its delta vector. As can be seen in Figure 12.27, the point at which this ray intersects the shifted plane describes the exact position where the center of the sphere should be when the surface of the sphere first intersects the actual plane. By simply shifting the plane, we have reduced the swept sphere/plane intersection test to a ray/plane intersection test (something we already know how to do very easily).

Let us put this in more formal terms:

We have the actual triangle plane defined using the plane equation (shown here in vector form):

$$P \bullet N + d = 0$$

N is the plane normal, *d* is the plane distance from the origin of the coordinate system and **P** is any point on the plane. However, we know that we are not trying to find a point on the triangle plane per se, but rather, we are trying to find the position (the center of our sphere) that is at a distance R from the plane. This is the position we would like to find since it describes the position of the center of the sphere when the surface of the sphere is touching the plane. So let us modify our plane equation to reflect this desire:

$$P \bullet N + d = R$$

For this equation to be true, the point **P** must be a distance of R from the original plane. If we subtract R from both sides of the equation, we zero out the RHS and introduce –R on the LHS:

$$P \bullet N + d - R = 0$$

As you can see, we now have the equation for the shifted plane (the original plane shifted by –R).

Next, let us substitute our ray into this equation (in place of **P**) and solve for *t*. Notice that we have placed (d – R) in brackets. This helps to more clearly identify that this is now a term describing the distance of the **shifted** plane from the origin of the coordinate system:

$$(O + tV) \bullet N + (d - R) = 0$$

where:

O = Initial Sphere Center

V = Sphere velocity vector

Now we will manipulate the equation using a bit of algebra and solve for *t*. Remember, we want to remove everything except *t* from the LHS of the equation.

$$(O + tV) \bullet N + (d - R) = 0$$

Let us first multiply out the brackets surrounding the ray by dotting the terms ***O*** and ***tV*** by ***N***:

$$O \bullet N + tV \bullet N + (d - R) = 0$$

Next we will subtract the term (*d* - *R*) from both sides, which removes it from the LHS and negates it on the RHS:

$$O \bullet N + tV \bullet N = -(d - r)$$

Now we will subtract $O \bullet N$ from both sides to remove it from the LHS. This obviously introduces the term $-O \bullet N$ on the RHS.

$$tV \bullet N = -(O \bullet N) - (d - R)$$

t is still multiplied by $V \bullet N$ on the LHS, so let us divide both sides by $V \bullet N$ leaving *t* alone on the LHS:.

$$t = \frac{-(O \bullet N + d) - R))}{V \bullet N}$$

Notice that we tidied up the numerator a little bit by moving ***+d*** from one set of negated brackets on the right into the other on the left. This way the coefficients for the original plane (the un-shifted plane) are grouped together as we are used to seeing them.

This can alternatively be written as:

$$t = -\frac{(O \bullet N + d) - R}{V \bullet N}$$

So what does this equation tell us? It tells us that all we have to do is calculate the distance from the ray origin to the triangle's plane and then subtract the sphere radius from this distance. This gives us the distance to the shifted plane in the numerator. We then divide this shifted plane distance by the length of the ray projected onto the plane normal. Of course, if you compare our final equation to the equation for the ray/plane intersection discussed in the previous section, you will see that the two are almost identical with the exception of the subtraction of R in the numerator. This small change allows the numerator to calculate the distance from the ray origin to the shifted plane instead of to the actual triangle plane.

Our swept sphere/plane intersection routine will be responsible for returning a *t* value. The calling function can then calculate the new position of the center of the sphere by performing:

New Sphere Center = Sphere Center + (t * Velocity)

where *t* is the value returned from the intersection routine we are about to write. It can be seen that because this intersection point lies on the shifted plane, it is at a distance of exactly Radius units from the actual plane and thus the sphere's surface is resting on the plane of the triangle at this time. Obviously, if the ray does not intersect the shifted plane, then the function should return false and the above step skipped.

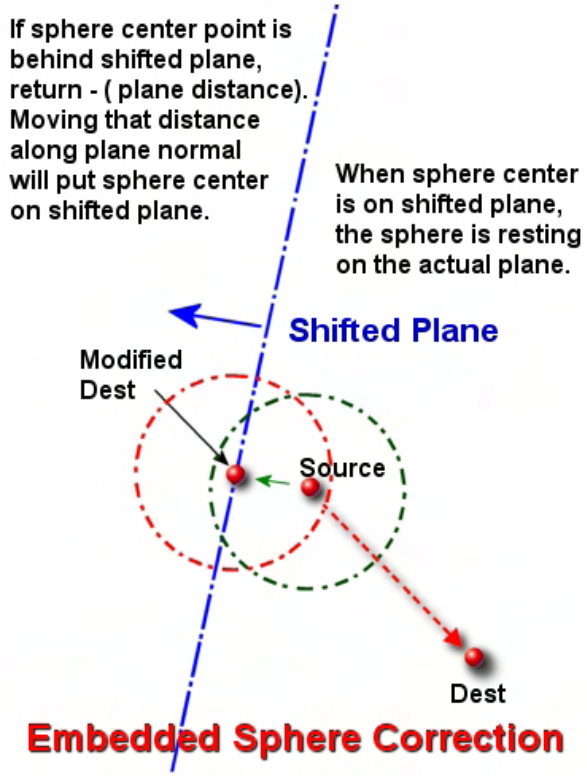

Figure 12.28

We are going to have to be vigilant about attempting to detect cases where things might not go as smoothly as planned. With floating point accumulation and rounding errors being what they are, it is possible that the sphere may have been allowed to become slightly embedded in the plane such that the ray origin actually lies behind the shifted plane of the triangle prior to the test being executed. While our collision detection system exists to stop the sphere ever passing through a triangle, there may be times when it has been moved a miniscule amount and it is partially embedded in the plane, but by a value larger than epsilon such that it is not considered to be on the plane by the intersection routines. We certainly do not want our collision detection system to fail when such an event occurs. It should instead calculate the value we need to move the sphere's center position back along the plane normal so that on function return, it is resting on the shifted plane. We will have then corrected the problem and properly moved the sphere center position back from behind the shifted plane to resting on it, as desired.

Figure 12.28 shows this additional test in action. The original center of the sphere (Source) is already behind the shifted plane when the ray intersection with the shifted plane is carried out. Usually, if the distance to the plane from the ray origin is negative in a ray/plane test, we return false for intersection. However, as Figure 12.28 demonstrates, in this particular case, we wish to calculate the distance from the center point to the plane and move it along the plane normal by that amount so that the center of the sphere is sitting on the shifted plane and we have the intersection point we were looking for. However, how do we know if the center of the sphere is legitimately behind the shifted plane of the triangle and should be corrected?

At this point we do not. Only if the intersection point with the shifted plane is later found to be within the edges of a polygon (in a separate point in polygon test) do we know if this is the case. Then we can update the position of the sphere so that it is no longer embedded. Remember, the ray origin will legitimately be behind thousands of planes as each triangle comprising the scene will lie on a plane. As planes are infinite, they will span the entire game level. We certainly do not want to move the ray origin back onto the plane for every one it is behind, as most will be nowhere near the sphere. What we will do

is narrow this down so that we only shift the ray origin back onto the shifted plane if the shifted plane itself is behind the sphere center position by a distance of no more than the radius of the sphere. In the worst cases it will never embed itself in a polygon by more than a fraction of that amount in a single update. This way we will not be performing this step needlessly for every shifted plane of every triangle which the sphere center position lays behind. Of course, we will still be needlessly moving it back for many planes since we really do not know, until we perform the point in poly tests later, whether this intersection point is within the edges of a polygon on that plane and whether the position of the sphere should really be updated in this way.

Let us now put to the test everything we have learned and examine the code to a function that performs an intersection test between a moving sphere and a plane. The following code is the exact code used in our collision system for this type of intersection. As discussed a moment ago, our intersection routines do not return the actual intersection point (a vector) but instead return only the *t* value. You will see in a moment that it is the parent function of our collision detection phase that uses the *t* value returned from its intersection routines to generate the final position of the sphere at the end of the process.

Notice first how we calculate the numerator of our equation (the distance to the shifted plane). We calculate the distance to the plane by dotting a vector from the sphere center to the point on the plane (passed as a parameter) and then subtract the radius of the sphere (just as our equation told us to do).

```
bool CCollision::SphereIntersectPlane( const D3DXVECTOR3& Center,
                                       float Radius,
                                       const D3DXVECTOR3& Velocity,
                                       const D3DXVECTOR3& PlaneNormal,
                                       const D3DXVECTOR3& PlanePoint,
                                       float& tMax )
{
    float numer, denom, t;

    // Setup equation
    numer = D3DXVec3Dot( &(Center - PlanePoint), &PlaneNormal ) - Radius;
    denom = D3DXVec3Dot( &Velocity, &PlaneNormal );

    // Are we already overlapping?
    if ( numer < 0.0f || denom > -0.0000001f )
    {
        // The sphere is moving away from the plane
        if ( denom > -1e-5f ) return false;

        // Sphere is too far away from the plane
        if ( numer < -Radius ) return false;

        // Calculate the penetration depth
        tMax = numer;

        // Intersecting!
        return true;

    } // End if overlapping

    // We are not overlapping, perform ray-plane intersection
    t = -(numer / denom);
```

```
    // Ensure we are within range
    if ( t < 0.0f || t > tMax ) return false;

    // Store interval
    tMax = t;

    // Intersecting!
    return true;
}
```

Notice the conditional code block in the middle of the function that handles the embedded case. As you can see, if the numerator is smaller than zero it means the distance to the shifted plane from the sphere center is a negative value. Also, if the denominator is larger than zero (with tolerance) it means the velocity vector is moving away from the plane and we just return false. We also return false if the distance from the ray origin to the shifted plane is larger than the radius (< -Radius). As discussed, planes that are this far away can safely be removed from consideration since the sphere could not have possibly embedded itself into a polygon this much in a single frame update. We then store the negative distance to the plane (the numerator) in the referenced parameter tMax so the caller will have access to this distance. This will describe to the caller the distance the sphere center should be moved backwards to rest on the shifted plane. In other words, it tells us how far back to move the sphere position so that it is no longer embedded in this plane.

Outside the embedded case code block we perform the usual calculation of the *t* value to generate a parametric value along the ray for the point of intersection. This is then returned to the caller via the tMax reference. Once again, in this section you can see that if t < 0.0 then we return false, since the intersection is behind the ray. Notice however that we also return false if tMax is smaller than the *t* value we just calculated. As you can see, tMax is not only an output, but it is also an input to the function.

To understand this, remember that the detection process will be run for each triangle and that we are only interested in discovering the closest intersection. Therefore, every time this function is called, it will only return true if the *t* value is smaller (closer to the sphere center point) than a previously calculated *t* value generated in a test with another triangle's plane. Thus, when we have tested every triangle, tMax will contain the *t* value for the closest colliding triangle.

Finally, if the sphere is not embedded in the plane, tMax will contain the parametric *t* value (0.0 to 1.0 range) on function return. But if the sphere *is* embedded, tMax will contain the actual distance to the shifted plane along the plane normal. The calling function will need to make sure it uses this information correctly when generating the intersection point on the plane, as shown next:

```
    if ( !SphereIntersectPlane( Center, Radius, Velocity,
                                TriNormal, v1, t )) return false;

    if ( t < 0 )
        CollisionCenter = Center + (TriNormal * -t);
    else
        CollisionCenter = Center + (Velocity * t);
```

In the above code, v1 is the first vertex in the triangle currently having its plane tested (i.e., the point on plane).

If input/output parameter *t* is negative on function return then it contains the actual distance to the plane. The point of collision on the shifted plane is calculated by moving the sphere center *t* units along the plane normal (we negate *t* to make it a positive distance). This moves it backwards so that the sphere center is now on the shifted plane and its surface is no longer embedded. If *t* is not negative then it is within the 0.0 to 1.0 range and describes the position of intersection (the new center point of the sphere) parametrically. Therefore, we simply multiply the velocity vector with the *t* value and add the result to the initial position of the center of the sphere. The end result is the same -- a position on the shifted plane which correctly describes what the position of the sphere should be such that its surface is resting on, but not intersecting, the triangle plane.

12.5 The SphereIntersectTriangle Function: Part I

Our collision system will invoke the collision detection phase by calling the CCollision::EllipsoidIntersectScene method. We will see later how this method will transform all the potential intersecting triangles into eSpace. It will then loop through each triangle and test it for intersection with the swept sphere. To test each triangle, it calls the CCollision::SphereIntersectTriangle method, which we will begin to construct in this section. This function will be a collection of different intersection techniques that we will implement. Below, we see the first part of this function using the intersection routine we discussed in the previous section.

```
bool CCollision::SphereIntersectTriangle( const D3DXVECTOR3& Center,
                                          float Radius,
                                          const D3DXVECTOR3& Velocity,
                                          const D3DXVECTOR3& v1,
                                          const D3DXVECTOR3& v2,
                                          const D3DXVECTOR3& v3,
                                          const D3DXVECTOR3& TriNormal,
                                          float& tMax,
                                          D3DXVECTOR3& CollisionNormal )
{

    float       t = tMax;
    D3DXVECTOR3 CollisionCenter;
    bool        bCollided = false;

    // Find the time of collision with the triangle's plane.
    if ( !SphereIntersectPlane( Center, Radius, Velocity, TriNormal, v1, t ))
       return false;

    // Calculate the sphere's center at the point of collision with the plane
    if ( t < 0 )
        CollisionCenter = Center + (TriNormal * -t);
    else
        CollisionCenter = Center + (Velocity * t);

    // If this point is within the bounds of the triangle,
    // we have found the collision
    if ( PointInTriangle( CollisionCenter, v1, v2, v3, TriNormal ) )
    {
        // Collision normal is just the triangle normal
```

```
        CollisionNormal = TriNormal;
        tMax            = t;

        // Intersecting!
        return true;

    } // End if point within triangle interior

    // We will need to add other tests here

}
```

This function is called for each collidable triangle and will be passed (among other things) a reference to a variable tMax which will be used to test for closer intersections. It will only return true if the *t* value of intersection (if it occurs) is smaller than the one already stored in tMax. The three vertices of the triangle (just 3D vectors) are passed in the v1, v2, and v3 parameters.

The first thing the function does is call the SphereIntersectPlane function we just wrote to test if the sphere intersects the plane of the triangle. Notice how we pass in the triangle normal and the first vertex of the triangle as the point on the plane (any vertex in the triangle will do). If the SphereIntersectPlane function returns false, then the SphereIntersectTriangle function can return false as well. If the sphere does not intersect the plane, it cannot possibly intersect the triangle on that plane. If the SphereIntersectPlane function returns true, the sphere did intersect with the plane and we continue.

The next thing we do is calculate the intersection point on the shifted plane. We can think of this position as the new position we should move the center of the sphere to so that its surface is resting on, but not intersecting, the triangle's plane. Of course, we still do know yet whether this collision point is within the triangle itself, so we must perform a Point in Triangle test. If it is inside, then we have indeed found the closest intersecting triangle so far and can return this new *t* value to the caller, which it can then use to update the sphere's position. Keep in mind that this function is called for each triangle, so we may find a triangle in a future test which is closer, overwriting the tMax value we currently have stored. We can also return the triangle normal as the intersection normal (for later use when creating the slide plane).

One thing that may have struck you as we have gone through this discussion is that we use the Point in Triangle function to test if the intersection point on the shifted plane is contained inside the polygon's edges. But the intersection point is on the shifted plane, not on the actual plane of the triangle. We can think of the intersection point as hovering above the actual polygon's plane at a distance of radius units (see Figure 12.29).

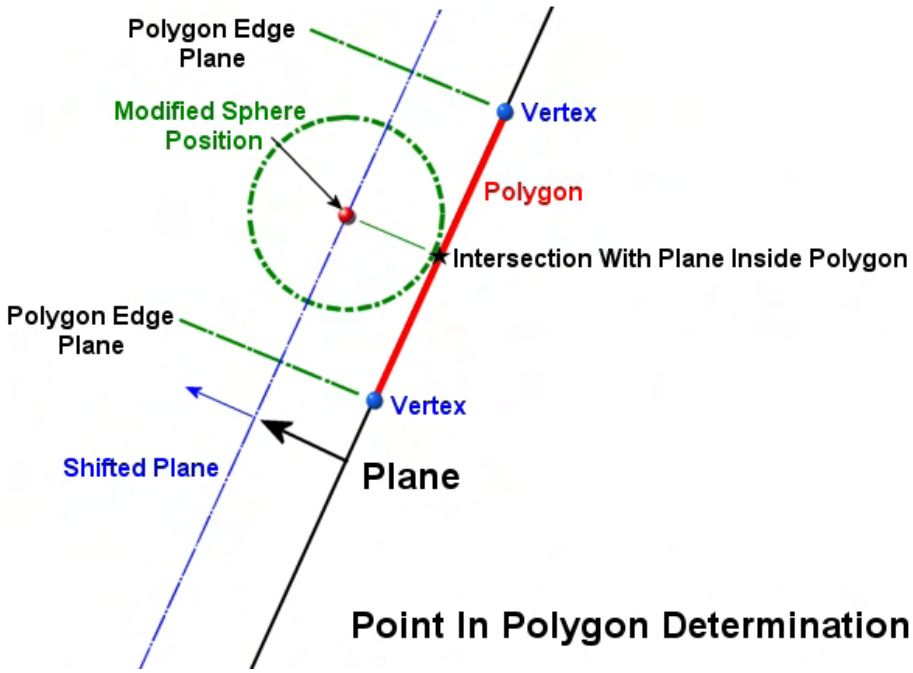

Figure 12.29

In Figure 12.29, the intersection point on the shifted plane describes the new non-intersecting position of the sphere center point. But it is not actually *on* the polygon's plane, so it raises the question as to whether or not we can use our Point in Triangle routine? The answer is yes. Recall that our Point in Polygon/Triangle routine returns true if the point is enclosed within the infinite planes formed by each edge of the polygon. Therefore, it is not necessary for the point to actually lie on the plane for the function to return true. If you refer back to Figure 12.22 you can see that a point hovering above the actual plane of the hexagonal polygon would still be inside the bounds of the infinite cylinder formed by the edge planes. In Figure 12.29, we see that the intersection point on the shifted plane (Modified Sphere Position) is indeed between the two edge planes, even though the point itself does not rest on the polygon's plane. Therefore, our Point in Triangle function would still correctly return true.

Unfortunately, our SphereIntersectTriangle method currently only handles the simplest and most common intersection case – when the sphere surface collides with the interior of the polygon. However, this is not the only case we must test for, and you will notice at the bottom of the code listing shown above we have highlighted a comment that suggests additional tests will need to be performed before we can rule out a collision between the sphere and the triangle currently being tested.

Figure 12.30 demonstrates the case where the sphere does intersect the plane and does intersect a polygon on that plane. However, the sphere does not intersect the *interior* of the polygon; it collides with one of its edges. Thus, edge tests are going to be required as well. What this essentially means is that our routine will go as follows… First we test to see if the sphere intersects the plane. If it does not, we can return false as shown in the above code. Then test to see if the intersection point on the plane is within the interior of the polygon (also shown above). If it is, then we have found the collision point and no further tests need to be performed. We simply return the *t* value of intersection. However, if the sphere did intersect the plane, but the intersection point is not within the interior of the polygon, we must test for an edge intersection (see Figure 12.30) because a collision may still occur.

Unfortunately, testing for collisions between a swept sphere and a polygon edge is not as simple as our other cases. The problem is that we can no longer rely on the fact that the first point of intersection on the surface of the sphere will be found at a distance of Radius units along the negated plane normal from the sphere center point. As Figure 12.30 demonstrates, at the time the sphere intersects the edge of the polygon, the sphere has (legally) passed through the plane. While the intersection point is still clearly at a distance of Radius units from the center of the sphere, it is no longer determined by tracing a line from the sphere center (Modified Dest) in the direction of the negated plane normal. That was how our previous test worked, but it will obviously not work here. When we call the SphereIntersectPlane function it will calculate the point at which the sphere first touches the plane. This point will not be inside the polygon, so the Point in Polygon test will return false. Thus, if the initial Point in Polygon test returns false, we must perform some more complicated edge tests before we can safely conclude that no collision has occurred.

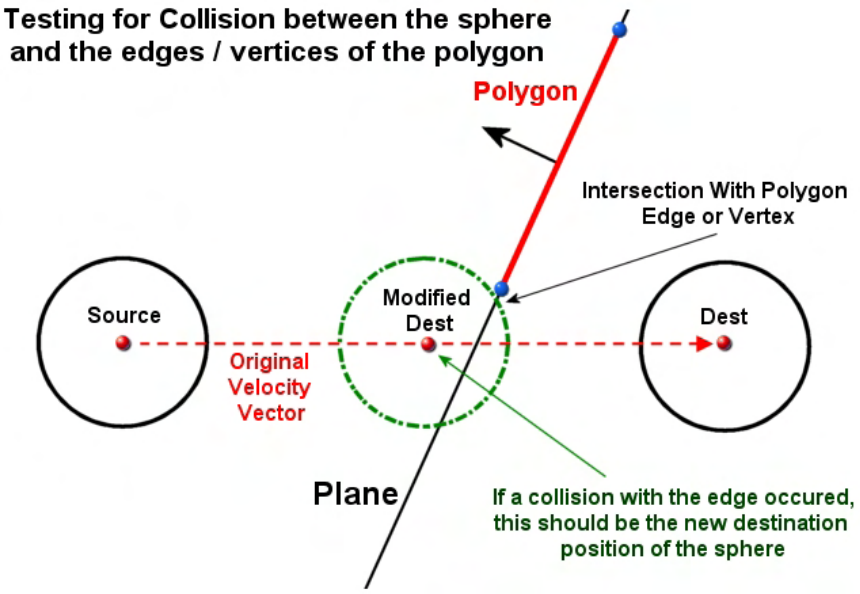

Figure 12.30

We will see later that tackling such a problem naturally leads us to a quadratic equation that will need to be solved. Because many students have not brushed up on quadratic equations since high school, the next section provides a quick refresher on quadratic equations and related ideas (including some very rudimentary mathematics like fraction multiplication and division, negative numbers, etc.). If you feel confident with respect to your ability to manipulate quadratic equations, get them into the standard form, and then solve them, please feel free to skip the next section. You should bear in mind that the remaining intersection techniques we examine will require that you have a good understanding of quadratic equations, so reading the next section is highly recommended if you are a little rusty.

12.6 Quadratic Equations

In this section we will discuss what quadratic equations are and how to solve them. If you have never encountered quadratic equations before then you will have to take a leap of faith for the time being and just believe us when we say that you will find the ability to solve them incredibly useful in your programming career. But before we get too far ahead of ourselves, we first have to discuss what a quadratic equation is and talk about a generic means for solving them. Only then will you be able to see why they are so useful in our collision detection code. Therefore, although this section will be talking about quadratic equations in an abstract manner initially, please stay with us and trust that their utility will become apparent as we progress with the lesson.

Hopefully we all recall that an equation is a mathematical expression stating that two or more quantities are the same as each other. You should also remember from high school algebra that a polynomial is a mathematical expression involving a sum of powers in one or more variables multiplied by coefficients (i.e., constants). For example, the following polynomial involves the sum of powers in one variable *t*. Polynomials are usually written such that the terms with the highest powers are arranged from left to right. This allows the degree of the polynomial to be more easily recognizable. In this example, we have a polynomial of the 3rd order because it involves a term that raises the unknown variable *t* to a maximum power of 3.

$$t^3 + at^2 + bt + c = 0$$

This is referred to as a *cubic polynomial* because the highest power of the unknown *t* is 3. **a**, **b** and **c** are referred to as *coefficients* (or constants) and contain the 'known' values, whatever they may be. Solving the above equation essentially means finding a value for *t* (i.e., the 'unknown') which makes the equation true. As you can imagine, it is no longer as easy to isolate *t* on the LHS of the equation (as it was with a linear equation such as the plane equation for example) since the unknown is now involved in multiple terms where it is being multiplied by coefficients.

A **quadratic** equation is a polynomial equation in which the highest power of the **single** unknown variable *t* is 2 and the coefficient of the squared term **a** is not zero. The **standard form** of the quadratic equation is the arrangement when the RHS is set to zero and the terms are stated as:

$$at^2 + bt + c = 0 \quad \textbf{\textit{(Standard Form)}}$$

As you can see, if **a** was set to zero, this would cancel out the squared term ($\mathbf{t^2}$) reducing the equation to a linear equation in the form:

$$bt + c = 0$$

Thus, the coefficient of the squared term must be non zero in order for it to be a quadratic equation.

> **Note:** The name 'Quadratic' given to such an equation is often the subject for much confusion. We know that the word 'Quad' means four and yet it is used to describe an equation which involves the 2nd power

and not the 4th. But there is another meaning for the word 'quad' which helps us make sense of why an equation of this type is called a Quadratic. Although the Latin word 'Quadri' does indeed mean four, the word 'Quadrus' means 'a square' -- a shape that has four sides. Quadratic equations arose from geometry problems involving squares, and as we know, the second power is also referred to as a square. Another Latin word 'Quadratus' means 'Squared', and several other words derive from this. For example, another name for the 'Square Dance' is the 'Quadrille' and the word 'Quadrature' (through the French language) describes the process of constructing a square of a certain area. Therefore, 'Quadratic' refers to an equation involving a single variable in which the highest power is raised to the power of two and is therefore said to be squared.

Not all quadratic equations are readily arranged into the shape the of the standard form $at^2 + bt + c = 0$. For example, the following list shows some quadratic equations which look initially to be using very different shapes. Notice however, that the single unknown (**x**) is still raised to the second power in one of the terms.

$$x^2 = 81$$

$$6x^2 + x = 100$$

$$-x^2 - 100 = 20$$

$$(x+3)^2 = 144$$

While these equations are all quadratic equations in **x**, they are not currently in the standard form. Later we will discuss the *quadratic formula*. This is a technique which can always be used to find the solutions to a quadratic equation that has been arranged in the standard form. Thus, in order to use the quadratic formula, we must first apply some algebraic manipulation to a quadratic equation to get it into the shape of the standard form $at^2 + bt + c = 0$. In the standard form, information we know about is stored in the coefficients **a**, **b** and **c** and *t* is the value we are trying to find. We need to be able to feed the correct **a**, **b** and **c** values into the quadratic formula so that it can be used to solve for the unknown *t* (**x** in the above list of examples).

Let us see how the above equations could be arranged into the standard form so that we could solve them using the quadratic formula. For now, do not worry about what the quadratic formula is or how we solve the above equations; for the moment, we are just going to focus on taking a quadratic equation in various forms and manipulating it into the standard form. Later on we will address the quadratic formula and find out how it can be applied to solve such equations.

Example 1: Representing $x^2 = 81$ in standard form.

The standard form has zero on the RHS of the equals sign, so let us first subtract 81 from both sides of the equation to make that true. Our equation now looks like this:

$$x^2 - 81 = 0$$

Notice that in our equation **x** is used as the label for the unknown, while in the standard form ***t*** is generally used. This really is just a mater of preference, so you can think of **x** in our equation as representing ***t*** in the standard form. Sometimes, **x** is also used to represent the unknown in the standard form. As you recall, in algebra, these are all just placeholders, so we can use whatever letters we wish (although it is helpful to follow convention, since it makes it easier for others to pick up on what is happening).

Now, if we look at the standard form $at^2 + bt + c = 0$, you should see that we essentially have what we are looking for. We know that in our current equation the squared term is not multiplied by anything (it has no **a** coefficient like the standard form). We also know that this is equivalent to having an **a** coefficient of 1 in the standard form.

$$1x^2 - 81 = 0$$

So we can see that **a=1** in this example. Our equation also has no **bt** (**bx**) term like the standard form does. This is equivalent to having a **b** coefficient of zero. Obviously, having a **b** value of zero would cancel out any contribution of the middle term, as shown below.

$$1x^2 + 0x - 81 = 0$$

We now have our equation in the standard form where **a**=1, **b**=0 and **c**= -81 as shown below. Compare it to the standard form:

$$1x^2 + 0x - 81 = 0$$

$$at^2 + bt + c = 0$$

If we wanted to use the quadratic formula to solve this equation we could simply feed in the values, **a**=1, **b**=0 and **c**=-81. Of course, $\mathbf{1x^2}$ is the same as just $\mathbf{x^2}$, and in the middle term, **0x** evaluates to nothing and the term is completely cancelled out. This can also be written as follows, which is the original equation we had:

$$x^2 - 81 = 0$$

or

$$x^2 = 81$$

To be sure, this is a very simple quadratic equation to solve, even without using the quadratic formula. But if you wish to solve it using the quadratic formula, you could use the inputs **a**=1, **b**=0 and **c**=-81, as we have just discovered.

Example 2: Representing $6x^2 + x = 100$ in standard form.

First, let us subtract the 100 from both sides of the equation to leave zero on the RHS as the standard form dictates:

$$6x^2 + x - 100 = 0$$

This example is actually a little easier to spot the relationship with the standard form. The standard form starts with at^2 and therefore we can see right away that **a** = 6. We can also see that the second term of the standard form is bt (***bx*** in our equation). Since bx is the same as x if **b** = 1, we know that the lack of a **b** coefficient in our current equation's middle term must mean that **b** = 1. We can also see that the removal of 100 from the RHS has introduced a **c** coefficient of –100 on the LHS, giving us the values **a**=6, **b**=1 and **c**= -100 in the standard form:

$$6x^2 + 1x - 100 = 0$$

$$at^2 + bt + c = 0$$

Therefore, we could solve the quadratic equation $6x^2 + x = 100$ by plugging the values **a=6**, **b=1** and **c=-100** into the quadratic formula to solve for **x**.

Example 3: Representing $-x^2 - 100 = -60$ in standard form.

Once again, the first thing we do is add 60 to both sides of the equals sign to leave us with zero on the RHS, as the standard form dictates.

$$-x^2 - 100 + 60 = 0$$

Currently, we have a **c** coefficient of (-100+60) and we can instantly simplify by adding +60 to –100 to get an equation with an equivalent **c** coefficient of -40:

$$-x^2 - 40 = 0$$

The lack of any middle term *bt* (or in our case, **bx**) means that **b** = 0, canceling that term out altogether. The lack of any coefficient next to the squared term must also mean **a** = -1 (as $-1*x^2$ is just $-x^2$). Therefore, in the standard form, our equation looks like the following (once again, shown alongside the standard form template for comparison):

$$-1x^2 + 0x - 40 = 0$$

$$at^2 + bt + c = 0$$

Thus, in order to solve our original equation $-x^2 - 100 = -60$ using the quadratic formula, we would feed in the values **a**=-1, **b**=0, **c**=-40.

Example 4: Representing $(x+3)^2 = 144$ in standard form.

This example looks quite different from any we have seen so far. Is this still a quadratic equation? Well the answer is yes even though it is being shown in its squared form on the LHS. To understand why it is indeed a quadratic, let us see what happens to the LHS if we multiply out the square. This will bring to our attention two **very important** algebraic identities.

We know that if we have the term i^2, then the term can be evaluated by performing $i * i$. You could say that we have multiplied the square out of the term, since we now have the value of $i * i$ and no longer have a power in that term. So how do we multiply the square out of a term like $(o+e)^2$? Well, we just treat the content inside the brackets (the squared term) as the single term '*i*'. Therefore, instead of doing $i * i$, we do:

$$(o+e)(o+e)$$

The next question concerns how we multiply the expression (o+e) by the expression (o+e). Hopefully most of you will remember learning about multiplying bracketed terms in high school. In particular you may remember the acronym FOIL. FOIL is used as an aid to remember the multiplication order for bracketed terms. The acronym stands for the words "**F**irst **O**uter **I**nner **L**ast and describes the paired terms that have to be multiplied. Let us do what it says and see what happens.

First we multiply the First terms in each bracket:

(o + e) (o + e) = o * o = o^2

Next we multiply the Outer terms of each bracket:

(o + e) (o + e) = oe

Then we multiply the Inner terms of each bracket:.

(o + e) (o + e) = eo (which is the same as **oe)**

And finally, we multiply the Last terms in each bracket:

(o + e) (o + e) = e^2

Adding the results of each separate multiplication together, we get the final expanded version of $(o+e)^2$:

$$o^2 + oe + eo + e^2$$

Since **oe** and **eo** are equivalent, we are just adding this value to the expression twice. Therefore, we can collect those terms and rewrite as follows:

$$o^2 + 2eo + e^2$$

And there you have it. We have expanded the original squared term out of its brackets. We have not changed the value of the expression in any way, but we have now discovered one very important algebraic identity. That is, we have found an equivalent way of writing the expression $(o+e)^2$. The three term polynomial $o^2 + 2eo + e^2$ is referred to as being a *perfect square trinomial* (PST) as it can instantly be written in its 'easier to solve' squared form of $(o+e)^2$.

Identity 1: $(o+e)^2 = (o+e)(o+e) = o^2 + 2eo + e^2$

We will see later when deriving the quadratic formula that this identity is very important. Remember it and make sure you understand it. It will become critical for you to know that when you have a LHS of an equation that looks like this: $o^2 + 2eo + e^2$, that it can also be written like this: $(o+e)^2$ without changing its evaluation. Being able to recognize patterns like this will help you understand how quadratic equations are solved and how to manipulate quadratic equations into the standard form.

Another very important identity that is used often in solving quadratic equations is very similar to the last one except it has a negative in the initial bracketed expression:

$$(o-e)^2$$

As we know, this is equivalent to multiplying the term (o-e) by itself:

$$(o-e)(o-e)$$

FOIL can once again be applied to multiply out the brackets.

First we multiply the First terms in each bracket.

(o - e) (o - e) = o * o = o^2

Next we multiply the Outer terms of each bracket. Here we are multiplying positive **o** with negative **e**. A positive times a negative gives us a negative, so:

(o - e) (o - e) = -oe

Now we multiply the Inner terms of each bracketed expression. This time we are multiplying negative **e** with positive **o** and once again we get a negative:

(o - e) (o - e) = -eo (which is the same as **-oe)**

Finally, we multiply the Last terms in each bracket. This time we are multiplying negative **e** by negative **e** which we know produces a positive:

(o - e) (o - e) = e^2

Adding the results of each separate multiplication together we get the final expanded version of $(o-e)^2$:

$$o^2 - oe - eo + e^2$$

Since **oe** and **eo** are equivalent, we are essentially subtracting **oe** from the expression twice, so we can collect those terms and rewrite as:

$$o^2 - 2eo + e^2$$

This is another very important algebraic identity. Learn it and remember it. It is important to recognize the shape of an expression such as $o^2 - 2eo + e^2$ and know that it can also be written as $(o-e)^2$. That is, $o^2 - 2eo + e^2$ is also a perfect square trinomial (PST) that can instantly be represented in its 'easier to solve' squared representation $(o-e)^2$.

Identity 2: $(o-e)^2 = (o-e)(o-e) = o^2 - 2eo + e^2$

Now we will get back to the task at hand and determine how we can represent our final example equation $(x+3)^2 = 144$ in standard form.

First, we know from the algebraic identities we just discovered that $(x + 3)^2$ can also be rewritten as shown in Identity 1. In our example, x is equivalent to the o variable in the identity and 3 is equivalent to the e variable.

Therefore, if

$$(o+e)^2 = (o+e)(o+e) = o^2 + 2eo + e^2$$

then

$$(x+3)^2 = (x+3)(x+3) = x^2 + 2x3 + 3^2$$

Our equation now looks as follows, when compared to the standard form:

$$x^2 + 2x3 + 3^2 = 144$$

$$at^2 + bt + c = 0$$

We are not quite there yet. However, our middle term (**2*x*3**) can also be written as **2*3*x**, which is the same as **(2*3)*x**. So we can simplify our term to **6x**. We also have no **a** coefficient, which means it is equivalent to having an **a** coefficient of 1. So let us reorder things a little and see what we get:

$$1x^2 + 6x + 3^2 = 144$$

$$at^2 + bt + c = 0$$

Nearly there! We currently have a **c** term of 3^2, which evaluates to 3*3=9:

$$1x^2 + 6x + 9 = 144$$

$$at^2 + bt + c = 0$$

The only difference now between the current form of our equation and the standard form is that we have a value of 144 on the RHS and the standard form has a value of zero. Therefore, we must subtract 144 from both sides of the equation so that we are left with 0 on the RHS:

$$1x^2 + 6x + 9 - 144 = 0$$

When shown along side the standard form we can see that we currently have a **c** term of (+9-144). Therefore, our **c** coefficient evaluates to 9-144 = -135. Below, we see the final version of our equation in the standard form.

$$1x^2 + 6x - 135 = 0$$

$$at^2 + bt + c = 0$$

If we wanted to use the quadratic formula to solve the quadratic equation $(x+3)^2 = 144$, we would feed in the known values: **a=1 , b=6 c=-135.**

This may all sound very abstract at the moment, since we are simply manipulating an equation into the standard form. But the standard form of the quadratic equation is very important to us because if we can get the quadratic equation we need to solve into this shape, we can use the quadratic formula to solve it.

Thus, if we wish to solve a problem that naturally gives rise to a quadratic equation, and we can manipulate the information we *do* know about the problem into the **a**, **b** and **c** coefficients, then we can use the quadratic formula to solve for the unknown *t*. This means we can use the quadratic formula to solve *any* quadratic equation in exactly the same way, so long as we mold the problem into the shape of the standard form first.

We shall see later that our collision system must perform an intersection test between a ray and a sphere. The equation of a sphere (which belongs to a family known as Quadric Surfaces) involves squared terms and as such, when we substitute the ray equation into the sphere equation of the sphere to solve for *t* (time of intersection along the ray), this naturally unravels into an equation where the unknown *t* is in a squared term. Therefore, we will have ourselves a quadratic equation that needs to be solved. When this is the case, we can manipulate the equation into the standard form and then solve for *t* using the quadratic formula giving us the time of intersection along the ray. Essentially, solving a quadratic equation boils down to nothing more than isolating t^2 on the LHS and finding the square roots of that term. We will learn more about this later.

12.6.1 Solutions to Simple Quadratic Equations

The quadratic formula we will study later in this lesson is not the only method for solving quadratic equations. Other approaches include *factoring* and a method called *completing the square*. Since factoring will not work with all quadratic equations, we will not be using this method. Instead we will concentrate on the methods that work reliably in all circumstances. It is also worth noting that we do not have to manipulate a quadratic equation into the standard form to solve it; we only need to do this if we wish to use the quadratic formula. Many quadratic equations are simple to solve and as such, manipulating them into the standard form and then using the quadratic formula would be overkill. So before we look at how to use the quadratic formula and examine its derivation, we will look at some simple quadratic equations that can be solved in a very simple way. This will allow us to examine the properties of a quadratic equation and the solutions that are returned.

Example 1: $x^2 = 81$

We examined this exact equation earlier and discussed how to represent it in standard form so that the quadratic formula could be used to solve it. Of course, this quadratic is extremely simple to solve without manipulation into standard form and indeed using such a technique would certainly be taking the long way round.

We know that we intend to find the value of x and we currently have x^2 on the LHS. We also know that the square root of x^2 is simply x. Therefore, to isolate x on the left hand side, we can just take the square root of both sides of the equation. Remember, it is vitally important that whatever you do on one side of the equals sign must be done on the other side too.

Step 1: Original equation is in its squared form

$$x^2 = 81$$

Step 2: Remove the squared sign from x by taking its square root. Remember to take the square root of the RHS as well.

$$\sqrt{x^2} = \sqrt{81}$$

Step 3 : The square root of x^2 is x and the square root of 81 is 9, so we have:

$$x = 9$$

This is correct, but we have forgotten one important thing. Every positive real number actually has two square roots -- a positive root and a negative root. If it has been a while since you covered this material in high school then that might come as a surprise. After all, if you punch 81 into a calculator and take its square root, you will have one answer returned: 9. Likewise, if you use the C runtime library's sqrt function, it too returns a single root. In both instances, we are getting the positive root of the number. However, we must remember that when we multiply a negative number by a negative number, we get a positive number. Thus, when we square a negative number we get a positive result. This leads to the conclusion that a positive number must have a negative square root as well.

For example, we know that 9 is the square root of 81 because:

$$9^2 = 9 * 9 = 81$$

Clearly 9 is the square root of 81 because 9 squared is 81. But as mentioned, this is actually only one of two square roots that exist (the positive root). –9 is also a square root of 81 because –9 multiplied by itself is 81:

$$-9^2 = -9 * -9 = 81$$

So, we can see that the square roots of 81 are in fact, 9 and –9. This means there are actually two possible solutions for **x** in our equation: 9 and –9. This duality is often indicated using the $\pm$ sign which is basically a plus and a minus sign communicating that there is a negative and positive solution to the square root. Therefore, we should correctly show our solution as:

$$x^2 = 81$$

$$x = \pm\sqrt{81}$$

$$x = \pm 9$$

Thus, there are two answers: **x =** +9 and **x =** –9.

The fundamental theorem of algebra tells us that because a quadratic equation is a polynomial of the second order, it is guaranteed to have two roots (solutions). However, some of these may be degenerate

and some of them may be complex numbers. We are only interested in real number solutions in this lesson, so we will consider a quadratic that returns two complex roots as having no roots (and thus no solutions for the equation). If you have never heard of complex numbers, do not worry because we are not going to need to cover them to accomplish our goals. However, you can learn more about complex numbers in our Game Mathematics course if you are interested in pursuing the subject further.

Example 2: $x^2 + 25 = 25$ (A Degenerate Root Example)

This example is interesting because it present a case where only one root exists. Actually, when this happens, we can perhaps more correctly say that two roots are returned, but both the negative and positive roots are the same. Let us solve this equation step by step.

Step 1: Let us first isolate x^2 on the LHS by subtracting 25 from both sides of the equation.

$$x^2 = 0$$

Step 2 : Now to find x we simply take the square root of both sides as shown below.

$$x = \pm\sqrt{0}$$

Now you can probably see where we are going with this. The solutions for x (the roots) are the negative and positive square root of zero. Since the square of zero is always just zero, negative zero and positive zero is just zero. Therefore, we do have two roots, but they are exactly the same. If ever we get to a point when solving a quadratic equation where we have isolated x^2 on the LHS and have zero on the RHS, we know we have a situation where we have multiplicity of the root and both roots evaluate to zero.

Example 3: $x^2 + 25 = 0$ (An example with no **real** solutions.)

This example demonstrates the case where no real numbered solutions can be found for the equation. You can probably spot why this the case right away just by looking at the equation, but if not, let us try to solve it and see what happens.

Step 1: Isolate x^2 on the LHS by subtracting 25 from both sides of the equation. This will cancel out the '+25' term on the LHS.

$$x^2 = -25$$

Step 2: Now we have to take the square root of both sides of the equation to get x isolated on the LHS.

$$x = \pm\sqrt{-25}$$

And here in lies our problem. We cannot take the square root of a negative number and expect a real number result. Just try punching a negative number into a calculator and hitting the square root button; it should give you an error. This is actually pretty obvious when only a few moments ago we said that multiplying a negative by a negative gives us a positive. Therefore, if squaring a negative number gives us a positive number then there can be no real number such that when it is squared results in a negative number. Therefore, a negative number cannot possibly have real square roots. This is actually one of the main reasons that complex numbers were invented. They actually fix this problem through the use of something called imaginary numbers. However, we are not interested in complex numbers in this lesson so we will consider any quadratic equation for which real roots cannot be found, to have no solutions. This is detectable because we know this situation arises as soon as we have x^2 on the LHS and a negative number on the RHS.

Example 4: $(x+3)^2 = 144$

This is also an interesting example because it is the first we have tried to solve in which the LHS is a squared expression instead of a single value. It just so happens that a quadratic equation such as this is very simple to solve. Let us go through solving it step by step.

Step 1: The expression x+3 is currently squared on the LHS, so we wish to remove the square. We do this by simply take the square root of both sides of the equation. The square root of $(x+3)^2$ is simply x+3 (we just remove the square sign) and the square root of the RHS (144) is ±12 .

$$x+3 = \pm\sqrt{144}$$

Step 2: This evaluates to:

$$x+3 = \pm 12$$

Step 3: **x** is still not isolated on the LHS, so we can fix that by subtracting 3 from both sides of the equation:

$$x = -3 \pm 12$$

Therefore, the two solutions for **x** are

$$x = -3+12 = 9$$

and

$$x = -3-12 = -15$$

So:

x = *9* and ***x*** = *-15*

At this point you may be wondering how we know which solution is the one we actually need to use. For example, when we solve a quadratic equation to find a *t* value along the ray at which an intersection occurs with a sphere, we will only be interested in the positive solution. If we think of an infinite ray passing through the center of the sphere however, we can see how it will intersect with the surface of the sphere twice; once on the way in and once again on the way back out. In fact, this is a property that defines a surface as being a quadric surface (a family of surfaces to which spheres, ellipsoids and cylinders belong).

If we imagine stepping along a ray, we would be interested in using the smallest solution, since this will be the first point of intersection along that ray. That is to say, we are interested in the time the ray first intersects the sphere. We will generally have no interest in the second solution which gives a *t* value for the ray passing out the other side of the sphere.

However, it is worth noting that we are interested in the smallest positive root. A negative *t* value describes an intersection occurring behind the ray origin. If we imagine a situation where our ray origin is inside the sphere to begin with, we will have a positive and a negative solution. The positive solution will be the point at which our ray intersects the far side of the sphere, and the negative solution will describe the distance to the surface backwards along the ray. However, it really does depend on what you are trying to do and the quadratic you are trying to solve. For example, you may well be interested in finding both intersection points with an infinite ray and a sphere. However, if the above example was returning intersection distances between our ray and the sphere surface, our collision system will only be interested in using the positive solution and we will discard information about intersections that have occurred behind the ray origin (more on this later).

Example 5: $x^2 + 6x + 9 = 144$ (Solving a Perfect Square Trinomial)

This example looks a lot harder to solve than the previous one where the LHS was already represented as a squared expression. Now you will find out why we discussed those two algebraic identities earlier in such detail and why it is vital that you recognize them.

Take a look again at Identity 1 that we discussed earlier:

Identity 1: $o^2 + 2eo + e^2 = (o + e)^2$

Now let us look at $o^2 + 2eo + e^2$ along side the LHS of our equation.

$$o^2 + 2eo + e^2$$
$$x^2 + 6x + 9$$

We can see that **x** in our equation is equivalent to **o** in the identity. We can also see that **2e** in the identity is equal to **6** in our equation. Of course, if **2e = 6** then **e** must equal 3. The identity has $\mathbf{e^2}$ as its third term and we know that in our equation **e = 3** and that $\mathbf{3^2 = 9}$. So our equation perfectly matches the shape of $(o + e)^2$ when expanded out of its brackets. Thus, our equation is a perfect square trinomial that can be readily written in its squared form:

If

$$o^2 + 2eo + e^2 = (o + e)^2$$

then

$$x^2 + 6x + 9 = (x + 3)^2$$

This means that our original equation:

$$x^2 + 6x + 9 = 144$$

can also be written as

$$(x + 3)^2 = 144$$

While this equation initially looked quite different from the last example, we now see that it is exactly the same equation. We can prove this by performing FOIL on $(x+3)^2$:

First we multiply the First terms in each bracket.

(x + 3) (x + 3) = x * x = x^2

Next we multiply the Outer terms of each bracket

(x + 3) (x + 3) = 3x

Now we multiply the Inner terms of each bracket.

(x + 3) (x + 3) = 3x

And finally, we multiply the Last terms in each bracket.

(x + 3) (x + 3) = 9

Adding the results of each separate multiplication together we get the final expanded version of $(x + 3)^2$:

$$x^2 + 3x + 3x + 9$$

As we are adding **3x** to the LHS expression twice, we can collect these like terms and rewrite the LHS as the following:

$$x^2 + 6x + 9$$

As you can see, this is the original LHS of the equation we started with.

Now that we have identified (and re-checked using FOIL) that we can write the LHS in its squared form, solving the equation becomes no different from the previous example with the steps shown below.

Step 1: Our original equation.

$$x^2 + 6x + 9 = 144$$

Step 2: Identify that the equation is a PST (perfect square trinomial) and can be readily written in squared form on the LHS.

$$(x + 3)^2 = 144$$

Step 3: Take the square root of both sides of the equation, removing the power from the LHS.

$$x + 3 = \pm\sqrt{144}$$

Step 4: This evaluates to + and – 12 on the RHS

$$x + 3 = \pm 12$$

Step 5 : Subtract 3 from both sides to isolate **x** on the LHS

$$x = -3 \pm 12$$

This yields two solutions for **x**:

$$x = -3 + 12 = 9 \quad \text{and} \quad x = -3 - 12 = -15$$

In this example we have illustrated the importance of recognizing when the LHS can be written in its squared form. This boils down to nothing more than pattern matching if your LHS is already a PST. As long as you can make this connection with the two algebraic identities discussed earlier, you can immediately represent the LHS of the equation in its much simpler squared form. This makes it much easier to find the solution and isolate the unknown.

12.6.2 Completing the Square

We have seen that it is easy to find the solution to a quadratic equation that is in the form $(x+3)^2$ on the LHS. We have also demonstrated how the LHS of a quadratic equation in the form $o^2 + 2eo + e^2$ is a perfect square trinomial and can be written as $(o+e)^2$ and easily solved. For example, we identified that the LHS of an equation in the form of $x^2 + 6x + 9 = 144$ can readily have its LHS written as $(x+3)^2 = 144$ because the LHS represents a polynomial that can be readily written as a squared expression.

The next question is, how do we solve an equation whose LHS is not a perfect square trinomial and therefore cannot be readily written as an expression in squared form? For example, how would we a find the solutions to a quadratic equation whose LHS is in the form: $2x^2 + 12x$. This equation's LHS is clearly not a PST in the form of $o^2 + 2eo + e^2$ and thus can not be written in $(o+e)^2$ form.

Example 6: $2x^2 + 12x = 0$ (Solving a Quadratic Equation that is not a square.)

A quadratic equation in this form is not so easy to solve because the LHS is not a perfect square. Therefore, we have to manipulate the equation so that the LHS becomes a perfect square trinomial allowing us to then represent it in its squared form. This process is known as **Completing the Square**.

> **Note:** Many sources cite the Babylonians as the first to solve quadratic equations (around 400BC). However, the Babylonians had no concept of an *equation*, so this is not quite fair to say. What they did do however was develop an approach to solving problems algorithmically which, in our terminology, would give rise to quadratic equations. The method is essentially one of completing the square. Hindu mathematicians took the Babylonian methods further to give almost modern methods which admit negative quantities. They also used abbreviations for the unknown, usually the initial letter of a colour was used, and sometimes several different unknowns occurred in a single problem.

In order to be able to represent the LHS in Example 6 in its squared form, we must somehow get it into a form that makes it a perfect square. That is to say, we must try to mold it into the form: $o^2 + 2eo + e^2$.

Let us see step by step how the process of completing the square is performed. We will start by showing the LHS of our equation alongside the form of the perfect square trinomial we are trying to mold it into:

$$o^2 + 2eo + e^2 = 0$$

$$2x^2 + 12x = 0$$

Step 1: In our equation **x** is the unknown, which corresponds to **o** in the square trinomial. We also have an **x** coefficient of 2. In the square trinomial the $\mathbf{o^2}$ term is on its own (it has no coefficient) so we want

to get $\mathbf{x^2}$ on its own also. Since **x** is currently multiplied by 2 in our equation, we can cancel it out by dividing the equation (both the LHS and the RHS) by 2:

$$x^2 + \frac{12}{2}x = \frac{0}{2}$$

As you can see, dividing $\mathbf{2x^2}$ by 2 yields $\mathbf{x^2}$, removing the coefficient of the $\mathbf{x^2}$ term as we intended. Actually, we could say that the $\mathbf{x^2}$ term now has an implied coefficient of 1. We must also divide every other term of the equation by 2 so that the equation stays balanced. We divide the term **12x** by 2 reducing the term to **6x.** The term on the RHS is divided by 2 also, but as it is currently is set to zero, dividing by anything will still result in a zero and as such, the RHS remains unchanged. This evaluates to the following equation (shown again along side the trinomial whose form we are trying to achieve):

$$o^2 + 2eo + e^2 = 0$$
$$x^2 + 6x = 0$$

Step 2: Remembering that **x** in our equation is equivalent to **o** in the PST, we can see that we have correctly reduced the $\mathbf{x^2}$ term on the LHS so that it has no coefficient (or an implied coefficient of 1). This is consistent with the $\mathbf{o^2}$ term in the PST. We can also see that in the middle term of the square trinomial, the unknown **o** has a coefficient of **2e.** In the middle term of our equation, **x** has a coefficient of 6. Therefore, we can say that in our equation **2e = 6** and thus, **e = 3**. All we have to do to make our equation a PST is add $\mathbf{e^2}$ to both sides of the equation (LHS and RHS must remain balanced). We have just discovered that if **2e = 6** then **e = 3** and thus $\mathbf{e^2 = 3*3 = 9}$. So, in this step we add 9 to both the LHS and the RHS of the equation, resulting in the following:

$$x^2 + 6x + 9 = 9$$

Now we have a perfect square trinomial where **o** is equivalent to **x** and **e** is **3**. Identity 1 tells is that the LHS of this equation can now be written in its squared form for simplicity:

$$(x+3)^2 = 9$$

Step 3: Now we can just solve as before. First we take the square root of both sides:

$$x + 3 = \pm\sqrt{9}$$

Step 4: Subtract 3 from both sides to leave **x** isolated on the LHS:

$$x = -3 \pm \sqrt{9}$$

This results in the two solutions for **x** shown below:

$$x = -3 + 3 = 0$$

and

$$x = -3 - 3 = -6$$

We have successfully found the solutions to the equation $2x^2 + 12x = 0$ by first completing the square and then solving as usual.

The technique of completing the square can be reliably used to solve any quadratic. Let us look at one more example of completing the square before moving on.

Example 7: $4x^2 + 12x - 100 = 0$ (Solving a Quadratic Equation that is not a square.)

Step 1: In this example, our equation is a trinomial to begin with, but not a perfect square. In a perfect square trinomial we need the 3rd term to be something very specific (e^2), so we really want to lose our current 3rd term on the LHS so that we can put something else there that completes the square. So let us first add 100 to both sides of the equation, which will remove the 3rd term (-100) from the LHS and add 100 to the RHS. After this step, our equation now looks as follows:

$$4x^2 + 12x = 100$$

Step 2: Our next job is to remove the coefficient of the squared term ($\mathbf{x^2}$) so that it matches its like term in the identity. If we divide every term by 4, this will eliminate the coefficient of the squared term. More correctly, it reduces it to an implied coefficient of 1, as shown below. Notice how dividing $\mathbf{4x^2}$ by 4 leaves us with $\mathbf{x^2}$, exactly as we want:

$$x^2 + \frac{12}{4}x = \frac{100}{4}$$

If we carry out the remaining divisions indicated above we can see that 12x/4 = 3x and 100/4 = 25, reducing the equation to the following:

$$x^2 + 3x = 25$$

Step 3: Now we have the LHS reduced to two terms with no leading coefficient accompanying the squared term. So we find ourselves with an equation in the same form as the previous example. We know from the identity that the coefficient of **o** in the middle term is **2e**, and we can see that as **x = o** in our equation, its coefficient **3** must be equal to **2e**. Therefore we have correctly identified that **e = 3/2 = 1.5**. We know that we can now complete the square by adding e^2 to both sides of the equation. Since **e = 1.5** and $\mathbf{e^2 = 2.25}$, we simply add **2.25** to both the LHS and the RHS to complete the square:

$$x^2 + 3x + 2.25 = 27.25$$

Step 4: Now that we have a PST on the LHS and we know that **o = x** and **e = 1.5**, we can write the LHS in $(o + e)^2$ form, as shown below:

$$(x + 1.5)^2 = 27.25$$

Step 5: We take the square roots of both sides of the equation, leaving us with x + 1.5 on the LHS and the positive and negative square roots of 27.25 on the RHS (which we will leave under the square root sign for now).

$$x + 1.5 = \pm\sqrt{27.25}$$

Step 6: Finally we can isolate **x** by subtracting 1.5 from the both sides of the equation, introducing –1.5 on the RHS.

$$x = -1.5 \pm \sqrt{27.25}$$

We now have the two values of **x** shown below. The first shows the calculation using the positive root of 27.27 (5.2201) .

$$x = -1.5 + 5.2201 = 3.7202$$

The second value of x is determined using the negative root of 27.25 (-5.2201)

$$x = -1.5 - 5.2201 = -6.7202$$

Therefore, the solutions are **x = 3.7202** and **x = –6.7202**.

Over the past few sections we have learned how to solve both simple and complex quadratic equations using a method known as completing the square. When completing the square we first mold the LHS into a perfect square trinomial. But early on, we discussed how to take a quadratic expression in any form an manipulate it into the standard form $at^2 + bt + c = 0$.

Since we learned how to solve standard and non-standard form quadratic equations, you may be wondering why we even bothered with the discussion of manipulating an equation into the standard form. We certainly do not need it in that form to solve it as we have shown. But while that is technically true, we do need to be able to solve quadratic equations in a consistent manner using a single method. This is especially true for us as programmers as we will need to write code that solves quadratic equations. We certainly do not want to have lots of conditionals testing the form of the quadratic equation so that a way to solve it can be determined.

As it happens, any quadratic equation that is in the standard form can be solved using a simple calculation called the quadratic formula. Thus if we want to write a function that can solve any quadratic equation with a minimum of code, we can just insist the equation passed into the function that needs to be solved is in the standard form. We can then use the quadratic formula to find the roots of the equation every time (assuming they exist). Whether the quadratic equation is being solved to determine the intersection between a ray and a sphere, a ray and a cylinder, or even for calculating cost analysis, provided it has been manipulated into the standard form, our code can always solve it using this simple technique. Naturally then, our next and final discussion on solving quadratic equations will be on the quadratic formula, since it is the method we will be using for solving our standard form quadratic equations.

12.6.3 The Quadratic Formula

It was determined quite a long time ago that the quadratic formula could be used to solve any quadratic equation in the standard form. Indeed, the quadratic formula is so useful that it has become required learning in high schools around the world. It really is an essential tool in the mathematicians' toolkit and can be used to solve quadratics very easily.

Provided a quadratic equation is in the form $at^2 + bt + c = 0$, we can solve for *t* using the quadratic formula, which is shown below.

$$t = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

The Quadratic Formula

It is well worth remembering this formula so that you can recall it at will. It will come in extremely handy down the road and will be the method we use when solving for intersections between a ray and a quadric surface (sphere or cylinder). Remember that the $\pm$ symbol essentially says that there is a positive and negative root of **b^2 - 4ac.** This indicates that as long **b^2 - 4ac** is not zero, there will be two real solutions for *t*. If we call the two roots *t1* and *t2*, we see the two solutions for *t* below.

$$t1 = \frac{-b + \sqrt{b^2 - 4ac}}{2a}$$

$$t2 = \frac{-b - \sqrt{b^2 - 4ac}}{2a}$$

The section of the formula under the square root sign $b^2 - 4ac$ has special properties which allow us to determine how many *real* roots (if any) can be found prior to performing the full calculation. For this reason, it is called the *discriminant* of the polynomial. We can see for example, that if the discriminant is zero, then both *t1* and *t2* will be identical and thus we might say that one real root exists.

We can also see that if the discriminant is a negative value, then the equation has no real roots. This lets us avoid applying the full quadratic formula logic since we know that we cannot take the square root of a negative number and expect a real result. This suggests to us that we should calculate the discriminant first and determine if it is a negative number. If so, no real roots exist.

Below we see how we might implement a new function called SolveRoots. It is passed the **a**, **b**, and **c** coefficients of a quadratic in standard form and will return the real roots of the equation, if they exist, in the output variables t1 and t2.

```
bool CCollision::SolveRoots( float a, float b, float c, float& t1, float &t2 )
{
    float d, one_over_two_a;

    // Calculate Discriminant first
    d = b*b - 4*a*c;

    // No discriminant is negative return false
    // as no real roots exist
    if (d < 0.0f) return false;

    // Calculate square root of b^2-4ac ( discriminant )
    d = sqrtf( d );

    // Calculate quadratic formula denominator ( 2a )
    one_over_two_a = 1.0f / (2.0f * a);

    // Calculate the two possible roots using quadratic formula.
    // They be duplicate is d = 0
    t1 = (-b - d) * one_over_two_a;
    t2 = (-b + d) * one_over_two_a;

    // Solution found
    return true;
}
```

These few lines of code are pretty much all there is to solving a quadratic equation in standard form using the quadratic formula. The actual function that solves the quadratic equations in our CCollision class is in a method called SolveCollision which is almost identical to this. The only difference is that the SolveCollision function will only return the smallest positive root. This is because the quadratic equation passed in (as we will see later) will represent the intersection of a ray with a sphere or cylinder. As negative *t* values will represent the distance to the surface behind the ray origin we are not interested in returning them. Additionally, since we wish to find the first point of intersection between the ray and the quadric surface (there may be two intersections since a ray can pass through a sphere's surface twice), we are only interested in the nearest intersection. Therefore, we are interested in the **smallest positive** *t* value.

Below we see the actual code to our CCollision::SolveCollision function.

```
bool CCollision::SolveCollision( float a, float b, float c, float& t )
{
    float d, one_over_two_a, t0, t1, temp;

    // Basic equation solving
    d = b*b - 4*a*c;

    // No root if d < 0
    if (d < 0.0f) return false;

    // Setup for calculation
    d = sqrtf( d );
    one_over_two_a = 1.0f / (2.0f * a);

    // Calculate the two possible roots
    t0 = (-b - d) * one_over_two_a;
    t1 = (-b + d) * one_over_two_a;

    // Order the results
    if (t1 < t0) { temp = t0; t0 = t1; t1 = temp; }

    // Fail if both results are negative
    if (t1 < 0.0f) return false;

    // Return the first positive root
    if (t0 < 0.0f) t = t1; else t = t0;

    // Solution found
    return true;

}
```

Notice that after we have found the two solutions, we store them in local variables t0 and t1. We then order them (possibly involving a swap) so that t0 always holds the smallest *t* value and t1 holds the larger one. We then test to see if t1 is smaller than zero. If it is then both *t* values are negative (because t1 is the largest value) and the intersections between the ray and the quadric surface happen behind the ray origin and are of no interest to us. Finally, we test if t0 (which now contains the smallest *t* value) is negative. If it is, then we return t1 which will be the smallest positive root. If t0 is not negative, then it must contain the smallest positive root, since we ordered them this way a few lines before. If this is the case, we return the value of t0.

Of course, at this point you are not supposed to understand how this function gets called and why we need to call it. This will all be discussed in a moment. However, hopefully you can see that this function is essentially doing nothing more than being passed the coefficients of a quadratic equation in standard form and then solving for the unknown *t*. If you follow the lines of code, you should see how we are performing the steps exactly as dictated by the quadratic formula. Regardless of whether we wish to intersect a ray with a sphere, a cylinder, or any other quadric surface, provided we can substitute the ray equation into the equation of the surface (discussed in a moment) and then manipulate that equation into the standard form, we can use this function to find the *t* values (i.e., the points of intersection parametrically along the ray).

Thus far you have taken for granted that the quadratic formula works but we have not discussed why it works and how it was arrived at in the first place. Therefore, let us see what happens if we try to solve a generic quadratic equation in standard form. You will find that we end up with the quadratic formula. This means you will understand not only what the quadratic formula is, but also why it works.

Step 1: We first determine that we wish to solve a quadratic equation in the standard form. Our objective is to isolate *t* on the LHS thus finding solutions for it. We will do this by manipulating the LHS into a perfect square in the form $\mathbf{o^2 + 2eo + e^2}$ which can then be written as $\mathbf{(o+e)^2}$ and easily solved. So let us start with the standard form quadratic equation template.

$$at^2 + bt + c = 0$$

Step 2: The first simple thing we can do in our quest to remove everything from the LHS (other than **t**) is to subtract **c** from both sides. This will eliminate the third term from the LHS and introduce **–c** on the RHS as shown below.

$$at^2 + bt = -c$$

Step 3: To make our perfect square trinomial, we know that the squared term $\mathbf{t^2}$ must have an implied coefficient of 1. Therefore, just as we have done many times before, we will divide the rest of the terms of the equation by **a**. This will set the coefficient of the squared term to 1 and leave just $\mathbf{t^2}$.

$$\frac{a}{a}t^2 + \frac{b}{a}t = \frac{-c}{a}$$

We know that a/a is just 1 and cancels itself out, so our equation now looks like what we see next. It is shown along side the PST whose form we are trying to replicate.

$$t^2 + \frac{b}{a}t = \frac{-c}{a}$$

$$o^2 + 2eo + e^2 = 0$$

Step 4: Looking at our equation we can see that **t** is equivalent to **o** in the PST. We can also see that the coefficient of **t** in the middle term of our equation is **b/a** which is equal to **2e** (the coefficient of **o** in the PST's middle term). Therefore, we have determined that **2e = b/a** in our equation and thus, **e** must equal **b/a** divided by 2.

When we multiply a fraction by a single value, we essentially treat that single value as a fraction with a denominator of 1. Therefore, multiplying **b/a** by 2 would look like this.

$$\frac{b}{a} x \frac{2}{1} = \frac{b*2}{a*1} = \frac{2b}{a}$$

As you can see, we multiply the two fractions by multiplying the numerators and denominators separately. When we wish to divide a fraction by a real number we essentially do the same thing. That is, we add a denominator of 1 to the single value to get it into fraction form. However, because we wish to divide one fraction by another instead of multiply, we still perform a multiply but will swap the numerator and the denominator of the second fraction (i.e., multiply by the *reciprocal*).

Therefore, since we know that **2e = b/a** in our equation, we can find the value of **e** by multiplying the fraction **b/a** with the fraction ½ as shown below.

$$e = \frac{b}{a} x \frac{1}{2} = \frac{b}{2a}$$

Step 5: Now that we know the value of **e**, we can add $\mathbf{e^2}$ to both sides of the equation to form a perfect square trinomial on the LHS which is ready to be written in its squared form. As we know that **e=b/2a**, $\mathbf{e^2}$ must be equal to multiplying the fractions (**b/2a**)*(**b/2a**) as shown below.

$$e^2 = \frac{b}{2a} x \frac{b}{2a} = \frac{b^2}{4a^2}$$

So we must add this result to both the LHS and the RHS of our equation to complete the square. Our equation now looks like this:

$$t^2 + \frac{b}{a}t + \frac{b^2}{4a^2} = -\frac{c}{a} + \frac{b^2}{4a^2}$$

Step 6: As we now know that we have a perfect square trinomial on the LHS and that **o = t** and **e = b/2a**, we can write the LHS of the equation in its squared form.

$$\left(t + \frac{b}{2a}\right)^2 = \frac{-c}{a} + \frac{b^2}{4a^2}$$

Step 7: At this point the RHS could do with a little cleaning up. It is currently represented as the addition of two fractions, which is not very nice. But we could merge these two fractions together if they both had the same denominator. For example, if the left fraction on the RHS had a denominator of $4a^2$ also, we could represent the RHS simply as

$$\frac{-c+b^2}{4a^2}$$

Of course, we cannot do that because the left fraction does not have a denominator of $4a^2$. However, we could multiply the left fraction (both the numerator and the denominator) so that it is scaled up to a fraction of the same proportion but with a denominator of $4a^2$. Many of you may remember this from high school as finding the lowest common denominator. The goal is to have all fractions use the same denominator to simplify our calculations.

What can we multiply the first fraction (**–c/a**) by such that its numerator and denominator stay proportional to one another and yet we wind up with a fraction whose denominator has $4a^2$? That is simple enough -- we multiply **–c/a** by the fraction **4a/4a** since multiplying the first fraction's denominator (**a)** by **4a** will scale it to **$4a^2$** as shown below.

$$\frac{-c}{a} * \frac{4a}{4a^2} = \frac{-4ac}{4a^2}$$

As you can see, multiplying the numerator **–c** by **4a** results in a numerator of **–4ac**. Multiplying the denominator **a** by **4a** results in the denominator we were after: **$4a^2$**. This now matches the denominator of the other fraction on the RHS.

$$\left(t+\frac{b}{2a}\right)^2 = \frac{-4ac}{4a^2} + \frac{b^2}{4a^2}$$

Since both the fractions on the RHS now have the same denominator, we can add the two fractions together to get a single result on the RHS:

$$\left(t+\frac{b}{2a}\right)^2 = \frac{-4ac+b^2}{4a^2}$$

What we will do now is rearrange the numerator of the RHS (we generally prefer to have the terms sorted by power going from left to right) to give:

$$\left(t+\frac{b}{2a}\right)^2 = \frac{b^2-4ac}{4a^2}$$

Those of you paying close attention will have noticed that the numerator on the RHS is actually the discriminant we discussed earlier.

Step 8: We currently have our equation in squared form. As we have done many times before, we now wish to take the square root of both sides of the equation. This will remove the squared brackets on the LHS leaving us with just **t + b/2a**, making **t** easier to isolate.

$$\sqrt{\left(t+\frac{b}{2a}\right)^2}=\sqrt{\frac{b^2-4ac}{4a^2}}$$

The square root of the LHS is simple. It just removes the squared brackets like so.

$$t+\frac{b}{2a}=\sqrt{\frac{b^2-4ac}{4a^2}}$$

Taking the square root of the RHS is easy also. We simply take the square root of the denominator and the numerator separately.

$$t+\frac{b}{2a}=\frac{\sqrt{b^2-4ac}}{\sqrt{4a^2}}$$

Looking at the numerator of the RHS first; the square root of $\mathbf{b^2-4ac}$ is something we just do not know since it cannot be reduced any further. So we will just leave the numerator as is with the square root sign still in place. However, the denominator is no problem at all. We know that:

$$2a*2a=4a^2$$

Thus, the square root of $4a^2$ is 2a. After we have taken the square roots of both sides, our equation now looks like this.

$$t+\frac{b}{2a}=\frac{\pm\sqrt{b^2-4ac}}{2a}$$

Step 10: We nearly have **t** isolated on the LHS. All that is left to do now is subtract **b/2a** from both sides of the equation:

$$t = \frac{\pm\sqrt{b^2 - 4ac}}{2a} - \frac{b}{2a}$$

Because both fractions on the RHS share a common denominator, we can add them and rearrange to look a little nicer. The result is the quadratic formula:

$$t = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

This wraps up our review of quadratic equations. As explained at the beginning of this section, the discussion has been completely abstracted from the topic of collision detection and as such, you may be wondering what any of this has to do with finding intersections with triangles. In the next section, you will finally get the answers to your questions and see that everything you have learned here will be put to good use.

12.7 The SphereIntersectTriangle Function: Part II

Earlier we discussed the progress we had made with respect to writing a function that would correctly detect the intersection point between a swept sphere and a polygon. As discussed, we currently have only implemented the first and most common case – testing against the plane. If the sphere did not intersect the plane of the triangle, the function can immediately return false. If an intersection with the plane has occurred then we tested the intersection point (on the plane) to see whether it was inside the polygon/triangle edges. If it was, then our task was complete. We have our intersection point on the shifted plane (the potential new sphere center position) and we have our intersection normal (the normal of the polygon which we can use for sliding). However, if we have intersected the plane but the intersection point is not in the triangle interior, then we must test for other cases. For starters, we must test if the swept sphere has collided with one of the three triangle edges (Figure 12.31).

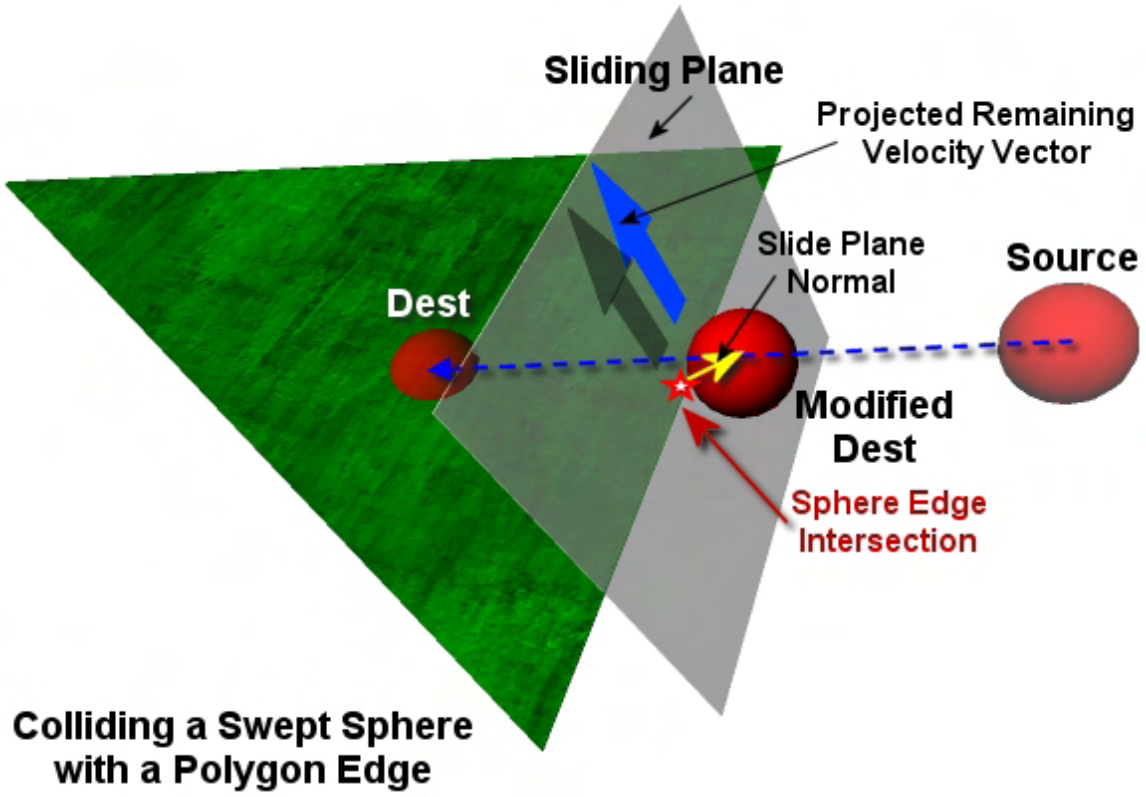

Figure 12.31

Figure 12.31 shows an intersection test between our swept sphere and a single edge. We will need to perform this test for each edge to make sure we catch all collision cases and return the closest intersection.

In Figure 12.31, **Source** and **Dest** describe the initial center position of the sphere and the desired destination of the sphere after the movement update. The blue dashed line connecting them describes the velocity vector we wish to move the sphere along to make that so. **Modified Dest** is the new center position we need to calculate which will position the sphere such that its surface is touching (but not intersecting) the triangle edge.

Once we have found this new position, we also have to return an intersection normal for later use as our slide plane normal. As Figure 12.31 shows, this will be calculated by creating a vector from the intersection point on the edge to the sphere center position and then normalizing the result. This is different from the normal returned when the sphere collides with the interior of a polygon. In the other case, the triangle normal is returned. But when we collide with an edge, we wish to slide around that edge smoothly. You should be able to see that the angle of approach made by the sphere with the intersected edge influences the orientation of the slide plane generated. If the sphere collides with the edge right in the center of its surface a very steep plane will be produced. With such a steep slide plane, any remaining velocity vector will be scaled down quite a bit when projected onto the slide plane (in the response phase) and only a little slide will happen. This is like hitting the edge head on. If however, the intersection occurs via a more shallow angle of approach (almost as if we are just clipping the edge

accidentally as we walk by it), the plane will not be as steep and the edge will be easily slid around without losing to much velocity during the velocity vector projection process in the response step.

While we do not yet know how to write a function that determines the intersection between a swept sphere and a triangle edge, for now we will stipulate that this test will be performed in a method called CCollision::SphereIntersectLineSegement. This will be the method that will be called for each edge of the triangle to test for intersection between the sphere and the line segment formed by the vertices of each edge. While we will discuss how to implement this function in a moment, we now have enough information to understand the final version of our CCollision::SphereIntersectTriangle function. The final code is shown below. The only difference from the version we saw earlier will be the three function calls that have been added to the bottom of the function (highlighted in bold).

```
bool CCollision::SphereIntersectTriangle(  const D3DXVECTOR3& Center,
                                           float Radius,
                                           const D3DXVECTOR3& Velocity,
                                           const D3DXVECTOR3& v1,
                                           const D3DXVECTOR3& v2,
                                           const D3DXVECTOR3& v3,
                                           const D3DXVECTOR3& TriNormal,
                                           float& tMax,
                                           D3DXVECTOR3& CollisionNormal )
{
    float       t = tMax;
    D3DXVECTOR3 CollisionCenter;
    bool        bCollided = false;

    // Find the time of collision with the triangle's plane.
    if ( !SphereIntersectPlane( Center, Radius, Velocity, TriNormal, v1, t ))
        return false;

    // Calculate the sphere's center at the point of collision with the plane
    if ( t < 0 )
        CollisionCenter = Center + (TriNormal * -t);
    else
        CollisionCenter = Center + (Velocity * t);

    // If this point is within the bounds of the triangle,
    // we have found the collision
    if ( PointInTriangle( CollisionCenter, v1, v2, v3, TriNormal ) )
    {
        // Collision normal is just the triangle normal
        CollisionNormal = TriNormal;
        tMax            = t;

        // Intersecting!
        return true;

    } // End if point within triangle interior

    // Otherwise we need to test each edge
    bCollided |= SphereIntersectLineSegment( Center, Radius, Velocity,
                                             v1, v2, tMax, CollisionNormal );

    bCollided |= SphereIntersectLineSegment( Center, Radius, Velocity,
```

```
                                          v2, v3, tMax, CollisionNormal );

    bCollided |= SphereIntersectLineSegment( Center, Radius, Velocity, v3, v1,
                                             tMax, CollisionNormal );

    return bCollided;
}
```

As you can see, if the sphere is intersecting the plane of the triangle and the intersection point is inside the triangle we return true. However, if the intersection point is not within the interior of the triangle we perform an intersection test between the swept sphere and each edge. We pass into the SphereIntersectLineSegment function the eSpace position of the center of the ellipsoid, the radius vector of the ellipsoid, and the eSpace velocity vector describing the direction and distance we wish to move the sphere. We also pass in the two vertices that form the edge we are testing. Obviously a triangle has three edges, so the function is called three times (once to test each edge). Each time a different vertex pair is used to describe the edge.

We also pass (by reference) the tMax variable that was itself passed in as a parameter to the function. Remember from our earlier discussions that this will always hold the smallest intersection distance (*t* value) that we have found so far. We are only interested in finding intersections that are closer than this value since if the intersection is further away, it means we have previously found another triangle that is closer to our sphere. Remember, the SphereIntersectTriangle function is called for every triangle in the collision database and the same tMax variable is overwritten as soon as we find an intersection that is closer than one we previously stored.

As the final parameter, we pass (by reference) CollisionNormal, which itself is a vector that was passed by reference into the function. If an intersection is found with the edge that is closer than any found so far, the function will store the collision normal in this variable. When the SphereIntersectLineSegment function returns, if an intersection has been determined to be closer than any found with previously tested triangles, the calling function will have access to both the intersection *t* value and the collision normal.

So the question that begs to be asked is, how do we detect an intersection between a moving sphere (swept sphere) and a polygon edge? The answer can be found in the next section.

12.7.1 Swept Sphere / Triangle Edge Intersection

Performing an intersection test between a swept sphere and a triangle edge sounds like it might be quite complicated. When we tested the swept sphere against a plane, we were able to reduce the entire test to a ray / plane test simply by shifting the plane along its normal by the radius of the sphere. The point at which the ray intersected the shifted plane described the exact center position of the sphere at the time the surface of the sphere will make contact with the actual plane. Certainly it would be nice if a similar technique could be employed to reduce the swept sphere / edge test to that of an intersection test between a ray and some other primitive type. As it turns out, there is indeed a way to do this.

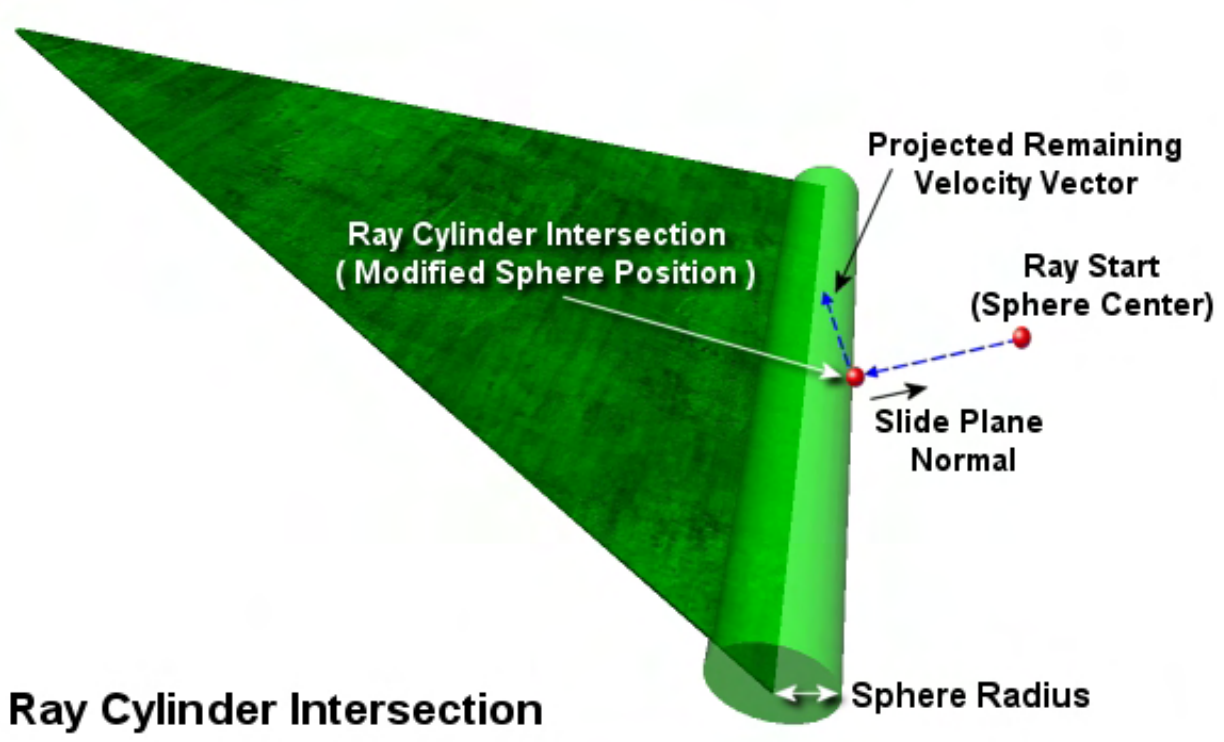

Figure 12.32

In the sphere / plane intersection test we were able to reduce the swept sphere to a ray by shifting the plane along the normal by the sphere radius. Imagine now, that we were to take the edge of the triangle that we currently want to test and expanded it outwards in all directions by the radius of the sphere. That is, we would give the edge a thickness equal to twice the sphere's radius. If we could do this, we would have essentially grown the edge into a cylinder, where any point on the surface of the cylinder will be located at a distance of sphere radius from its central spine.

As Figure 12.32 illustrates, if the edge becomes a cylinder, the swept sphere can once again be treated as a ray, where the original eSpace center position of the sphere becomes the ray origin (Ray Start) and the eSpace velocity vector becomes the ray's delta vector. If we find the intersection point along the ray with the surface of the cylinder, it will be at a distance of sphere radius from the actual edge and will thus describe the exact location where the center of the sphere should be positioned at the time the surface of the sphere is touching the actual edge (the time of intersection). Remember, the true edge is the central spine of the cylinder which is at a distance of radius units from any point on the surface of the cylinder. All we have to do is implement a function that will find the *t* value along a ray which intersects the surface of a cylinder. This will provide us with the new position for the center of the sphere at the time of intersection between the sphere's surface and the triangle edge.

Once we have this intersection point on the surface of the cylinder, we can also calculate the slide plane normal by generating a vector from the intersection point on the actual edge to the new sphere center we just calculated (and normalizing the result).

The equation for a cylinder is.

$$\left\|(P-V1)\times E\right\|^2 = Radius^2$$

Let us analyze this formula. **P** is a point on the surface of the cylinder and **V1** is the first vertex in the edge that forms the cylinder's central spine (axis). This is the point at the base of the cylinder. **E** is the unit length direction vector of the cylinder's central spine. Therefore, if the edge of the triangle is given by vertices **V1** and **V2**, **E** is created by normalizing the vector (**V2 - V1**) as shown in Figure 12.33.

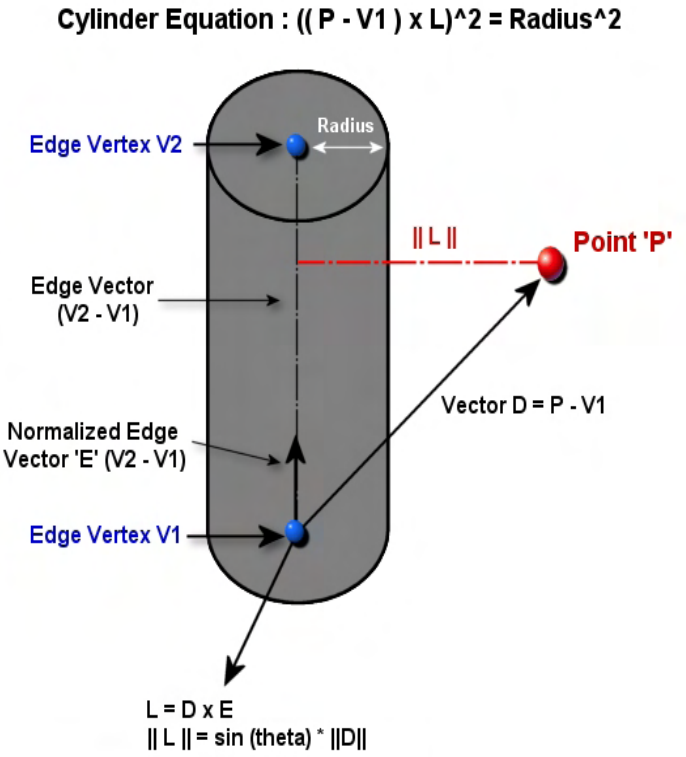

Figure 12.33

The cylinder equation says that if the squared length of a vector, (generated by crossing a vector from **V1** to the point **P** with the unit length direction vector of the cylinder's central axis **E**) is equal to the squared radius of the cylinder, the point **P** is on the surface of the cylinder. In Figure 12.33, the point **P** is clearly not on the surface of the cylinder, but what is the relationship between the squared length of the vector we have created from that cross product (**(P-V1)xE**) on the LHS of the equation and the radius of the cylinder?

In this example, **P** in the cylinder equation is **Point P** in the diagram. We can see that it is not on the surface of the cylinder, but this was done intentionally to clarify the relationships we are about to discuss. We can also see that if we create a vector from **V1** at the bottom of the cylinder (first vertex in the edge) to the point **P**, we have vector **D** in the diagram. If we look at unit vector **E**, we can imagine how this forms the adjacent side of a triangle where the vector **D** forms the hypotenuse. What we need to know is the distance from **Point P** to the edge (red dashed horizontal line in Figure 12.33). To calculate this distance we start by performing the cross product between vectors **D** and **E**. We know that when we perform the cross product between two vectors we get a vector returned that is perpendicular to the two input vectors. This is vector **L** in the diagram (assumed to be pointing out of the page). The direction of this vector appears to have nothing to do with what we are trying to accomplish, and indeed it does not. However, our interest in is the length of this vector, not its direction. Why? Because the length of the vector returned from a cross product given as:

$$\left\|D\times E\right\| = \left\|D\right\|\left\|E\right\|\sin\alpha$$

The length of the vector returned from crossing **D** and **E** is equal to the sine of the angle between them multiplied by the length of vector **E** and the length of vector **D**. In our cylinder equation, **E** is a unit length vector and thus this equation simplifies to:

$$\|D \times E\| = \|D\| \sin \alpha$$

So when we cross **D** and **E**, we are returned a vector whose length is equal to the sign of the angle between the two input vectors scaled by the length of vector **D** (the hypotenuse).

Now, if you refer back to Figure 12.33 and envisage **D** as the hypotenuse and **E** as the adjacent of a right angled triangle, we can see that what we actually wish to determine is the length of the opposite side of that triangle. The opposite side is the line from the point **P** to the adjacent side formed by the central spine of the cylinder. How do we get the length of the opposite side of a right angled triangle?

The helpful acronym **SOH CAH TOA** tells us that we can find the sine of the angle by dividing the length of the opposite side by the length of the hypotenuse.

$$\sin \alpha = \frac{Opposite}{Hypotenuse}$$

Therefore, in order to find the length of the opposite side, we simply multiply each side of this equation by the length of the hypotenuse leaving the opposite side isolated on the RHS.

$$\sin \alpha * Hypotenuse = Opposite$$

or more nicely arranged:

$$Opposite = Hypotenuse * \sin \alpha$$

So we know that we can find the length of the opposite side of a triangle by multiplying the length of the hypotenuse by the sine of the angle. Does that help us? Yes it does, because that is exactly what the cross product just gave us. Remembering once again that vector **D = (P – V1)** is the hypotenuse of our triangle and vector **E** is unit length, the cross product of **DxE** returns a vector **L** with the following length.

$$\|L\| = \|D \times E\|$$

The above states that our vector **L** is the result of crossing vectors **D** and **E**. The length of vector **L** (||**L**||) is then obviously the length of the vector returned from crossing **D** and **E**. Since vector **D** is generated by subtracting vector **V1** from point **P**, using substitution for **D**, this can also be written as:

$$= \|(P - V1) \times E\|$$

The result of the cross product is a vector whose length is equal to the sine of the angle between them multiplied by the lengths of each input vector. Since input vector **E** is unit length, the result is simply the sine of the angle scaled by the length of the non-unit vector **D** (i.e., **P - V1**).

$$= \|(P - V1)\| \sin \alpha$$

Since vector **P-V1** forms the hypotenuse of our triangle, the length of this vector is equal to the length of the hypotenuse, so we can write this as:

$$= \|Hypotenuse\| \sin \alpha$$

As we just discovered, scaling the length of the hypotenuse of a right angled triangle by the sine of its angle gives us the length of the opposite side,

$$= \|Opposite\|$$

And there we have it. As **D** is the hypotenuse and **E** is unit length, the length of the resulting vector **L** is equal to the length of vector **D** multiplied by the sine of the angle between **D** and **E**. This is the length of the hypotenuse multiplied by the sine of angle, which trigonometry tells us is the length of the opposite side. This is the length of the red dashed horizontal line in the diagram and is the distance from point **P** to the cylinder's central spine (i.e., the triangle edge).

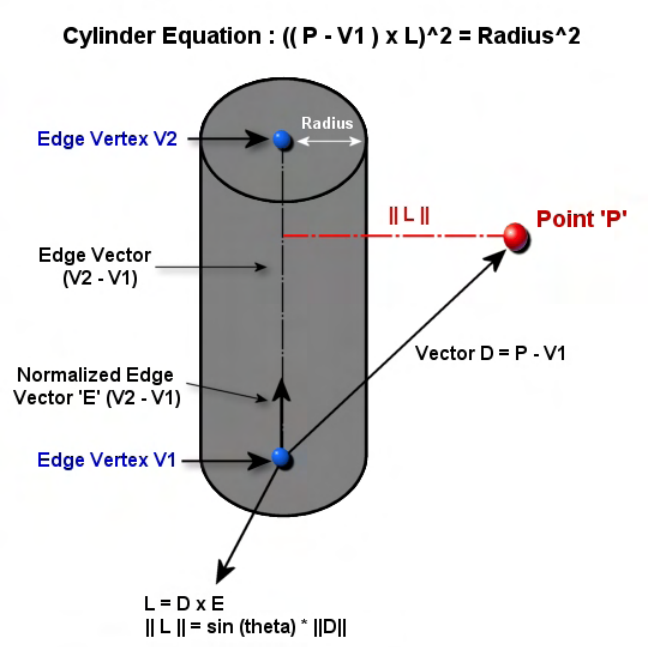

Figure 12.34

In Figure 12.34 we can now see exactly why we compare the squared length of vector **L** against the squared radius. The length of vector **L** describes the distance from the point **P** to the edge (the central axis). Since the cylinder's surface is a distance of Radius units from its central axis, if the squared distance from point **P** to the edge (||**L**||) is equal to the Radius squared, the point must be on the surface of the cylinder. In Figure 12.34 we can see that the length of vector **L** would be much greater than the radius of the cylinder and therefore the point **P** is not considered to be on the surface of the cylinder.

Of course, if we were only interested in determining whether or not a point is on the surface of the cylinder, we would be all set. However, we wish to find a ***t*** value along a ray which describes a point on the surface of the cylinder (i.e., the *t* value at which the ray intersects the cylinder). Just as we did when intersecting a ray with a plane, we must substitute the equation of our ray into the cylinder equation in place of point **P**.

If the cylinder equation is:

$$\|(P - v1) \times E\|^2 = Radius^2$$

and the equation of our ray is defined by an origin **O**, a delta vector **V**, and a parametric value ***t*** describing a point along that ray:

$$O + tV$$

Substituting our ray into the cylinder equation in place of **P** gives us:

$$\|(O + tV - V1) \times E\|^2 = Radius^2$$

Because we are dealing with vectors from an algebraic point of view, we can treat the double bars || as brackets, since we know that they mean the length of a vector. Because this length is squared in the equation, we also know that we can get the squared length of a vector by dotting it with itself (a vector multiply). Therefore, let us re-write our equation in bracket form. Many of you may consider this approach a little relaxed, but we find it helpful.

$$((O + tV - V1) \times E)^2 = Radius^2$$

This is not a very attractive equation at the moment since we want to isolate ***t*** as much as possible. Well, we know that subtracting vector **V1** from the vector (**O + tV**) is equivalent to subtracting vector **V1** from vector **O** and then adding vector **tV** afterwards, so we can swap them around.

$$((O - V1 + tV) \times E)^2 = Radius^2$$

We also know, that because the vector (**O-V1**) and the vector **tV** are inside brackets that are crossed with vector **E**, this is equivalent to removing those inner brackets and crossing the vector (**O-V1**) and **tV** with **E** separately. As you can hopefully see, we are slowly breaking this equation down into smaller more manageable and components.

$$((O - V1) \times E + (tV \times E))^2 = Radius^2$$

We also know that *t* is a scalar not a vector. Scaling vector **V** by *t* and then crossing with **E** is equivalent to crossing **V** and **E** and then scaling the result. Therefore, we can move *t* outside the brackets, isolating it even more.

$$((O - v1) \times E + (V \times E)t)^2 = Radius^2$$

This is all looking good so far. However, everything on the LHS is still in squared form. Thus, everything on the LHS can be removed from the squared brackets by multiplying the LHS with itself as we discussed earlier (refer back to multiplying an expression in squared brackets). Since the expression in both brackets is a vector, and the vector form of a multiply is a dot product, we should use the dot symbol as shown below when we multiply the expression by itself:

$$((O - v1) \times E + (V \times E)t) \bullet ((O - v1) \times E + (V \times E)t) = Radius^2$$

This is starting to look a little more complex, but that is no problem. We just have a set of bracketed terms that we have to perform **FOIL** on. For the time being, we will just concentrate on the LHS of the equation.

The **First** term in each bracket is $(O - v1) \times E$. Therefore, we are multiplying vector $(O - v1) \times E$ by itself. This gives us a new first term of:

$$((O - v1) \times E) \bullet ((O - v1) \times E) \; = \; (O - v1) \times E)^2$$

The **Outer** term of the first bracket is $(O - v1) \times E$ whilst the outer term of the second bracket is $(V \times E)t$. Both of these are vectors and therefore, our second new term is calculated as:

$$((O - v1) \times E) \bullet ((V \times E)t)$$

The **Inner** terms of the brackets are $(V \times E)t$ and $(O - v1) \times E$ for the first and second brackets respectively, giving us an identical term to the last one if we swap them around (which we can do without altering its evaluation):

$$((O - v1) \times E) \bullet ((V \times E)t)$$

Finally, we multiply the last terms of each bracket, which are the same for both $(V \times E)t$:

$$(V \times E)t \bullet (V \times E)t \quad = \quad (V \times E)^2 t^2$$

Let us now add the four results together and see our new expanded equation. We have put each FOIL result on its own line for clarity at this stage, but this is all just the LHS of our equation.

$$\begin{aligned}
&((O - v1) \times E)^2 + \\
&((O - v1) \times E) \bullet (V \times E)t + \\
&((O - v1) \times E) \bullet (V \times E)t + \\
&(V \times E)^2 t^2
\end{aligned}$$

One thing is immediately obvious. Since *t* is the unknown we wish to find and it is raised to a power of two in one of the expressions, we have ourselves a quadratic that needs solving. We know how to solve quadratic equations using the quadratic formula, but we need our equation in the standard form.

$$at^2 + bt + c = 0$$

Looking at our equation and searching for the squared term, we can immediately identify the value of our **a** coefficient. It is the expression that shares the term with $\mathbf{t^2}$, $(V \times E)^2$. Therefore, let us move that entire expression to the front of the equation so that it resembles its position in the standard form.

$$(V \times E)^2 t^2 +$$
$$((O - v1) \times E)^2 +$$
$$((O - v1) \times E) \bullet (V \times E)t +$$
$$((O - v1) \times E) \bullet (V \times E)t$$

We have the squared term exactly where it should be now and we can quickly see that

$$a = (V \times E)^2$$

In other words, **a** should be set to the squared length of the vector produced by crossing the velocity vector (the ray delta vector) with the unit length direction vector of the edge (the cylinder's central spine).

We have to find the **a**, **b**, and **c** coefficients in order to solve our quadratic, and we now have one of them. So let us now work on finding the **b** coefficient.

We know from studying the standard form that **b** must be calculated from expressions that accompany *t* (not t^2). There are actually two terms in our above equation that contain *t* in its non-squared form – currently, the third and fourth terms (which are actually identical terms). Therefore, we know that we must be able to construct **b** by isolating *t* from these terms. The two terms of our equation that contain *t* in our current equation are shown below.

$$((O - v1) \times E) \bullet (V \times E)t + ((O - v1) \times E) \bullet (V \times E)t$$

Since these two expressions are the same, we are essentially adding $((O - v1) \times E) \bullet (V \times E)t$ twice to the LHS of our equation. In each term we are taking the dot product of two vectors **(O-v1)xE** and **VxE** and scaling the result by *t*. Since the result of the dot product in each of the above terms is scaled by *t*, we can scale the sum of the combined dot products by *t* in a single step instead of separately in each term. What that means (in generic terms) is, instead of doing something like **A.Bt+A.Bt,** we can instead write **2(A.B)t**. Therefore, the above two terms can be combined into a single term like so:

$$2(((O - v1) \times E) \bullet (V \times E))t$$

Let us swap the positions of the two bracketed terms since it looks a bit nicer (our humble opinion). Thus, we have simplified the two terms that involve *t* to the following:

$$2((V \times E) \bullet ((O - v1) \times E))t$$

We have now isolated *t* on the right hand side of this expression and can see that the **b** coefficient that accompanies *t* in the middle term of the standard form must be:

$$b = 2((V \times E) \bullet ((O - v1) \times E))$$

Our equation now looks like this:

$$(V \times E)^2 t^2 +$$
$$((O - v1) \times E)^2 +$$
$$2((V \times E) \bullet ((O - v1) \times E))t$$

We are getting there! However, we know that in the standard form the t^2 term goes on the far left, the t term goes in the middle and the constant term **c** is written to the right. Therefore let us be consistent and write our equation that way too. Currently we have the t term (the middle term in the standard form) at the end of our equation rather than the middle, so let us swap the last two terms so that we have the term involving the squared unknown on the left and the non-squared unknown in the middle:

$$(V \times E)^2 t^2 + 2((V \times E) \bullet ((O - v1) \times E))t + ((O - v1) \times E)^2 = Radius^2$$

What is left must be the constant term **c** of the standard form, but we can see now that in its current form **c** must be:

$$c = ((O - v1) \times E)^2$$

Do not forget that in the standard form, we must have a zero on the RHS of the equals sign. That is no problem either. We can just subtract the squared radius from both sides of the equation leaving zero on the RHS and introducing **–Radius^2** on the LHS.

We now have our ray/cylinder intersection equation in the standard quadratic form:

$$(V \times E)^2 t^2 + 2(V \times E)((O - v1) \times E)t + ((O - v1) \times E)^2 - Radius^2 = 0$$

Finally, we have the **a**, **b**, and **c** coefficients of our quadratic in standard form and can simply plug them into our SolveCollision function to generate the t value of intersection (if one exists) between the ray and the cylinder. Below we show our final calculations for the coefficients in the more correct vector form. That is, that the terms inside the brackets are vectors, not single values, and as such a multiply must be replaced with the vector version of a multiply (a dot product operation). As you can see, any vectors that were in a squared form in the previous version of the equation have had there square sign removed by multiplying out the square. Therefore, **(VxE)^2** becomes **(VxE)•(VxE)** for example. This yields the final results of our coefficients exactly as we will calculate them in code.

$$a = (V \times E) \bullet (V \times E)$$
$$b = 2((V \times E) \bullet ((O - v1) \times E))$$
$$c = ((O - v1) \times E) \bullet ((O - v1) \times E) - (Radius * Radius)$$

You now know how to determine when the swept sphere collides with the edge of a triangle. If it does, the *t* value returned will describe (indirectly) the new position the center of the sphere should be moved to so that its surface is touching (but not intersecting) the edge.

You could say that for the test between the swept sphere and our triangle, the triangle was inflated by the radius of the sphere. The plane was shifted during the initial tests with the interior of the polygon, so we can liken this to inflating the depth of the polygon away from the plane so that it would have a height of Radius when viewed from any point on that plane. We have also learned that to test each edge, we should also inflate that edge by the same amount, forming a cylinder. It would seem that with these two techniques, we have fully thickened our polygon in all directions by a distance equal to the sphere's radius. This allows us safely reduce the swept sphere to a ray in our intersection tests. However, our inflating technique is still missing one thing which will cause gaps to be created. Treating the swept sphere as a ray without fixing these flaws would fail (causing the sphere to get stuck on the geometry). Let us now examine where these gaps exist that would cause collision testing to fail.

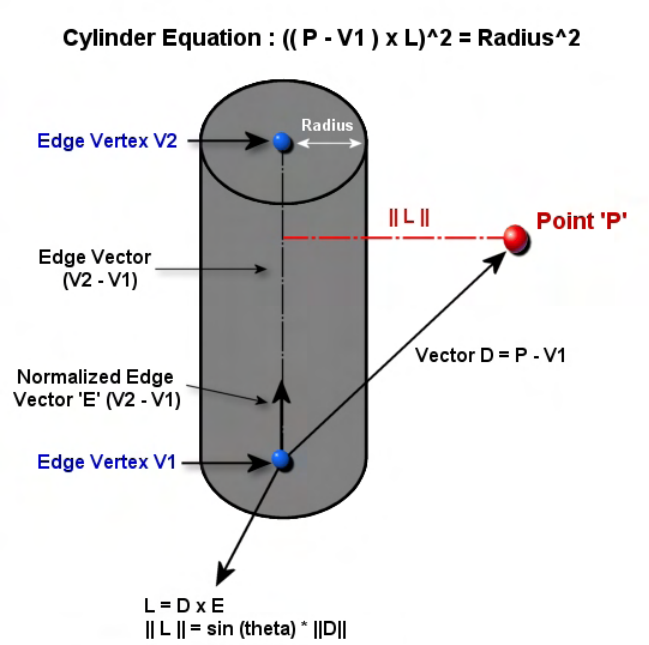

Figure 12.35

When we look at how we constructed a cylinder from our triangle edge, we must pay close attention to the type of cylinder we have created. The cylinder has no caps; it is just an infinite tube with no top or bottom. However, when testing our ray against this cylinder, we will project the intersection point on the surface of the cylinder onto the edge itself (the central spine of cylinder) to get that actual point on the infinite line where the intersection has occurred. If the intersection point projected onto vector **E** (the adjacent side) is outside the line segment (**V2-V1**) then it will be considered to have not intersected the edge. This means we have only bloated the edge in two dimensions and not three.

To understand the problem that we have, imagine that point **P** in Figure 12.35 was raised up so that it was only slightly higher than vertex **V2**. When the ray intersection point is projected onto the infinite line on which the edge is defined, it will be found to be higher than vertex **V2** and therefore, considered to be outside the line segment (**V2-V1**). In other words, the opposite side of the triangle (||L|| in Figure 12.35) is connecting with the central spine of the cylinder higher than vertex **V2**. The intersection with the infinite line is considered to occur beyond the edge extents when this is the case. However, we have not taken into consideration that the ends of each edge (the vertices themselves) should also be inflated by a distance equal to the sphere's radius to give complete padding around the edge end points. Where our edges end at the vertices, we should have domes filling these gaps. Figure 12.26 shows the gaps we currently have in our inflated triangle technique causing intersection tests to fail if not corrected. As you can see, we have not entirely padded the perimeter of the triangle as we should.

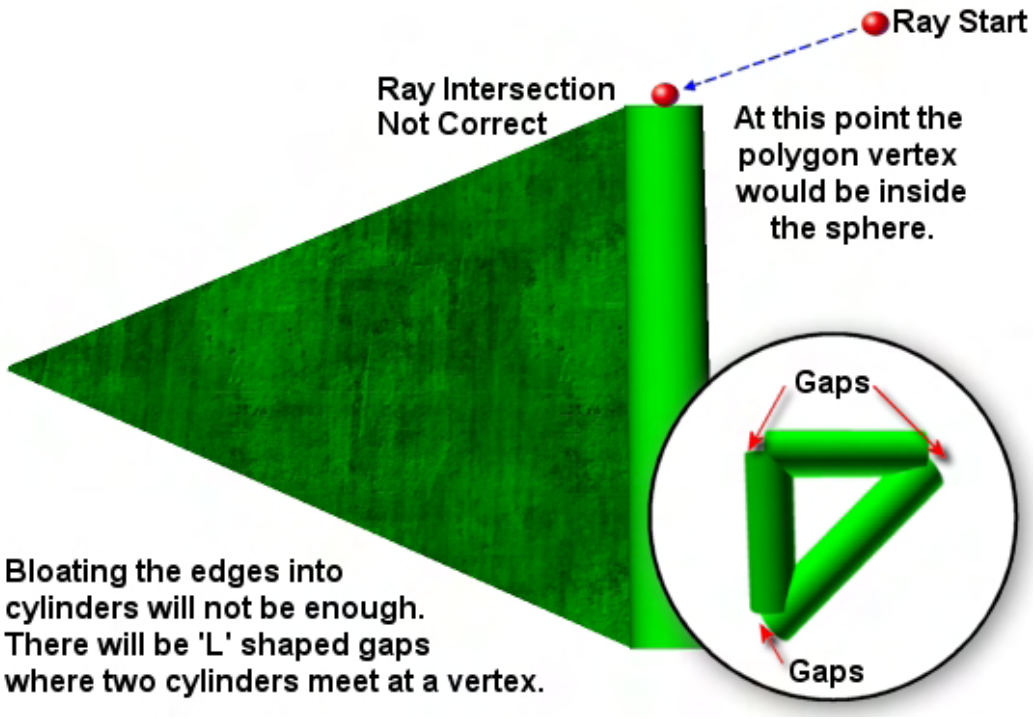

Figure 12.36

In Figure 12.36 we see a ray that is intersecting the top vertex of the edge currently being tested. Since we essentially discount any intersection with the surface of the cylinder that (in this diagram) is higher or lower than the two vertices that form the edge, the ray/cylinder test would return false for intersection in this case. However, it is clear that the ray collides right with the top of the cylinder, where the cap should be. Unfortunately the top vertex in the diagram has had no inflating applied and the intersection is undetected. Remembering that the *t* value returned from our intersection tests is used to calculate the new position of the **center** of the sphere, we can see that if we imagine the position at the end of the ray in Figure 12.36 to be allowed to be the new position of the sphere center, the sphere surface would be embedded in the polygon when its radius is taken into account.

If you look at the circular inset in Figure 12.36, you can see that were we to do nothing other than the edge tests so far described, there would be gaps at the ends of each edge. This can cause the swept sphere to become embedded around the areas of the vertices.

To fix this problem we have to perform an additional test with the vertices when the ray does not intersect the cylinder (i.e., the swept sphere did not intersect the interior of the edge). To remove the gaps at our vertex positions, we need to inflate those areas too so that we have a consistent radius thick buffer around the entire triangle perimeter.

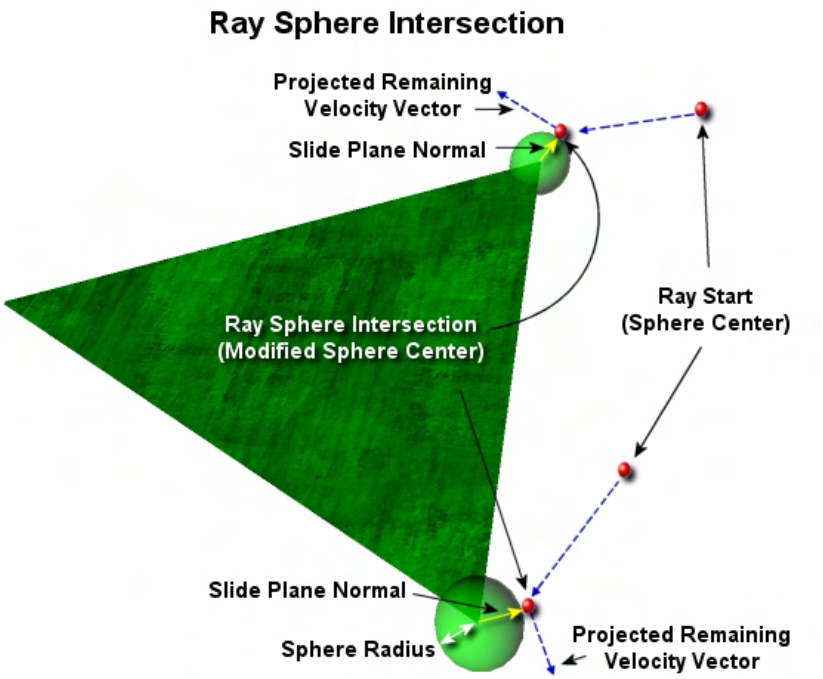

Figure 12.37

We can do this using a similar method to the previous test. We can just inflate each vertex by the radius of our sphere (in all directions). This turns each vertex in the edge into a sphere of the correct radius and allows us to treat our swept sphere as a simple ray. We can then calculate the intersection between the swept sphere and a vertex using a ray/sphere intersection test.

Thus, for each edge, we will first test the ray against the inflated edge (a cylinder) as previously discussed. If no intersection occurs, we will then test the same ray against each inflated vertex (a sphere) in that edge. This fully buffers the edge of the triangle currently being tested. In fact, if we examine the buffering effect with respect to both tests, we see that each edge is transformed into a capsule. In Figure 12.38, we see how the edge looks from the perspective of our ray when all intersection tests for that edge are taken into account. The first edge test inflates the edge into a cylinder and that is followed by a test on each vertex of the edge. As the vertices are inflated into spheres, we form a smooth capsule around the edge for our response system to slide around.

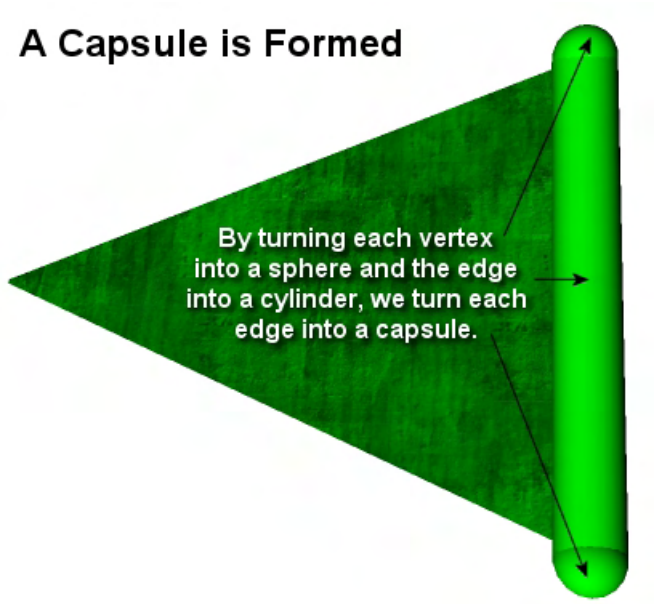

Figure 12.38

You will see in a moment that our edge intersection function will now have to solve (potentially) three quadratic equations. The first quadratic equation is for the intersection between a ray and a cylinder. Then we will have to perform two more intersection tests to determine if the ray (the swept sphere) intersects the spheres (the vertices) at each end of the capsule. As mentioned previously, the sphere tests only need to be performed if the ray has not collided with the cylinder.

When an intersection has occurred with one of the edge vertices (instead of the interior of the edge), the collision normal will be calculated by generating a normalized vector from the vertex (which is the center of the sphere) to the ray intersection point which is on the surface of the sphere (inflated vertex) as shown in Figure 12.39. This will generate a slide plane for the response phase allowing the ellipsoid to slide smoothly around the vertex after a collision.

Before we can look the code that determines these intersections, we still have a little more math to do. In order to test the ray against the sphere formed by each vertex, we must first learn how to substitute the ray equation into the sphere equation and manipulate the resulting quadratic equation into the standard form. Once we have learned how to do that, we will finally look at the complete set of code for the CCollision::SphereIntersectLineSegment function that performs all of these tests. This is the function that we called from CCollision::SphereIntersectTriangle for each edge in our triangle.

It should be noted that while the SphereIntersectLineSegment function is the main function call, for clarity the ray/sphere tests are performed in a separate helper function called SphereIntersectPoint. This function will be called from SphereIntersectLineSegment which directly handles only the ray/cylinder test.

12.7.2 Swept Sphere / Vertex Intersection

Figure 12.39 illustrates what we are trying to achieve with this intersection test. **Source** and **Dest** describe the initial and desired destination points for our swept sphere in this update. If we inflate the vertices into spheres equal to the radius of our swept sphere, we can treat our swept sphere as a ray. The ray will therefore intersect the sphere around the vertex giving us a new destination (**Modified Dest**) position for the center of the sphere that will be at an exact distance of Radius units from the actual vertex. This means, in reality, the surface of our sphere will be touching (but not intersecting) the vertex at this time. Therefore, the *t* value of intersection between the ray and the sphere surrounding the vertex

provides the furthest point along the velocity vector that the center of the sphere can move to before penetrating the vertex.

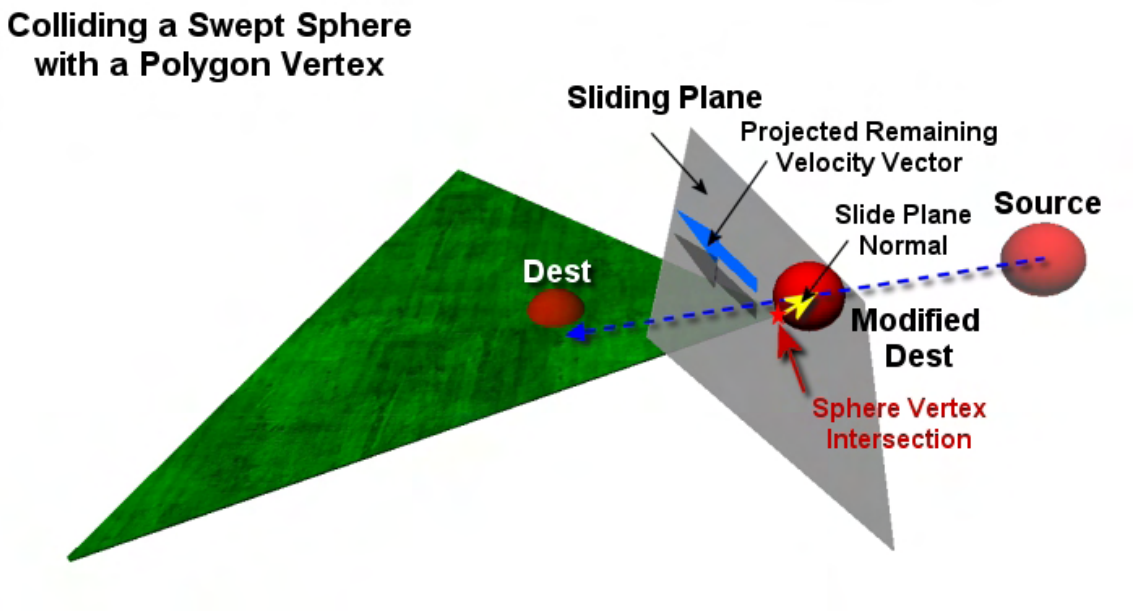

Figure 12.39

As can also be seen in Figure 12.39, the response step will require a sliding plane. The slide plane normal (collision normal) is calculated by returning a normalized vector pointing from the vertex position to the intersection point (**Modified Dest**) that serves as the new position of the center of the sphere.

Before coding can commence, we need to examine the ray/sphere intersection test. Therefore, we must start with the sphere equation, substitute the ray equation into that sphere equation, and then manipulate the resulting quadratic into the standard form so that we can call SolveCollision method to solve for *t*.

The equation for a sphere that we will use is shown below. **P** is any point that is on the surface of the sphere if the equation is true. **C** is the position of the center of the sphere and R is the radius of the sphere.

$$\|(P - C\|^2 = R^2$$

It is a rather simple equation to understand. If the squared length of a vector created from the position of the center of the sphere to an arbitrary point **P** is equal in length to the squared radius of the sphere, the point must be on the surface of the sphere. For any point not on the surface of the sphere, the equation will not be true.

We do not wish to simply test a point **P** using this equation; instead we want to find the position *t* along a ray at which the equation becomes true. If we can do that, we have found the point on the ray that is at a distance of Radius units from the sphere center and is therefore the exact time at which the ray pierces the sphere surface.

We need to substitute the equation of our ray:

$$O + tV$$

into the sphere equation in place of **P** and then solve for *t*. After substituting **O+tV** for **P** in the sphere equation we have the following equation:

$$\|O + tV - C\|^2 = R^2$$

We must first expand the LHS so it is no longer a squared expression. We know that the squared length of the vector **O+tV-C** can be obtained by multiplying this vector by itself, so let us multiply out the square on the LHS:

$$(O + tV - C) \bullet (O + tV - C) = R^2$$

Now we have to multiply two bracketed terms again, but this time each bracket contains three terms instead of two. Although the equations we used FOIL on previously had only two terms, it still works the same way. We just start with the first term in the left brackets working from left to right, and for each term on the left, we multiply it with each term on the right and finally sum the results of each test to get the final result.

Step 1: First we multiply the first term in the left brackets with the first term in the right brackets.

$$O \bullet O = O^2$$

Step 2: Now we multiply the first term in the left brackets with the second term on the right. In this step we rearranged the result to have *t* on the right. This is really a matter of preference thing at this stage. As *t* is the unknown, we will eventually be trying to isolate it as much as possible, and moving it to the right keeps the vectors (**O** and **V**) together in the term and keeps *t* separate. Remember *t* is just a scalar so we have not altered the evaluation of the expression by doing this; we simply rearranged the term more to our liking:

$$O \bullet tV = O \bullet Vt$$

Step 3: Multiply the first term in the left brackets with the last term in the right brackets. Since **O** · **–C** is the same as **–O** · **C**, we write it like this to make a tidier term with the sign on the left.

$$O \bullet -C = -O \bullet C$$

Let us have a look at what our equation looks like so far by summing the three results we have:

$$O^2 + O \bullet Vt - O \bullet C$$

Step 4: We have now performed all steps for the first term in the left brackets, so we do it all again now for the second term. That is, we will multiply each term in the right brackets with the second term in the left brackets (***t*V**).

$$tV \bullet O = O \bullet Vt$$

We rearrange the order of the result again to make it easier later when simplifying the equation. Since we already have an **O · Vt** term (see above), collecting like terms will be very straightforward.

Step 5: Now we multiply the second term in the left brackets with the second term in the right brackets.

$$tV \bullet tV = tV^2 = t^2V^2 = V^2t^2$$

It is pretty clear now that this is definitely a quadratic-- it has a term that involves the unknown *t* raised to the second power.

Step 6: Next we multiply the second term in the left brackets with the last term in the right brackets, yielding the following:

$$tV \bullet -C = -C \bullet Vt$$

At this point we have multiplied the first and second terms in the left brackets with all terms in the right brackets. We could say at this point that we have two thirds of our equation's LHS complete. After the six steps we have completed, we have six terms which, when added together, yields this current LHS:

$$O^2 + O \bullet Vt - O \bullet C + O \bullet Vt + V^2t^2 - C \bullet Vt$$

Step 7: Finally, we have to multiply the final term in the left brackets with each term in the right brackets, giving us the final three terms for our expanded equation. First, we multiply the last term in the left brackets with the first term in the right brackets. We rearrange this to **–O · C** since we already have a term in this shape:

$$-C \bullet O = -O \bullet C$$

S**tep 8:** Next we multiply the last term on the left with the middle term on the right.

$$-C \bullet tV = -C \bullet Vt$$

Step 9: And lastly, we multiply the two final terms of each bracket. This is the multiplication of two negatives **–C** and **–C** giving the positive result $\mathbf{C^2}$.

$$-C \bullet -C = C^2$$

Let us now see the final (and quite large) left hand side of our fully expanded quadratic equation:

$$O^2 + O \bullet Vt - O \bullet C + O \bullet Vt + V^2t^2 - C \bullet Vt - O \bullet C - C \bullet Vt + C^2$$

That initially looks pretty daunting, but there are lots of like terms we can collect. For example, look at the third term **(-O ·C**) and the and seventh term (also **–O · C**). As these are identical and we are just subtracting **–O · C** from the LHS twice, the equation can be collected in the third term like so:

$$O^2 + O \bullet Vt - 2(O \bullet C) + O \bullet Vt + V^2t^2 - C \bullet Vt - C \bullet Vt + C^2$$

We also have many terms containing *t* (not t^2) and we should collect these to form the middle term of our quadratic in standard form. If we collect *t* terms and then isolate *t*, we will also have our **b** coefficient for our standard form quadratic.

Let us just collect all the terms with *t* in them and line them up together:

$$O \bullet Vt + O \bullet Vt - C \bullet Vt - C \bullet Vt$$

We can see that we are adding together two (**O · Vt**) terms on the LHS and also subtracting the term (**C · Vt**) twice from the LHS. Thus, we can collapse these four terms into two terms:

$$2(O \bullet Vt) - 2(C \bullet Vt)$$

That looks a lot nicer, but we still need this arranged into a single term with an isolated *t*, so that we have our **b** coefficient available. Finding a common factor will solve all of our problems. With common factors, if there is some shared multiple across all terms, that multiple can be moved outside the brackets. In our case, we see that both terms have the number **2** and both terms have ***t***. Thus, both **2** and ***t*** are common factors which can be placed outside a set of brackets that contains the rest of the expression (we call this "factoring out" the 2 and the t):

$$2t(O \bullet V - C \bullet V)$$

Using the same logic, we can see that the two terms inside the brackets both contain **V**. Therefore, we can move **V** outside a new set of brackets that contain **O - C**.

$$2t(V \bullet (O - C))$$

Notice how we are careful to preserve the dot product sign since both **O - C** and **V** are vectors and should be vector multiplied.

Finally, let us put *t* over on the right hand side of the outer brackets to isolate it more clearly. This does not change the evaluation of the expression, but it does provide clarity for showing us what the **b** coefficient is going to be in standard form (**2 * (V · (O – C))**:

$$2(V \bullet (O - C))t$$

Plugging this back into our original equation in place of all the *t* terms we had before gives us the following LHS:

$$O^2 + 2(V \bullet (O - C))t - 2(O \bullet C) + V^2 t^2 + C^2$$

Looking at this equation we can instantly see what our **a** coefficient is going to be. It is the value accompanying $\boldsymbol{t^2}$. We can see that this is $\mathbf{V^2}$. Let us move that term to the left of the equation so that it assumes its rightful position in the standard form:

$$V^2 t^2 + O^2 + 2(V \bullet (O - C))t - 2(O \bullet C) + C^2$$

We can also see what the **b** coefficient in standard form is going to be. It is the expression accompanying ***t*** in the non-squared term: $\mathbf{2(V \cdot (O - C))}$. Therefore, let us move the *t* term to its rightful position in the standard form:

$$V^2 t^2 + 2(V \bullet (O - C))t + O^2 - 2(O \bullet C) + C^2$$

Thus, we can see that our **c** coefficient (so far) must be $\mathbf{O^2 - 2(O \cdot C) + C^2}$. That expression is a little lengthy. But wait just a moment. Do we recognize any pattern in the term? Indeed we do. It matches the identity:

$$O^2 - 2OE + E^2 = (O - E)^2$$

In our current constant term we can see that **O** = **O** and **E** = **C** and thus, the identity tells us that it can it also be written in its more compact form $\mathbf{(O - C)^2}$. Below we show the full equation (RHS as well) so far:

$$V^2 t^2 + 2(V \bullet (O - C))t + (O - C)^2 = R^2$$

We are almost there! The standard form quadratic must have zero on the RHS, so we must subtract $\mathbf{R^2}$ from both sides of the equation. This gives us the final ray/sphere intersection quadratic equation in standard form:

$$V^2 t^2 + 2(V \bullet (O - C))t + (O - C)^2 - R^2 = 0$$

We can write this slightly differently to reflect a pattern that is more convenient for programmers (it is the same equation though):

$$(\mathrm{V} \bullet \mathrm{V})\mathrm{t}^2 + 2(\mathrm{V} \bullet (\mathrm{O} - \mathrm{C}))\mathrm{t} + (\mathrm{O} - \mathrm{C}) \bullet (\mathrm{O} - \mathrm{C}) - \mathrm{R} * \mathrm{R} = 0$$

Therefore, the final a, b, and c coefficients that we were searching for (which will be fed into our SolveCollision function to solve for *t*) are:

$$a = V \bullet V$$

$$b = 2 * (V \bullet (O - C))$$

$$c = (O - C) \bullet (O - C) - R * R$$

12.8 The SphereIntersectLineSegment Function

We are now ready to put everything we have learned in the last two sections into practice and write a function that will determine if a swept sphere intersects a triangle edge. Remember, this function is called three times from the SphereIntersectTriangle function (once per edge). Since the function is passed the current closest *t* value that has been found so far (tMax), it will only return true if an intersection happens with the edge at a distance closer than one already found. If this happens, the current *t* value will be overwritten with the new *t* value.

This first version of the function shows the code for the equations we have discussed. You will see in a moment that we will add some additional code to this function to correct the situation where the sphere may already be embedded in the edge prior to the intersection test being performed. Since this will complicate things slightly, we will first show the pure code and then worry about the special case handling.

```
bool CCollision::SphereIntersectLineSegment( const D3DXVECTOR3& Center,
                                             float Radius,
                                             const D3DXVECTOR3& Velocity,
                                             const D3DXVECTOR3& v1,
                                             const D3DXVECTOR3& v2,
                                             float& tMax,
                                             D3DXVECTOR3& CollisionNormal )
{
    D3DXVECTOR3 E, L, X, Y, PointOnEdge, CollisionCenter;
    float       a, b, c, d, e, t, n;

    // Setup the equation values
    E = v2 - v1;              // E = triangle Edge V2-V1
    L = Center - v1;          // L = Hypotenuse ( Vector from V1 to Ray Origin )
    e = D3DXVec3Length( &E );  // e = length of triangle edge

    if ( e < 1e-5f ) return false;  // Safety test:
                                    // If triangle edge has no length return false

    E /= e;             // Normalize E ( Unit length Adjacent )

    // Generate cross values
```

```
    D3DXVec3Cross( &X, &L, &E );      // ||X|| = Length of Opposite side
                                      // ( Hypotenuse * sin a )
                                      //    = Distance from Ray Origin to Edge
    D3DXVec3Cross( &Y, &Velocity, &E );  //  Y = Velocity x E

    // Setup the input values for the quadratic equation
    a = D3DXVec3LengthSq( &Y );           // ( VxE ) dot ( VxE )
    b = 2.0f * D3DXVec3Dot( &X, &Y );     // 2 *(RayOrigin - v1 x E) dot ( V x E )
    c = D3DXVec3LengthSq( &X ) - (Radius*Radius); // ( RayOrigin -v1 x E )^2 – R*R

    // Solve the quadratic for t
    if ( !SolveCollision(a, b, c, t) ) return false;
```

If you cross reference the way we calculate the a, b and c coefficients above, you should see that this matches exactly what we determined they should be when we arranged the ray/cylinder equation into a standard form quadratic equation. We simply plug these values into the SolveCollision function which solves the quadratic equation using the quadratic formula. Remember that the SolveCollision function will return in its output parameter *t*, the smallest positive solution to the quadratic. Therefore, if the function returns true, the ray did intersect the cylinder and local variable *t* will contain the first point of intersection in front of the ray origin. If no intersection is found, we can return false from this function immediately and pass program flow back to the calling function SphereIntersectTriangle (which will then proceed to test the other edges for intersection).

Notice that we have added a test that checks the length of the edge vector (*e*). If *e* is zero (with tolerance) then we have been passed a degenerate edge and return immediately.

The last half of this function is shown below. It first tests to see if the *t* value returned from SolveCollision is larger than the value passed in the tMax parameter. At this point, tMax will contain the closest *t* value found while testing all previous triangles/edges. We are only interested in finding the closest intersecting triangle, so if we have previously detected a collision with a triangle that happens closer to the ray origin than is described by the current *t* value we have just had returned, we can return immediately since we are not interested in this intersection. In that case, we have already hit something that is in front of it.

```
     if ( t > tMax ) return false; // Intersection distance is larger
                                   // than one already found so return false
```

If no closer intersection has yet been found, then we need to calculate the intersection point along the ray. This will also be the point of intersection on the surface of the cylinder. After testing all remaining triangles, if our detection phase determines that this is the closest intersection, this position (stored in the local CollisionCenter variable) will describe the new center position of our sphere (i.e., ellipsoid) such that the surface is just contacting the edge. Calculating this position along the ray is easy now that we have our *t* value.

```
    // Use returned t value to calculate intersection position along velocity ray
    CollisionCenter = Center + Velocity * t;
```

Now that we have a temporary position on the cylinder surface where intersection will occur, we create a vector from the base of the cylinder (v1) to this position. This forms the hypotenuse of a triangle with the edge as its adjacent leg. If we dot this vector with unit length edge vector E, we will scale the length of the hypotenuse by the cosine of the angle between them. This gives us the length of the adjacent leg. This length will describe the exact distance along the edge from vertex v1 to the point where the intersection with the edge has occurred. This allows us to test whether this point is between vertices v1 and v2. All we are essentially doing is projecting the collision point on the cylinder surface onto the infinite line on which the edge is contained.

```
    // Project this onto the line containing the edge ( v2-v1 )
    d = D3DXVec3Dot( &(CollisionCenter - v1), &E );

    if ( d < 0.0f ) // The intersection with the line happens before
                    // the first vertex v1, so test vertex v1 too
        return SphereIntersectPoint( Center, Radius, Velocity,
                                     v1, tMax, CollisionNormal);
    else
    if ( d > e )     // The intersection with line happens past
                     // the last vertex v2 so test vertex v2 too
        return SphereIntersectPoint( Center, Radius, Velocity,
                                     v2, tMax, CollisionNormal);
```

Once we have *d* (the distance from v1 to the point of intersection along the infinite line that contains the edge), we test to see if it is smaller than zero. If it is, then the intersection with the edge has occurred before the first vertex and therefore, the ray is considered non-intersecting with our main cylinder. In this case, we call the SphereIntersectPoint point function to test for intersection against vertex v1. However, if the distance to the point of edge intersection (*d*) from vertex v1 is larger than the length of the edge (*e*), an intersection may have occurred with the second vertex (v2), so the same intersection test is done for vertex v2. Notice that either way we return at this point.

The SphereIntersectPoint function is passed all the information it needs to perform its tasks properly. It is passed the tMax value so that it will store a new *t* value and return true only if an intersection occurs that is closer than the current value in tMax. It is also passed the output parameter CollisionNormal so that it can calculate a collision normal and return it back to the caller.

Finally, if we get past this part, we know we have an intersection with the edge cylinder closer than any that has previously been found. All our collision detection phase wants us to return at this point (and the same was true for the calling function SphereIntersectTriangle) are two pieces of information: the *t* value tMax and a collision normal (slide plane normal). We will calculate the normal by building a normalized vector from the point of intersection on the actual edge, to the point at which the ray intersected the surface of the cylinder (as described earlier). What we are actually doing then, is generating a vector from the point of intersection on the edge, to the center of the swept sphere at the time of intersection.

We calculate the point of intersection on the edge by scaling the unit length edge vector E by the distance to the point of intersection from the start of the edge (*d*) and adding the resulting vector to the edge start vector (v1).

```
    // Calculate the actual Point of contact on the line segment
    PointOnEdge = v1 + E * d;

    // We can now generate our normal, store the interval and return
    D3DXVec3Normalize( &CollisionNormal, &(CollisionCenter - PointOnEdge) );
    tMax = t;

    // Intersecting!
    return true;

}
```

With the collision normal generated, we also overwrite the value currently stored in tMax with the new closer *t* value we have found and then return true. We will look at the complete code to this function in one block in a moment after we discuss something else that must be added.

12.8.1 Ray / Cylinder Intersection: Embedded Object Correction

Recall that the first intersection test we call in SphereIntersectTriangle is the SphereIntersectPlane function. This is a simple ray/plane test where the swept sphere is reduced to a ray by shifting the plane. However, recall that we performed tests within that function to determine if the sphere was already embedded in the plane prior to the test being performed. When this is the case, we have very few options other than to calculate a new position for the sphere so that it is no longer intersecting. To address this issue we calculated the distance from the ray origin to the plane (that was behind it) and then moved the ray origin back along the normal so that it was sitting on the plane instead of behind it. This worked well because the ray origin represents the center of the sphere, and when the sphere center is located on the shifted plane, its surface is touching the actual plane (and is no longer embedded).

Note that when this embedded case correction had been performed, the *t* value returned was not a positive parametric ray position in the range [0.0, 1.0]. It was a negative value describing the actual world space distance to the plane. In other words, the *t* value describes to the detection phase how far the sphere should be moved backwards so that it is no longer embedded.

It seems reasonable that we should perform these same embedded tests and corrections when performing our cylinder and sphere tests. For example, it is quite possible that our swept sphere's surface may already be embedded in the triangle edge prior to the intersection test being performed.

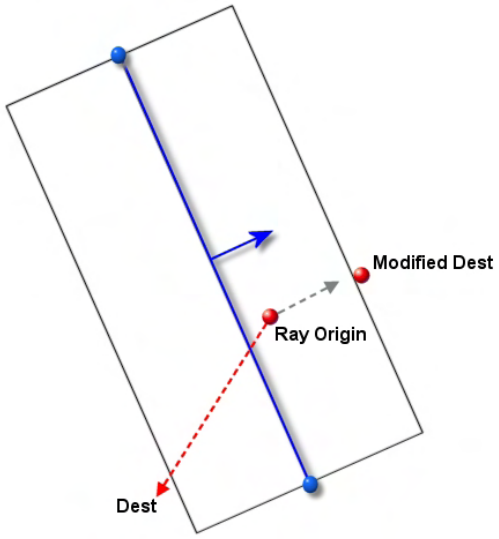

Figure 12.40

In Figure 12.40 we can see that the **Ray Origin** is inside the cylinder formed from the edge prior to the test being performed. **Dest** illustrates the position that the sphere is being requested to move to. In this case (like the plane case), we just ignore the velocity vector

and move the sphere center (ray origin) in the direction of the edge normal so that it is no longer inside the cylinder and is instead located on the surface. Although we do not have the normal of the edge at this point, we can easily calculate it by projecting the ray origin onto the edge. We can then create a vector from the projected point on the edge to the original ray origin and make it unit length. Once we have the unit length edge normal, we can shift the ray origin along it. The distance we need to shift is equal to the radius of the cylinder minus the distance from the ray origin to the edge.

When this is the case, our SphereIntersectLineSegment function will not even have to bother solving the quadratic equation. We simply calculate the negative distance from the ray origin to the surface of the cylinder and return this as the *t* value to the detection phase. The collision normal returned will be the normal of the edge.

> **Note:** It is important to remember that none of our intersection techniques return or update the actual sphere position. That is done by the parent detection function (which we have not yet covered) that is called by our CollideEllipsoid function. All the intersection functions return is a slide plane normal and a *t* value of intersection. If negative, the *t* value will describe the actual world space distance the sphere must be moved so it is no longer embedded.

The question has to be asked, how do detect whether our ray origin is already within the cylinder? As it happens, we already have this answer stored in the **c** coefficient of our quadratic equation. Recall that the **c** coefficient was calculated like so:

$$c = ((O - v1) \times E) \bullet ((O - v1) \times E) - (Radius * Radius)$$

Where:

O = Sphere Center (Ray Origin)
v1 = First vertex in edge
E = Unit length edge vector

Therefore,

((O-v1)xE)•((O-v1)xE) = Squared Distance from ray origin to edge

Since we subtract the squared radius when calculating **c**, this value will be zero if the ray origin is on the surface of the cylinder, positive if the ray origin is outside the cylinder, and negative if the ray origin is inside the cylinder (i.e., distance between the ray origin and the edge is smaller than the radius).

So after we have calculated the coefficients for the ray/cylinder quadratic equation, but before we have solved it, we can test **c**. If it is negative, we can execute the following code in lieu of solving the quadratic equation.

```
    if ( c < 0.0f )
    {
        // Product Ray Origin onto Edge 'E'
        d = D3DXVec3Dot( &L, &E );

        // Is this before or after line start?
```

```
        if (d < 0.0f)
        {
            // The point is before the beginning of the line,
            // test against the first vertex instead
            return SphereIntersectPoint( Center, Radius, Velocity,
                                         v1, tMax, CollisionNormal );

        } // End if before line start
        else if ( d > e )
        {
            // The point is after the end of the line,
            // test against the second vertex
            return SphereIntersectPoint( Center, Radius, Velocity,
                                         v2, tMax, CollisionNormal );

        } // End if after line end
```

The first section of this code calculates *d*. This is calculated by projecting the length of the vector from v1 to the ray origin (L) onto the unit length edge vector E. This gets us the distance from vertex v1 to the ray origin (hypotenuse) projected onto vector E (adjacent). The length of this adjacent side L describes the distance from vertex v1 to the ray origin projected onto the line containing the edge. If this distance value is smaller than zero or larger than the length of the edge (*e*), then the sphere is not embedded in the actual cylinder, but may be embedded in the vertices (the spheres). Therefore, if *d* is negative, we perform an embedded correction test for v1, or if $d > e$, we perform the embedded correction test against v2. In both cases, we will let the SphereIntersectPoint function sort out the embedded correction.

If *d* contains a distance value between v1 and v2 then the ray origin is inside the cylinder and we need to correct it. As shown below, we first calculate the point on the actual edge. This is the ray origin projected onto the line that contains edge (v2-v1). Since we already have *d* (the distance to this projected point along the edge from v1), we can calculate the actual point on the edge by adding the vector E**d* to v1.

```
        else
        {
            // Point within the line segment
            PointOnEdge = v1 + E * d;

            // Generate collision normal
            CollisionNormal = Center - PointOnEdge;
            n = D3DXVec3Length( &CollisionNormal );
            CollisionNormal /= n;

            // Calculate negative t value as actual distance
            // by subtracting distance from edge to ray origin
            // ( which is smaller than radius ) the radius.
            t = n - Radius;

            if (tMax < t) return false;

            // Store t and return
            tMax = t;

            // Edge Overlap
```

```
            return true;

        } // End if inside line segment

    } // End if sphere inside cylinder
```

After we have the point on the edge, we now have to calculate the edge normal. We do this by creating a vector from the point on the edge to the ray origin. We then record the length of this vector in *n*, which describes the distance from the ray origin to the actual edge. Next we divide the collision normal by *n* to normalize it and we have the vector we will use as our slide plane normal later on. Now we just have to calculate the *t* value (shown above). Since *n* describes the distance from the ray origin to the edge, and this is now guaranteed to be smaller than the radius of the cylinder, subtracting the radius from *n* will give us a negative *t* value describing the distance from the ray origin to the surface of the cylinder. Because this *t* value is negative, it is guaranteed to overwrite any non-embedded *t* value that has been recorded in tMax while checking previous triangles. We record this value in tMax and return. Our function will have returned the *t* value and collision normal back to the parent detection function.

Let us now merge all of these concepts together to create the final code to our CCollision::SphereIntersectLineSegment function (complete with embedded case correction).

12.8.2 The Final SphereIntersectLineSegment Function

```
bool CCollision::SphereIntersectLineSegment( const D3DXVECTOR3& Center,
                                             float Radius,
                                             const D3DXVECTOR3& Velocity,
                                             const D3DXVECTOR3& v1,
                                             const D3DXVECTOR3& v2,
                                             float& tMax,
                                             D3DXVECTOR3& CollisionNormal )
{
    D3DXVECTOR3 E, L, X, Y, PointOnEdge, CollisionCenter;
    float       a, b, c, d, e, t, n;

    // Setup the equation values
    E = v2 - v1;              // E = triangle Edge V2-V1
    L = Center - v1;          // L = Hypotenuse ( Vector from V1 to Ray Origin )
    e = D3DXVec3Length( &E ); // e = length of triangle edge

    if ( e < 1e-5f ) return false;  // Safety test…
                                    // if triangle edge has no length return false

    E /= e;             // Normalize E ( Unit length Adjacent )

    // Generate cross values
    D3DXVec3Cross( &X, &L, &E );      // ||X|| = Length of Opposite side
                                      // ( Hypotenuse * sin a )
                                      //    = Distance from Ray Origin to Edge
    D3DXVec3Cross( &Y, &Velocity, &E );   //  Y     = Velocity x E

    // Setup the input values for the quadratic equation
```

```
    a = D3DXVec3LengthSq( &Y );          // ( V x E ) dot ( V x E )
    b = 2.0f * D3DXVec3Dot( &X, &Y );    // 2*( RayOrigin-v1 x E ) dot ( V x E )
    c = D3DXVec3LengthSq( &X ) - (Radius*Radius); // ( RayOrigin-v1 x E )^2 – R*R

    if ( c < 0.0f )
    {
        // Product Ray Origin onto Edge 'E'
        d = D3DXVec3Dot( &L, &E );

        // Is this before or after line start?
        if (d < 0.0f)
        {
            // The point is before the beginning of the line,
            // test against the first vertex instead
            return SphereIntersectPoint( Center, Radius, Velocity, v1,
                                         tMax, CollisionNormal );

        } // End if before line start
        else if ( d > e )
        {
            // The point is after the end of the line,
            // test against the second vertex
            return SphereIntersectPoint( Center, Radius, Velocity,
                                         v2, tMax, CollisionNormal );

        } // End if after line end
        else
        {
            // Point within the line segment
            PointOnEdge = v1 + E * d;

            // Generate collision normal
            CollisionNormal = Center - PointOnEdge;
            n = D3DXVec3Length( &CollisionNormal );
            CollisionNormal /= n;

            // Calculate negative t value as actual distance
            // by subtracting distance from edge to ray origin
            // ( which is smaller than radius ) the radius.
            t = n - Radius;

            if (tMax < t) return false;

            // Store t and return
            tMax = t;

            // Edge Overlap
            return true;

        } // End if inside line segment

    } // End if sphere inside cylinder

    // If we are already checking for overlaps, return
    if ( tMax < 0.0f ) return false;

    // Solve the quadratic for t
```

```
    if ( !SolveCollision(a, b, c, t) ) return false;

    if ( t > tMax ) return false; // Intersection distance is larger
                                  // than one already found so return false

    // Use returned t value to calculate intersection position along velocity ray
    CollisionCenter = Center + Velocity * t;

    // Project this onto the line containing the edge ( v2-v1 )
    d = D3DXVec3Dot( &(CollisionCenter - v1), &E );

    if ( d < 0.0f ) // The intersection with the line happens
                    // before the first vertex v1 so test vertex v1 too
        return SphereIntersectPoint( Center, Radius, Velocity,
                                     v1, tMax, CollisionNormal);
    else
    if ( d > e )     // The intersection with line happens
                     // past the last vertex v2 so test vertex v2 too
        return SphereIntersectPoint( Center, Radius, Velocity,
                                     v2, tMax, CollisionNormal);

    // Calculate the actual Point of contact on the line segment
    PointOnEdge = v1 + E * d;

    // We can now generate our normal, store the interval and return
    D3DXVec3Normalize( &CollisionNormal, &(CollisionCenter - PointOnEdge) );
    tMax = t;

    // Intersecting!
    return true;

}
```

One line worth drawing your attention to is highlighted in bold:

```
  // If we are already checking for overlaps, return
  if ( tMax < 0.0f ) return false;
```

If we have gotten to this point in the function, the swept sphere is not embedded in the edge currently being tested. Normally, a quadratic equation would then be solved to find the *t* value of intersection along the ray. However, if the tMax value passed in is already negative, then we will not waste time determining the intersection point along the ray since we have already found a triangle (in a previous test) in which the swept sphere is embedded. From that point on, we are only interested in finding triangles for which the swept sphere is potentially *more* embedded.

You can think about our intersection routines as working in one of two modes. Until we find an embedded triangle, we solve quadratic equations to find a closest *t* value. In this mode, the *t* value will be a parametric distance along the ray in the range of [0.0, 1.0]. However, as soon as we find an embedded triangle, tMax is set to a negative distance value which describes how to correct the situation by moving the sphere. At this point, the intersection tests are switched into what we might call ‘Embedded Correction Mode’. For the remainder of our tests, we are only interested in other triangles that the sphere is embedded in. Therefore, tMax becoming negative switches into this Embedded

Correction Mode, and this can be done by the SphereIntersectPlane, SphereIntersectLineSegment and SphereIntersectPoint functions.

We have just one more function to write before we have completed the methods needed to sweep a sphere against a triangle. The SphereIntersectLineSegment function calls a function called SphereIntersectPoint. This is the final missing piece we need to discuss. We will then have covered every separate intersection test called directly or indirectly by the SphereIntersectTriangle function.

12.9 The SphereIntersectPoint Function

SphereIntersectPoint is called by the previous function if no intersection is found between the ray and the cylinder formed by the edge. This additional test looks to see if the ray intersects the sphere that we construct around each vertex (which we do to fully pad the triangle edge). The code just calculates the **a**, **b**, and **c** coefficients of the quadratic equation and passes them into our SolveCollision. It will return either true or false depending on whether the ray intersects the sphere. If the *t* value returned is greater than the one we currently have in the tMax parameter, we ignore it and return false for intersection; otherwise, we overwrite the value stored in tMax with our new, closer intersection *t* value so that it can be returned to the caller. We then calculate this new position along the ray (which is on the surface of the inflated sphere at a distance of Radius units from the vertex). Finally, we calculate the collision normal by generating a unit length vector from the vertex to the intersection point on the surface of the sphere.

As with the previous function, if that was all we had to worry about then the function would be extremely small. However, we also have to cater for the case where the ray origin is already inside the sphere surrounding the vertex. If it is then we will not bother solving the quadratic equation and will simply calculate the distance we need to move the sphere center position (the ray origin) along the collision normal so that it is no longer penetrating the vertex. In other words, just as we have done in all of our intersection functions, we will return a negative *t* value which describes the actual distance (not parametric) we have to move the sphere center position back so that it is correctly positioned at a distance of Radius from the vertex, just contacting the inflated sphere surrounding that vertex.

We will look at this function in a few sections. In the first part of the function we calculate the **a**, **b**, and **c** coefficients of the quadratic equation using the mathematics we discussed earlier.

```
bool CCollision::SphereIntersectPoint( const D3DXVECTOR3& Center,
                                       float Radius,
                                       const D3DXVECTOR3& Velocity,
                                       const D3DXVECTOR3& Point,
                                       float& tMax,
                                       D3DXVECTOR3& CollisionNormal )
{
    D3DXVECTOR3 L, CollisionCenter;
    float       a, b, c, l, l2, t;

    // Setup the equation values
    L  = Center - Point;
```

```
    l2 = D3DXVec3LengthSq( &L );

    // Setup the input values for the quadratic equation
    a = D3DXVec3LengthSq( &Velocity );
    b = 2.0f * D3DXVec3Dot( &Velocity, &L );
    c = l2 - (Radius * Radius);
```

We only need to solve this equation if the **c** coefficient is non-negative. The **c** coefficient contains the squared length of a vector from the ray origin to the vertex, minus the squared radius of the sphere. If it is negative, then the distance from the vertex to the ray origin is smaller than the radius of the inflated sphere surrounding the vertex. This tells us that the ray origin is already inside the sphere. In reality, this means the vertex is embedded inside our swept sphere and we need to back the swept sphere away from the vertex so that this is no longer the case. The code that calculates the *t* value to accomplish this is shown below.

```
    // If c < 0 then we are overlapping, return the overlap
    if ( c < 0.0f )
    {
        // Remember, when we're overlapping we have no choice
        // but to return a physical distance (the penetration depth)
        l = sqrtf( l2 );
        t = l - Radius;

        // Outside our range?
        if (tMax < t) return false;

        // Generate the collision normal
        CollisionNormal = L / l;

        // Store t and return
        tMax = t;

        // Vertex Overlap
        return true;

    } // End if overlapping
```

We store the distance from the ray origin (the center of the swept sphere) to the vertex (the center of our inflated sphere) in local variable *l*. Since we know that this value is already smaller than the radius of the inflated sphere (otherwise we would not be in this code block) we can subtract the radius from this value to get the negative distance (*t*) we need to move the ray origin so that it is located on the surface of the inflated sphere (i.e., the vertex is now just touching the surface of the swept sphere). If this *t* value is larger than the one already stored in tMax, it means that we have found another intersection in which the swept sphere is more deeply embedded. So we can ignore the current one and return false for intersection. Otherwise, we calculate the collision normal as the unit length vector from the vertex to the ray origin. We then store our *t* value in tMax and return true for intersection. From this point on, our detection phase will only be intersected in finding embedded polygons that are more deeply embedded than this one.

Beneath this code block is the code that gets executed when the current vertex is not already embedded in our swept sphere. Before solving the quadratic, we first test whether the current value stored in tMax

is negative. If it is, it means a previous intersection test found an embedded situation and we are no longer interested in anything other than finding another triangle, edge, or vertex that is more deeply embedded than the current one. So we return false for intersection.

If that is not the case, we are still searching for a closer intersection along the ray and we call our SolveCollision function to see whether the ray intersects the sphere surrounding the vertex. If not, we return false; otherwise, we test the returned *t* value and return false if it is found to be greater than the value we already have stored in tMax. We do this because, although we have found an intersection, it is happening at a further distance along the ray from the origin than an intersection we found on a previous test. Remember, our collision detection phase is only interested in finding the closest colliding triangle.

```
    // If we are already checking for overlaps, return
    if ( tMax < 0.0f ) return false;

    // Solve the quadratic for t
    if (!SolveCollision(a, b, c, t)) return false;

    // Is the vertex too far away?
    if ( t > tMax ) return false;
```

Finally, we calculate the point of intersection along the ray and use this to create a collision normal. The normal is generated by normalizing a vector from the vertex to the intersection point on the surface of the inflated sphere surrounding the vertex.

```
    // Calculate the new sphere position at the time of contact
    CollisionCenter = Center + Velocity * t;

    // We can now generate our normal, store the interval and return
    D3DXVec3Normalize( &CollisionNormal, &(CollisionCenter - Point) );

    tMax = t;

    // Intersecting!
    return true;
}
```

As can be seen above, we store the new *t* value in tMax so the calling function can pass it back to the collision detection phase and use it for comparisons in future triangle intersection tests.

And there we have it. We have discussed all the intersection techniques that we need to understand in order to implement this collision system. Primarily we have described exactly how we test a swept sphere against a triangle. First, we test against the plane of the triangle, then we test against the interior of the triangle, and finally tests are performed against each edges and vertices of the triangle.

Before leaving this section, here is another look at the SphereIntersectTriangle function:

```
bool CCollision::SphereIntersectTriangle(  const D3DXVECTOR3& Center,
                                           float Radius,
                                           const D3DXVECTOR3& Velocity,
```

```
                                          const D3DXVECTOR3& v1,
                                          const D3DXVECTOR3& v2,
                                          const D3DXVECTOR3& v3,
                                          const D3DXVECTOR3& TriNormal,
                                          float& tMax,
                                          D3DXVECTOR3& CollisionNormal )
{

    float       t = tMax;
    D3DXVECTOR3 CollisionCenter;
    bool        bCollided = false;

    // Find the time of collision with the triangle's plane.
    if ( !SphereIntersectPlane( Center, Radius, Velocity, TriNormal, v1, t ))
        return false;

    // Calculate the sphere's center at the point of collision with the plane
    if ( t < 0 )
        CollisionCenter = Center + (TriNormal * -t);
    else
        CollisionCenter = Center + (Velocity * t);

    // If this point is within the bounds of the triangle,
    // we have found the collision
    if ( PointInTriangle( CollisionCenter, v1, v2, v3, TriNormal ) )
    {
        // Collision normal is just the triangle normal
        CollisionNormal = TriNormal;
        tMax            = t;

        // Intersecting!
        return true;

    } // End if point within triangle interior

    // Otherwise we need to test each edge
    bCollided |= SphereIntersectLineSegment( Center, Radius, Velocity,
                                             v1, v2, tMax, CollisionNormal );

    bCollided |= SphereIntersectLineSegment( Center, Radius, Velocity,
                                             v2, v3, tMax, CollisionNormal );

    bCollided |= SphereIntersectLineSegment( Center, Radius, Velocity,
                                             v3, v1, tMax, CollisionNormal );

    return bCollided;
}
```

Keep in mind that while at several points in the various intersection techniques we temporarily calculate the actual intersection point, the only thing this function actually returns to the caller is a *t* value and a collision normal. It is the caller that will use this information to return the actual position of the closest intersection back to the CollideEllipsoid function as the new position of the moving entity.

We have spent the last several sections discussing how to detect the intersection between a swept sphere and a triangle. However, we have not yet introduced the function which serves as the glue that binds the

detection phase together. Earlier we covered the code to the CollideEllipsoid function, which was called by the application each time it wanted to update a moving entity. This function would invoke the collision detection phase to determine an intersecting position for the entity and generate a collision normal if an intersection occurred. This would serve as the data for a new sliding plane, upon which we would project our velocity and attempt to shift positions. The function would go back and forth between detection and response until the initial velocity was all used up (via projection onto the slide plane) or until a slide vector was calculated that the sphere could move along and spend the remainder of its velocity without any further intersections. CollideEllipsoid would iteratively make the call to the EllipsoidIntersectScene function, which is the main function in the detection phase. It is this function that will call the SphereIntersectTriangle function for every potential colliding polygon in the collision system's geometry database. It is this function that, after calling the SphereIntersectTriangle function for every triangle, will calculate the updated position for the ellipsoid and return it back to the response phase. Let us look at this function then so that we can get a final view of our overall collision system.

12.10 The EllipsoidIntersectScene Function

This function is the front end for the collision detection phase and is ultimately responsible for returning collision data back for use in the response phase. You will recall from our earlier discussions that it was passed the eSpace position of the center of the ellipsoid, the ellipsoid's radius, and the eSpace velocity vector. Hopefully, you also remember that our CCollision class maintains an array of **CollIntersect** structures which are used to transport collision information back to the response phase. Although the detection phase is only interested in returning the new position of the ellipsoid based on the closest intersection, it may be the case that the sphere intersects several triangles at exactly the same time. When this is the case, the information about each intersection will be returned in this array.

```
struct CollIntersect
{
    D3DXVECTOR3     NewCenter;
    D3DXVECTOR3     IntersectPoint;
    D3DXVECTOR3     IntersectNormal;
    float           Interval;
    ULONG           TriangleIndex;
};
```

The CollIntersect structure stores the new position of the ellipsoid so that the application can update the position of the moving entity. It also stores the actual intersection point on the surface of the ellipsoid and the collision (slide plane) normal. It should be noted that these vectors are all currently in eSpace and should be transformed back into world space before being handed back to the application. We saw that this is exactly what the CollideEllipsoid function did before returning the final position and integration velocity back to the application. The *t* value of intersection is also stored in the Interval float. If multiple collisions occur simultaneously, the information will be returned in multiple CollIntersect structures. When this is the case, keep in mind that the new position of the ellipsoid in eSpace and the interval will be exactly the same in each structure. Since we only return information for the nearest intersection, they must share the same *t* value.

Each structure also returns the index of the triangle in the collision system's geometry database that was intersected. This can be very useful to an application. For example, imagine you were using this collision system to track a ball around a pinball table. When the ball hits certain triangles, our application may want to know which ones they were since this may increase or decrease the player's score. Alternatively, you might decide to check some application associated triangle material property and play a certain sound effect (maybe a different footstep sound depending on the material underfoot) or trigger a scripted event upon a particular collision.

Although we have not focused much on how the collision geometry will be stored in our collision system (this is covered in detail in the workbook), for now just know that we use registration functions such as CCollision::AddIndexedPrimitive to register all the triangles in a mesh with the collision system. In fact, there is even a CCollision::AddActor function which steps though the frame hierarchy of an actor, transforms each mesh into world space, and then adds the triangles of each transformed mesh to the collision database. This means that we could load an entire scene from a hierarchical X file into an actor, and then register all the triangles in that scene with the collision system with a single function call.

Ultimately, each triangle that is registered with the collision system has its vertices added to an internal array of D3DXVECTOR3s. In our case, we are only interested in the positional information at each vertex and there is no need to store other per vertex properties. The CCollision class uses an STL vector to manage this data. The following line of code is located in CCollision.h and defines an STL vector of D3DXVECTOR3 structures called CollVertVector. The vertices of every triangle registered with the collision system will be added to this single array.

```
typedef std::vector<D3DXVECTOR3>    CollVertVector;
```

A vector of this type is then declared as a member variable of the CCollision class as shown below.

```
CollVertVector      m_CollVertices;
```

When the vertices of a triangle are added to the vector, its indices are also stored inside a CollTriangle structure (also defined in CCollision.h) along with other per triangle properties such as its normal and a surface material index which we might find useful. This structure is shown below.

```
struct CollTriangle
{
        ULONG       Indices[3];
        D3DXVECTOR3 Normal;
        USHORT      SurfaceMaterial;
}
```

We called our triangle data a material index since it is common for collision systems to use surface material properties to determine responses (e.g., the application of friction). Of course, you could decide to make this a more generic data storage concept. As discussed a moment ago, you might use this member to store a value that can be added to the player's score or health when a triangle of this type is collided with. Or you might even decide to use this value to index into an array of callback functions. Basically, the idea is to provide us the ability to store a per-triangle code that might be useful in our application.

Every triangle that is added to the collision system is stored in one of these structures. Its three indices reference into the CollVertVector array describing the vertices that comprise the triangle. Triangle storage will take the form of a dynamic array (another STL vector) of CollTriangle structures as shown below. This array is called CollTriVector.

```
typedef std::vector<CollTriangle>   CollTriVector;
```

A vector of this type is declared as a member of the CCollision class as shown below.

```
CollTriVector       m_CollTriangles;
```

It is not important in this discussion to understand how the triangle data gets added to these arrays; the workbook will discuss such application specific topics. However, we do know that our EllipsoidIntersectScene function can access all the triangle and vertex data in these two arrays. Indeed our collision geometry database at this point is basically just these two STL vectors.

Now that we know how the collision data is stored inside the CCollision class, let us have a look at the parameter list to the function.

```
bool CCollision::EllipsoidIntersectScene( const D3DXVECTOR3 &Center,
                                          const D3DXVECTOR3& Radius,
                                          const D3DXVECTOR3& Velocity,
                                          CollIntersect Intersections[],
                                          ULONG &IntersectionCount )
```

The Center parameter and the Velocity parameter describe the center position of the ellipsoid and the direction and magnitude for the movement request. Recall that before this function was called by the CollideEllipsoid function, these values were already in eSpace. We also pass in the radius vector of our ellipsoid, which is used to convert each triangle into eSpace prior to testing it for intersection. As the fourth parameter, the CCollision object's CollIntersect array is passed so that the detection function can fill it with intersection information and return it to the response phase. The final parameter is passed by reference from the CollideEllipsoid function. It is a DWORD value which will keep track of how many CollIntersect structures in the passed array contain valid intersection information. Remember, this array is re-used to transport information every time this function is called.

> **Note:** If necessary, please refer back to our discussion of the CollideEllipsoid function. This is the function that calls EllipsoidIntersectScene and retrieves the information from the CollIntersect array.

Let us now look at this final function one section at a time. It is responsible for testing each triangle in the database for intersection and recording the nearest intersection results in the input **CollIntersect** array.

The first part of the function calculates the inverse radius vector of the ellipsoid. This will be needed to scale the vertex of each triangle into eSpace. We also copy the passed parameters Center and Velocity into two local variables called eCenter and eVelocity.

```
bool CCollision::EllipsoidIntersectScene( const D3DXVECTOR3 &Center,
                                          const D3DXVECTOR3& Radius,
                                          const D3DXVECTOR3& Velocity,
                                          CollIntersect Intersections[],
                                          ULONG & IntersectionCount )
{
    D3DXVECTOR3 eCenter, eVelocity, InvRadius;
    D3DXVECTOR3 ePoints[3], eNormal;
    D3DXVECTOR3 eIntersectNormal, eNewCenter;
    ULONG       Counter, NewIndex, FirstIndex;
    bool        AddToList;
    float       eInterval;
    ULONG       i;

    // Calculate the reciprocal radius to minimize division ops
    InvRadius = D3DXVECTOR3( 1.0f / Radius.x, 1.0f / Radius.y, 1.0f / Radius.z );

    eCenter   = Center;
    eVelocity = Velocity;

    // Reset ellipsoid space interval to maximum
    eInterval = 1.0f;

    // Reset initial intersection count to 0 to save the caller having to do this.
    IntersectionCount = 0;
```

Notice above that the local variable eInterval is initially set to one. It is this variable that we will be passing into the intersection routines as tMax. As closer intersections are found, the value of eInterval will be overwritten to contain the nearer *t* values. Initializing it to 1.0 describes an intersection time at the very end of the ray. That is, the ray is completely clear from obstruction unless our intersection routines detect a collision somewhere along the ray and update it with a smaller value. We also set the passed IntersectCount variable to zero because we have not yet found any intersections and thus, have not added anything useful to the passed CollIntersect array.

Now we have to loop through each triangle in the database. We create an STL iterator to step though the CollTriVector one triangle at a time. Then we use the triangle's indices array to fetch the correct vertices from the m_CollVertices array. We scale the vertex positions (using theVec3VecScale function) by the Inverse ellipsoid radius vector, transforming them into eSpace, and store them in the local vector array ePoints.

```
    // Iterate through our triangle database
    CollTriVector::iterator Iterator = m_CollTriangles.begin();
    for ( Counter = 0; Iterator != m_CollTriangles.end(); ++Iterator, ++Counter )
    {
        // Get the triangle descriptor
        CollTriangle * pTriangle = &(*Iterator);
        if ( !pTriangle ) continue;

            // Get points and transform into ellipsoid space
            ePoints[0] = Vec3VecScale( m_CollVertices[ pTriangle->Indices[0] ],
                                       InvRadius );
            ePoints[1] = Vec3VecScale( m_CollVertices[ pTriangle->Indices[1] ],
                                       InvRadius );
```

```
            ePoints[2] = Vec3VecScale( m_CollVertices[ pTriangle->Indices[2] ],
                                       InvRadius );

            // Transform normal and normalize
            // (Note how we do not use InvRadius for the normal)
            eNormal = Vec3VecScale( pTriangle->Normal, Radius );
            D3DXVec3Normalize( &eNormal, &eNormal );
```

We convert the normal of the current triangle into eSpace as well, by scaling it with the radius of the ellipsoid and normalizing the result. Note that we do not use the inverse radius as is the case with the vertices; it works the other way around for direction vectors.

At this point we have the three eSpace vertices for the current triangle we are about to test and also have its eSpace normal. We now have everything we need to call our very familiar SphereIntersectTriangle function:

```
        // Test for intersection with a unit sphere
        // and the ellipsoid space triangle
        if ( SphereIntersectTriangle( eCenter, 1.0f, eVelocity,
                                      ePoints[0], ePoints[1], ePoints[2], eNormal,
                                      eInterval, eIntersectNormal ) )
```

When we call this function we pass in the eSpace center of the ellipsoid (the ray origin) and the radius of the ellipsoid in eSpace. We know that this is always 1.0 since the ellipsoid in eSpace becomes a unit sphere. We also pass in the eSpace velocity vector (ray delta vector) followed by the three eSpace vertices of the triangle. The eighth parameter is the eInterval local variable which was set to 1.0 at the start of the function. If an intersection occurs between the swept sphere and this triangle, this variable will contain the new (smaller) *t* value on function return. As the final parameter we also pass in a local 3D vector variable (eIntersectNormal) which will store the collision normal if the function returns true for intersection.

The next section of code is inside the conditional code block that is executed if an intersection occurs (i.e., SphereIntersectTriangle returns true). Let us look at this code a few sections at a time.

The first thing we do is test the value currently stored in the local eInterval variable. If we are in this code block, then SphereIntersectTriangle not only determined an intersection, but it also found one that occurs closer to the ray origin then any previous found. Since eInterval is passed into this function for *t* value storage, the value stored in the variable at this point will be the new *t* value of intersection along the velocity vector.

If this is a positive value, then eInterval contains the parametric distance of the intersection point along the ray and will be in the 0.0 to 1.0 range. When this is the case, the new sphere position can be calculated by scaling the velocity vector by this amount and adding it to the current center position of the sphere. If eInterval is a negative value then it means the sphere was embedded in the triangle. When this is the case, eInterval will store the actual world space distance by which the sphere's center must be moved back in the direction of the triangle plane normal. This will assure that the surface of the sphere is no longer embedded.

```
    {
            // Calculate our new sphere center at the point of intersection
            if ( eInterval > 0 )
                eNewCenter = eCenter + (eVelocity * eInterval);
            else
                eNewCenter = eCenter - (eIntersectNormal * eInterval);
```

At this point we now have the new eSpace position of the sphere. Of course, we have many triangles to test, so we may find closer intersections and overwrite the new sphere center position with an even closer one in future iterations of the loop.

As discussed, the intersection information will be returned from this function using the Intersections array that was passed in. At first the IntersectCount value will be zero and we will store this new intersection information at the start of the array. If we find that our new intersection *t* value is smaller than the information we currently have stored in the Intersections array, we will overwrite it with the new information. Remember, all we wish to return in the Intersections array is the closest collision. If intersection happens simultaneously with multiple triangles, this will require us to store the information for each of these collisions in its own CollIntersect structure.

If we do find an intersection which element in the array should we store it in? We first test to see if IntersectionCount equals zero. If it does, then this is the first intersection we have found and therefore, we will store this information at index zero in the Intersections array. If the interval is smaller than the interval currently stored in the first element in the array, it means that our new one is closer and we should discard all the others and add this new one in their place. To do this we simply say that if the new intersection interval is smaller than the intervals currently stored in the intersection array, set the index to 0 so that it overwrites the first element in the array. Then set the number of intersections to 1 so all older information (that may still be stored in elements 2, 3, and 4, etc.) are ignored.

```
            // Where in the array should it go?
            AddToList = false;
            if ( IntersectionCount == 0 || eInterval < Intersections[0].Interval )
            {
                // We either have nothing in the array yet,
                // or the new intersection is closer to us
                AddToList         = true;
                NewIndex          = 0;
                IntersectionCount = 1;
            } // End if overwrite existing intersections
```

The else code block associated with the conditional above is executed only if the new interval returned for this latest intersection matches (with tolerance) the interval values currently stored in the intersection array. Essentially we are saying that if our intersection interval is the same as the intervals we currently have stored in our intersection array, then we have found another collision that happens at the exact same time as those already in the list. Thus, the size of the array should be increased and the new data added to the end.

```
            else if ( fabsf( eInterval - Intersections[0].Interval ) < 1e-5f )
            {
```

```
                // It has the same interval as those in our list already, append to
                // the end unless we've already reached our limit
                if ( IntersectionCount < m_nMaxIntersections )
                {
                    AddToList         = true;
                    NewIndex          = IntersectionCount;
                    IntersectionCount++;

                } // End if we have room to store more

            } // End if the same interval
```

Studying the two code blocks above you should be able to see that if the intersect array contained 10 CollIntersect structures describing collisions that happen at time $t = 0.25$, as soon as a intersection happens with a t value of 0.15 (for example), the structure at the head of the array would have its data overwritten and the array would be snapped back to an effective size of 1 element.

Provided one of the above cases was true, the local AddToList Boolean will be set to true. Checking that this is the case, we then finally add the collision data to the intersection array. NewIndex was calculated in the above code blocks and describes whether we are adding the data to the back of the array, or whether we are overwriting the head of the array.

```
            // Add to the list?
            if ( AddToList )
            {
                Intersections[ NewIndex ].Interval  = eInterval;
                Intersections[ NewIndex ].NewCenter = eNewCenter +
                                                      (eIntersectNormal * 1e-3f);
                Intersections[ NewIndex ].IntersectPoint = eNewCenter –
                                                           eIntersectNormal;
                Intersections[ NewIndex ].IntersectNormal = eIntersectNormal;
                Intersections[ NewIndex ].TriangleIndex = Counter;

            } // End if we are inserting in our list

        } // End if collided

    } // Next Triangle

    // Return hit.
    return (IntersectionCount > 0);
}
```

We do this for every triangle and finally return true or false depending on whether at least one intersection was found (i.e., IntersectionCount > 0).

Notice in the above code how interval, the collision normal (eIntersectNormal) and the triangle index (Counter) are copied straight into the relative fields of the CollIntersect structure. Also note how the new non-intersecting position of the center of the sphere (moved as far along the velocity vector as possible) is slightly pushed back from the plane by a distance of 0.0001. This is something we added to provide a little more stability when working in the world of floating point inaccuracies. Although we know that our intersection functions have correctly determined an interval value that was used to create the new

position of the center of the ellipsoid, it is positioned such that its surface is just contacting the triangle. We do not want floating point rounding errors to turn this into an embedded situation, so we slightly shift the sphere away from the triangle by a very small amount to give us a little bit of space between the surface and the ellipsoid.

Finally, notice that we return the intersection position (in eSpace). If you refer back to our discussion about how the slide plane normal is generated, you will see that moving the new sphere position along the slide plane normal (which is unit length and also equal to the radius of the unit sphere) will provide us with the intersection point in eSpace on the surface of the unit sphere. Although our particular response implementation may not require all of this data, it seemed better to provide as much information about the collision as we can and let the caller choose what they need to accomplish their specific objectives.

Believe it or not, at this point, we have now finished our core collision detection and response system implementation discussion. Moving forward, we now have a robust way to collide and slide our entities as they intersect with static scene geometry. This will certainly make our demos feel much more 'game-like' than before.

12.11 Final Notes on Basic Detection/Response

We have obviously discussed a good deal of code in this textbook, but we have tried to keep that discussion as tied into the theory and the mathematics as possible. Utility functions that add polygons to the collision system's database and such minor players have not been covered here. These will fall into the domain of the chapter workbook and as such, a more complete description of the source code can be found there.

We have now learned how to implement a collision detection and response system that works nicely with moving entities and static scene geometry. However, some of you may have crossed referenced the code shown in this chapter with the code in Lab Project 12.1 and encountered some differences. For example, while the core intersection routines are the same, the CollideEllipsoid function and the EllipsoidIntersectScene functions probably look a bit more complicated in Lab Project 12.1. Of course, there is a perfectly good reason for this -- in Lab Project 12.1, we have implemented a more fully featured system that supports terrains, actors, and even referenced actors. In other words, the collision system supports animated frame hierarchies. This means that we could register an actor with the collision system where that actor has moving doors, lifts, and conveyor belts that are updated every time the actor's AdvanceTime function is called. Our collision system will track the movement of these dynamic objects and make sure that the entity that is having its position updated correctly intersects and responds to this dynamic geometry. For example, if the player stands on an animated lift platform, when the lift moves upwards, the player's ellipsoid should also be pushed upwards with it. Doors that swing or slide open should correctly knock the player back, and so on.

This is quite a complex system and its code could not possibly be tackled until the foundation of a more simplistic collision detection and response phase was put into place. Therefore, the majority of this chapter has been focused on presenting a system that deals only with static geometry. That is, once the

mesh/actor/terrain/etc. triangles are registered with the collision system's database in world space, that is how they will remain. This works perfectly for many situations and definitely has allowed us to come to grips with implementing a 'collide and slide' system.

Now the time has come to take the next step along this road and look to include support for dynamic collision geometry. All of the work we have done so far has not been in vain; supporting dynamic objects will involve adding features to the code we currently have, not replacing it. Our discussions of adding dynamic object management to our collision system will be from a relatively high level here in the textbook and we will save the detailed source code examination for the workbook.

12.12 Dynamic Collision Geometry

Our collision system currently stores its geometry using two dynamic arrays. Every single triangle added to the system will have its vertices stored in the CCollision::m_CollVertices array and its triangle information (indices, normal, etc.) stored in the CCollision::m_CollTriangles array. As we have seen, it is these two arrays that contain all the geometry that we wish to be considered as collidable with respect to our moving objects. We will see in the workbook that when we add a mesh to the collision system, all its vertices and indices will be added to these arrays.

We can add an entire CActor to the collision system also. The CCollision::AddActor function is passed an actor and will automatically traverse the frame hierarchy looking for mesh containers. For each mesh container it finds, it will grab its vertices and indices and add them to these two arrays. This single function could be used to register your entire scene with a single function call were it all to be stored in a single frame hierarchy loaded into a CActor object. We even have functions to register our CTerrain objects with the collision database.

All of these functions are simple helper functions that will take the passed object (CActor, CTerrain, etc.) and collect its polygons, transform them into world space, and add them to the two collision geometry arrays. This means we can integrate our collision system into our games with only a few simple calls to such registration functions. Once we have done this for each object we wish to register, our CCollision geometry database (m_CollVertices and m_CollTriangles) will contain every triangle we need to test against whenever a moving entity is updated. As we have seen, it is these two arrays that are looped through in the EllipsoidIntersectScene function. One at a time, each triangle is fed into the SphereIntersectTriangle function to determine if a collision occurred.

So far, so good. But the collision database currently has no capability to manage dynamic scene objects. Earlier in the course we spent a good deal of time covering the D3DX animation system and our CActor class fully supports it. If we register an actor with our collision system and that actor contains animation data, if we use its animation functions after we have registered the actor with the current collision database, we will be in for some real trouble. After all, as we just mentioned, those triangles are going to be converted to world space during collision registration and remain static.

Consider a scene that models the interior of a building. Animations might be triggered that make doors open and close, lifts go up and down, etc. As soon as an animation is played that moves the position of

any of these meshes, the triangle data that the collision system has in its static arrays will be out of date and will no longer represent what the scene actually looks like to the player. Keep in mind that our collision and render geometry are separate things. So a door that opens for example, would visually appear to present a new path for the player to explore, but if it was registered with the collision system in an initially closed state, it would remain so and prevent the player from crossing the threshold (and vice versa if the door was registered in an open state).

Clearly, we need some way of letting the collision system know that some of its geometry is dynamic. As such, a new mechanism will have to be added to our collision system for such objects. Processing dynamic scene objects will place an even greater burden on our CPU (more so than testing collisions against our static geometry arrays), so we should only use the dynamic object system for meshes or hierarchies that we intend to animate. Geometry that will never change should still be added to the collision system as before for storage in the static arrays. What we will add is a secondary sub-system that will maintain a list of dynamic objects which the collision system needs to be kept informed about. This way it can track positional and/or rotational changes.

After reading this section, you should go straight to the workbook where we will finally implement everything we have discussed. This section of the textbook will focus primarily on the type of system design we need to think about and also discuss how to sweep a sphere against moving scene objects.

12.12.1 Sweeping a Sphere against Dynamic Objects

A dynamic object's data structure will contain the model space vertex and index data and a pointer to the object's world matrix. Because this is a matrix pointer, the collision system will always have access to the current object matrix, even when its contents are modified from outside the collision system by the application.

Our EllipsoidIntersectScene function must additionally perform the sphere/triangle tests against the geometry of each dynamic object. Nothing much has changed with respect to our intentions in the detection step -- we are still searching for the closest intersecting triangle. Whether that triangle exists in the static triangle array or in the triangle array of the one of the dynamic objects is for the most part irrelevant. What is quite different however is how we sweep the sphere against the dynamic objects. We can no longer just sweep the sphere as we did previously since the dynamic object is theoretically moving as well.

It would seem that we have to sweep the sphere along its velocity vector and the dynamic object along its velocity vector and then determine the intersection of the two swept volumes. Indeed that is one possible approach, but it is made complicated by the fact that the shape of the dynamic object might be something as simple as a cube or as complex as an automobile mesh. We know that we can sweep a sphere/ellipsoid easily (which is why it was used to bound our moving entity), but we hesitate to use crude approximations like this when sweeping the dynamic scene objects since we are after exact triangle intersections, not just the intersections of two swept bounding volumes.

Our system will take a different view of the problem. In fact, we will not have to sweep the dynamic scene object at all. What we will do is cheat a little bit by taking its movement into account and extending the swept sphere to compensate. That is, for each dynamic object we will maintain its current world matrix and its previous world matrix. Every time the application updates the position or orientation of a registered dynamic object, it will inform the collision system and the system will copy the currently stored matrix into the previous matrix variable. These two matrices will tell the collision system where the object is now and where it was in the previous collision update. By inverting the previous matrix and multiplying it with the current matrix we essentially end up with a relative movement matrix (we call this a *velocity matrix* in our system). This matrix describes just the change in position and orientation from the previous collision update to the current one for the dynamic object. We can use this information to grow the size of our swept sphere so that it compensates for how much the dynamic object has moved since the previous update. Since we have grown our sphere by the amount the object has moved from its previous position, we can now sweep it against the triangles of the dynamic scene object in its previous position. This once again reduces our intersection testing to a simple sphere/triangle test for each triangle in the dynamic object, and we already have functions written to do that.

Let us have a look at some diagrams to clarify this point. In Figure 12.40 we see our sphere about to be moved along its velocity vector. As we know, our collision system will use this information to create a swept sphere which can then be intersected against each of the triangles in the scene database. In Figure 12.40, we also see a blue cube, which we will assume is a dynamic object, which is currently stationary.

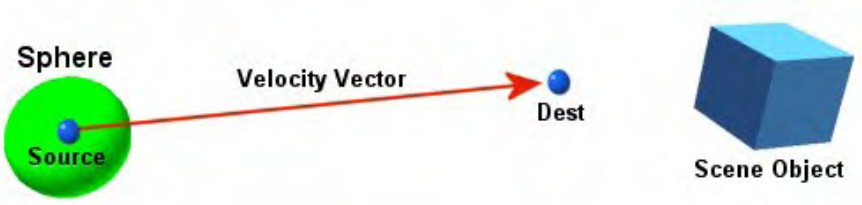

Figure 12.40

When this is the case, our job is no different then detecting collisions between our swept sphere and any other object that has been added to the static geometry database.

We know that if the dynamic object is not currently being treated as dynamic, then we can just use the SphereIntersectTriangle function to sweep the sphere against each triangle in its triangle array. Remember, each dynamic object will store its own array of triangles and vertices and therefore, even when not currently in motion, our collision system will have to loop through each dynamic object and test its triangles against the swept sphere. This is in addition to the triangle tests performed on the static geometry array. At the end of the day, we are just trying to find the closest intersecting triangle so that we can adjust the sphere's position so that it only moves along the velocity vector up to the time the sphere is in contact with the surface. This position and the corresponding slide plane normal are then returned back to the collision response phase.

In Figure 12.41, the sphere will not intersect the cube while moving along its current velocity vector. We know that in this case, the final position returned to the application for the

Figure 12.41

ellipsoid will be the original one that was requested (Sphere Center + Velocity Vector). This is shown as Dest in Figure 12.40.

Complications arise as soon as we start moving these dynamic objects around in our application. As discussed, each dynamic object will also maintain a pointer to the matrix that the application is using to position it in world space. This means our collision system always has access to the current position of any of its dynamic objects. Figure 12.42 depicts the problem we need to solve when the dynamic object is moving. In this example, the position the sphere wants to move to bypasses the position the dynamic object wants to move to. As such, a head on collision would occur somewhere along their respective paths.

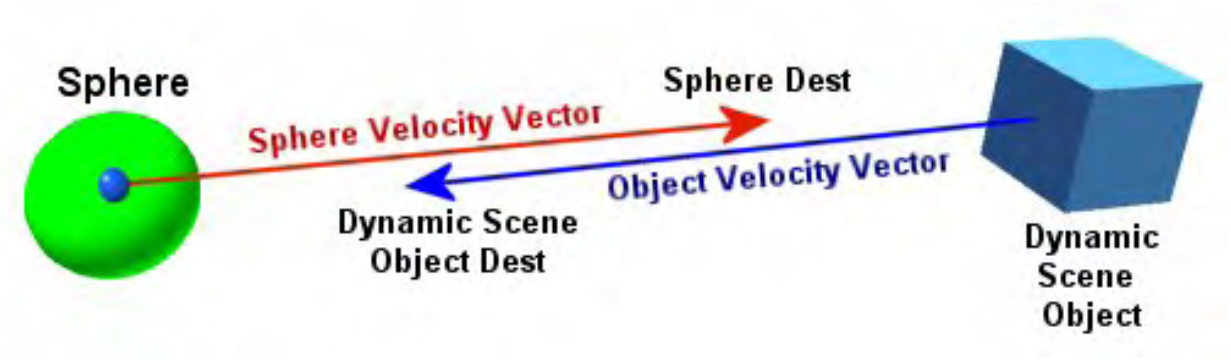

Figure 12.42

We can see clearly that there is a section of overlap between the two projected movement paths and a collision is definitely going to happen. The question is, what should our response be? Should the sphere and the cube stop at the point of intersection? Should they both bounce backwards as a result of impact?

With some caveats, in our implementation, we have decided to provide the dynamic scene objects with movement precedence. Since our collision system only has control over positioning the sphere, it was simplest just to give the dynamic scene object total right of way. However, this does not mean a user cannot implement complex responses, like allowing for various principles of physics to come into play. Our system does have a pointer to the object's world matrix and as such, it could overwrite the values in that matrix with anything it pleases. Of course, while this is certainly true, we would have to proceed very carefully.

Imagine for example a situation where we have registered an actor as a dynamic object with our collision system. The CCollision::AddActor function will have a Boolean parameter used to indicate whether we would like the meshes in the actor's frame hierarchy to be added to the collision system's static database or whether we would like to add each mesh in the hierarchy as a dynamic object. Obviously, if we intend to play animations on our actor, we will want it registered as set of dynamic objects (assuming multiple meshes). Now imagine that our cube in Figure 12.42 was one of many dynamic objects that were created from that single actor. The matrix pointer that the collision detection system stored would point directly at the combined frame matrix for the mesh. When an animation is played, since those animations are pre-recorded, we cannot simply move the cube backwards when an impact occurs. Even if our collision system were to alter the matrix of the dynamic object, the values it placed in there would be overwritten in the next frame update when the application advanced the animation time and the absolute frame matrices were all rebuilt. Therefore, only for a split second would

these matrices, stored external to the collision system, contain the values placed in them by the collision system. As you can see, at least in this type of situation, we are going to have to forget about updating the matrices of the dynamic objects and update the position of the sphere instead.

This is not necessarily such a bad thing. Usually we want the animations that were recorded to play out the same way regardless of where the player may be. For example, we might load a scene which has animations that control large pieces of machinery in some part of the level. If the player was to walk into a swinging piece of the machinery, they should probably be knocked out of the way, leaving the machinery to carry out its animation unimpeded. This is also generally true when dealing with lifts. When the player is standing on the lift and animation is played which raises the lift up, we are relying on this behavior to make sure that the lift always moves the player up and does not bounce off the feet of the player when the two collide. Therefore, when the sphere collides with a moving object, we will move the sphere back so that its new position is simply contacting the object. It might even be the case that the new center position of the sphere is actually behind its original starting position if the sphere has been pushed backwards by a moving scene object (given some amount of force that might be applied).

To be fair, this approach is not always going to be the ideal way to handle every single scenario you and your design team might come up with. For very heavy objects like the machinery we just mentioned, this probably works well enough, but for objects with little mass or momentum, you might decide to go ahead and actually work out a way to modify the animation on the fly or take some other action. For example, you might decide to add a mechanism to the system which allows you to pass in a callback function at registration time. That callback could be triggered by the system when an object collides with the dynamic object. The callback might be passed information about the colliders such as their masses, linear and angular velocities, etc. You could then make some decisions based on the relative physical differences between the two colliders. If the dynamic object was a ceiling fan for example, you might decide to immediately stop the pre-recorded animation and take no action on the moving entity. Different situations will require different responses, but you get the idea. In our case, we will simply allow the dynamic objects to proceed with their animations and limit our response results to the moving entity only. This will make things much easier to implement and understand in the short tem.

Figure 12.43 illustrates this concept using the previous example. In Figure 12.42 we saw how the sphere and the cube wanted to move along paths that would cause a collision. In Figure 12.43 we see the result of such an impact. The cube is allowed to move from its previous position into its new position and the sphere is moved back so that it is now resting against the new position of the cube.

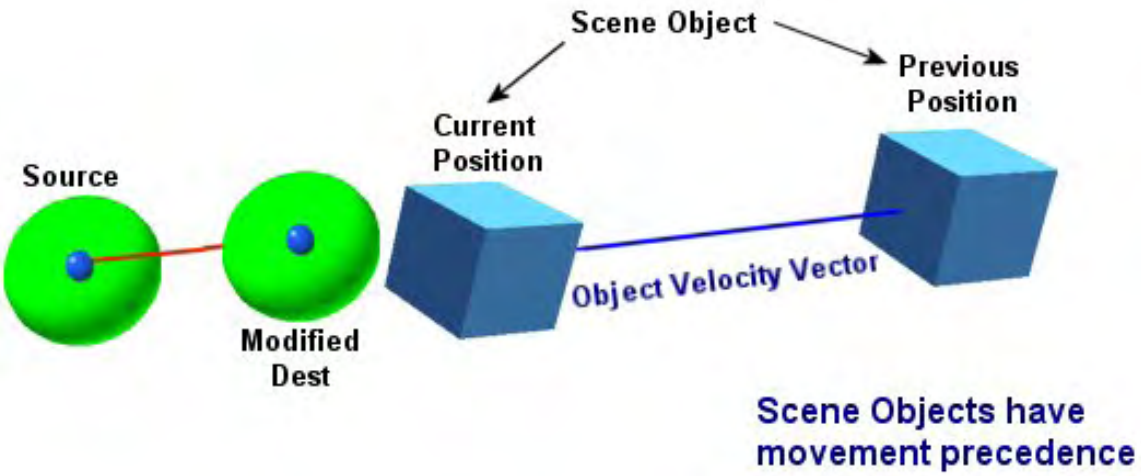

Figure 12.43

So we know how we want our ellipsoid to intersect with moving objects. But how do we find the final position for the sphere in the above situation? As discussed, the cube will have its matrix updated by the application. So what we have is the new cube position and the velocity we wish to move along. Now, you might assume that all we have to do it sweep the sphere against the cube in its current position. This would certainly seem to work in the above diagram and it would also mean that the test is once again reduced to a static test between the swept sphere and the triangles of the cube in its new position. However, imagine a situation where the cube was moving so fast, that while its start position was in front of the swept sphere (as in Figure 12.43), its final position is actually behind the swept sphere. In other words, with a single matrix update, the dynamic object has leapt from one side of the swept sphere to the other. Neither the previous or current positions of the cube intersect the swept volume, so our collision system would determine that the sphere could move to its desired location. The problem is that between these two frame updates, the cube has just passed straight through our sphere with no ill effect. So what should have happened instead? The sphere should have been knocked backwards by the moving cube (via some amount of applied force).

We discussed previously that a dynamic object will contain a pointer to its current application controlled matrix and we will cache its previous matrix as well. When we add a dynamic object to our collision system, a new DynamicObject structure will be allocated to contain this information along with some other data. If an actor is registered with the collision system, a DynamicObject structure will be created for every mesh in its hierarchy. Our DynamicObject structure will look like this:

Excerpt from CCollision.h

```
struct DynamicObject
{
    CollTriVector   *pCollTriangles;
    CollVertVector  *pCollVertices;
    D3DXMATRIX      *pCurrentMatrix;
    D3DXMATRIX       LastMatrix;
    D3DXMATRIX       VelocityMatrix;
    D3DXMATRIX       CollisionMatrix;
    long             ObjectSetIndex;
    bool             IsReference;
};
```

CollTriVector *pCollTriangles

This is a pointer to an STL vector of CollTriangle structures. This vector contains one entry for each triangle in the mesh of the dynamic object. A CollTriangle contains the indices into the pCollVertices vector and the triangle normal.

CollVertVector *pCollVertices

This is a pointer to an STL vector of D3DXVECTOR3 structures. This vector will contain all of the *model space* vertex positions for the dynamic object's mesh.

D3DXMATRIX *pCurrentMatrix

When a dynamic object is added to the collision system via the CCollision::AddDynamicObject method, we must also pass in the address of the dynamic object's world matrix. This matrix will be owned and altered by the application. A pointer to this matrix is stored in the pCurrentMatrix member so that the collision system can always have immediate access to the matrix and any changes the application may have made to it. Our collision system will never write any values to this matrix; it will instead use it only to copy the values from this matrix into the dynamic object's LastMatrix member when the collision system is notified that the matrix has changed. If the dynamic object is part of a frame hierarchy, this member will point to the associated frame's combined matrix.

D3DXMATRIX LastMatrix

Every time the application alters the position of an object, it has to inform the collision system that the object has been updated and its matrices need recalculating inside the collision system. This is done via the CCollision::ObjectSetUpdated method. The pCurrentMatrix pointer will always point to the matrix of the object with the updated values, so we will use this matrix to copy the values into the LastMatrix member. Thus, the LastMatrix member will always contain the current world matrix of the object during collision tests.

D3DXMATRIX CollisionMatrix

When the ObjectSetUpdated function is called, the matrix that was previously the current position/orientation of the object is stored in LastMatrix. This is now about to be overwritten by the new values in the matrix pointed to by the pCurrentMatrix pointer. Before we do that, we copy the previous matrix into the CollisionMatrix member so that at the end of the update, LastMatrix contains the new current position of the object and CollisionMatrix holds the previous position of the object. The reason it is called the collision matrix and not something like 'PreviousMatrix' is something that will become clear shortly.

D3DXMATRIX VelocityMatrix

The velocity matrix is calculated for the dynamic object every time its position is updated by the application and the ObjectSetUpdated function is called. We need this matrix to describe the direction and magnitude the object has travelled from its previous position since the last collision frame update. That is to say, this matrix will describe the current position/orientation of the object relative to the previous position/orientation currently stored in Collision Matrix. How do we calculate it? We take the previous object world matrix and invert it. We then multiply this with the current object world matrix. Because we inverted the previous world matrix prior to the multiply, this has the effect of subtracting the position and orientation stored in the previous matrix from the position and orientation stored in the current matrix. The result is our velocity matrix which describes the new position and orientation of the

object relative to its previous one. You will see in a moment how we will use this matrix to stretch the swept sphere to compensate for the movement of the dynamic object from its previous position. This will then allow us to sweep this extended sphere against the triangles of the dynamic object in their previous positions (described in CollisionMatrix) using the usual static sphere/triangle intersection code we developed for our static scene geometry tests.

long ObjectSetIndex

Every time a dynamic object is registered with the collision system it will return an ObjectSetIndex. This is just a numeric value that uniquely identifies this object to the system. You can think of it as a way for the application to tell the collision system which object had its matrix updated. When adding a single dynamic object to the system, the dynamic object will be added to the collision system's dynamic object array and its internal dynamic object counter incremented. This will be returned as the object set index for the newly added object. The application should store this away so that it can always identify which object needs to be updated in the collision system. What we do in Lab Project 12.1 is add this as a new member in our CObject structure, which we have been using in one shape or form since the beginning of this course series. The updated CObject structure is shown below.

```
class CObject
{
public:
                CObject( CTriMesh * pMesh  );
                CObject( CActor   * pActor );
                CObject( );
    virtual     ~CObject( );

    D3DXMATRIX                m_mtxWorld;
    CTriMesh                 *m_pMesh;
    CActor                   *m_pActor;
    LPD3DXANIMATIONCONTROLLER m_pAnimController;
    long                      m_nObjectSetIndex;
};
```

Notice that even if the object contains an actor comprised of many meshes, only one object set ID is assigned by the collision system for all the meshes contain within. This is by design. When an actor is registered with the collision system, every mesh in the hierarchy will have a dynamic object created for it and added to the collision system's dynamic object database. However, every object created from the hierarchy will also be assigned the same object set index. This ID is used to identify a set of objects that have some relationship. To see why this is necessary, imagine the situation where you have registered an actor containing 50 meshes with the collision system. Then imagine that the application moves the entire actor to a new position in the world. When the actor's hierarchy is updated, all the absolute matrices in the hierarchy will be rebuilt to describe new world space positions of all 50 meshes contained within. The 50 dynamic objects in the collision database that we created from that hierarchy have just all had their current matrices changed. Because we have assigned every dynamic object in that hierarchy the same ID, we can call the ObjectSetUpdated function, passing in the actor's ID, and it will re-cache the matrices for every dynamic object with a matching ID (i.e., the 50 dynamic objects that were originally created from the hierarchy we just updated). Thus the object set ID does not just describe the unique ID of a single dynamic object, it can also represent a family of dynamic objects that will always need to be updated together.

bool IsReference

The final member of the DynamicObject structure is a boolean that indicates whether or not this dynamic object should be a reference. Referencing will be discussed in the workbook, but essentially this just provides a way for multiple dynamic objects to share the same triangle and vertex data.

We have now covered all the members of the DynamicObject structure. To understand the collision system, we first should understand how the application informs the collision system that a dynamic object has been updated. We will assume at this point that the objects have already been registered with the collision system and have been assigned object set index numbers. The registration functions are fairly simple and as such will be covered in the workbook. All we are interested in discussing here is how the dynamic system is going to work from a high level.

The CScene::AnimateObjects function is another familiar method. It is called from CGameApp::FrameAdvance function to give the scene class a chance to update the positions of any objects it wishes to animate. Since learning about animation, we have always used this function to advance the timer of each actor being used by the scene. Below we see the first part of the function from Lab Project 12.1. There is nothing new in this first section; it loops though each CObject and tests to see if an actor lives there. If not, then there is nothing to animate so it continues to the next iteration of the loop. If an actor does live there, then it attaches the CObject's animation controller to the actor.

Excerpt from CScene.h

```
void CScene::AnimateObjects( CTimer & Timer )
{
    ULONG i;

    // Process each object for coll det
    for ( i = 0; i < m_nObjectCount; ++i )
    {
        CObject * pObject = m_pObject[i];
        if ( !pObject ) continue;

        // Get the actor pointer
        CActor * pActor = pObject->m_pActor;
        if ( !pActor ) continue;

        // If we are instancing, make sure that the cloned controller
        // is re-attached (no need to resynchronize the animation outputs
        // as we're about to call 'AdvanceTime'.)
        if ( pObject->m_pAnimController )
             pActor->AttachController( pObject->m_pAnimController, false );

        // Advance time
        pActor->AdvanceTime( Timer.GetTimeElapsed(), false );
```

The next section is new.

If the object has a value in the m_nObjectSetIndex member of -1, then it means this object has not been registered with the collision system and we can simply continue on to process the next object. If this is not the case and we have a valid collision ID stored in m_nObjectSetIndex, then we know that the actor we are animating is also a dynamic object in the collision system and the system needs to be informed of

the changes we have made to its position/orientation. We first set the actor world matrix so that all its absolute frame matrices get built, and then we call the CCollision::ObjectSetUpdated to inform the collision system about the event. The collision system can then grab the current state of the matrices for each dynamic object created from this hierarchy and calculate the collision and velocity matrices.

```
        // If the object has a collision object set index,
        // update the collision system.
        if ( pObject->m_nObjectSetIndex > -1 )
        {
            // Set world matrix and update combined frame matrices.
            pActor->SetWorldMatrix( &pObject->m_mtxWorld, true );

            // Notify the collision system that this set of dynamic objects
            // positions, orientations or scale have been updated.
            m_Collision.ObjectSetUpdated( pObject->m_nObjectSetIndex );

        } // End if actor exists

    } // Next Object

}
```

Let us now take a look at the CCollision::ObjectSetUpdated function. Although we do yet understand how the collision detection is performed, looking at this function will show us how the collision matrix and velocity matrix are created every time the object is updated. It is important that we understand this process since these two matrices will be used by our EllipsoidIntersectScene function when sweeping the sphere against the triangles of dynamic objects.

This function is very small and it has a simple task to perform. It is passed an object set index which it will use to locate dynamic objects in the collision database that share the same ID. If you look in CCollision.h you will see that the CCollision class stores its dynamic object structures in an STL vector.

```
typedef std::vector<DynamicObject*> DynamicObjectVector;
DynamicObjectVector m_DynamicObjects;
```

As you can see, the member variable m_DynamicObjects is an STL vector that stores DynamicObject structures. Let us now have a look at the function itself.

Excerpt from CCollision.cpp

```
void CCollision::ObjectSetUpdated( long Index )
{
    D3DXMATRIX mtxInv;

    // Update dynamic object matrices
    DynamicObjectVector::iterator ObjIterator = m_DynamicObjects.begin();
    for ( ; ObjIterator != m_DynamicObjects.end(); ++ObjIterator )
    {
        DynamicObject * pObject = *ObjIterator;

        // Skip if this doesn't belong to the requested set.
        if ( pObject->ObjectSetIndex != Index ) continue;
```

In this first section of code we create an iterator to allow us to loop through and fetch each DynamicObject structure from the STL vector. We store a pointer to the dynamic object in the pObject local variable for each of access. We then check to see of this object's ObjectSetIndex is the same as the index passed into the function. If it is not, then it means the current object does not belong to the family of objects we are updating, so we continue on to test the rest of the list.

This next section of code is only executed if we have determined that the index of the current object matches the index passed in by the application. If this is the case, then the application has updated the matrix of the dynamic object and we need to do some matrix recalculation inside the collision system.

The first thing we do is access the matrix that is currently stored in the dynamic object's LastMatrix member. This matrix describes the world matrix of the object before the application recently updated it. Inverting it gives us a matrix that essentially subtracts this transformation from any matrix. Thus, if we multiply it with the dynamic object's current matrix, we essentially subtract the old position and orientation from the new one to leave us with a matrix that describes only the relative motion that has taken place since the last update. Remember, pCurrentMatrix is a pointer to the object's actual matrix and we have immediate access to it. We store the relative movement result in the VelocityMatrix member.

```
        // Generate the inverse of the previous frame's matrix
        D3DXMatrixInverse( &mtxInv, NULL, &pObject->LastMatrix );

        // 'Subtract' the last matrix from the current to give us the difference
        D3DXMatrixMultiply( &pObject->VelocityMatrix, &mtxInv,
                            pObject->pCurrentMatrix );
```

Next we copy over the previous matrix of the object from the LastMatrix member into the Collision Matrix member before we update the LastMatrix member with the new current position of the object. We now have everything we need. We have the velocity matrix calculated and the previous world matrix stored in CollisionMatrix which describes the world space position of the object that we will collide against. Further, we have updated LastMatrix with the current matrix so that this whole pattern can repeat again the next time UpdateObjectSet is called.

```
        // Store the collision space matrix
        pObject->CollisionMatrix = pObject->LastMatrix;

        // Update last matrix
        pObject->LastMatrix = *pObject->pCurrentMatrix;

    } // Next Object
}
```

Once again, please do not concern yourself at the moment with how the dynamic objects are created and how the scene registers the dynamic objects with the collision database. This is all pretty routine code which will be discussed in detail in the workbook. For now, all you need to know is that when our application calls the CollideEllipsoid method to move an object about the game world, the collision system will have a velocity matrix describing its movement from its previous position, and a matrix that describes this previous position (CollisionMatrix). This will be stored for every dynamic object.

In the EllipsoidIntersectScene function we now know that in addition to testing the swept sphere against the static scene database, we also have to test for collisions against the triangles of each dynamic object. We have at our disposal the previous transform state of each dynamic object (CollisionMatrix) and the velocity matrix that describes how much that state has changed since the last collision test. We now have to use this information to determine if the dynamic object intersected the swept sphere during its state change. If so, the position of the sphere will need to be adjusted to account for this collision.

Take a look at Figure 12.44. Source and Dest represent the amount the user wishes to move the ellipsoid (in eSpace). The red arrow represents the velocity vector for the ellipsoid (in eSpace) describing the distance and direction we wish to travel. Before testing each triangle of a dynamic object for collision, we will first transform it by the collision matrix so that the triangle is placed in the world at its previous position. Since this is a per-triangle process, we will describe it with respect to a single triangle for now.

The solid green line illustrates the current triangle to be tested from the dynamic object. It is transformed into its previous position. The green dashed line shows where the triangle is in its current position. The blue arrow shows the distance the triangle has moved since the last collision test. Since we know that our triangle intersection routines will inflate the triangle by the radius of the sphere, we know the swept sphere can now be treated as a ray. This is the red line in Figure 12.44. Although the ray does not intersect the triangle in its previous position, it certainly does in its current position. We need to extend the ray such that it compensates for the movement of the triangle from its previous position to the current position. If we do this, we can simply test the ray against the triangle in its previous position. Once we have the intersection point, we can then shift it back by the distance the triangle has moved. This will give us the final intersection point (Modified Dest) along the ray such that the sphere is now resting against the polygon in its current position. More importantly, it will also catch the awkward case where the movement of the triangle was so large between frames, that it is completely bypassed by the ray. That is, we will develop a method that will always reliably catch the situation when the moving object intersects the sphere (even if the sphere is not moving).

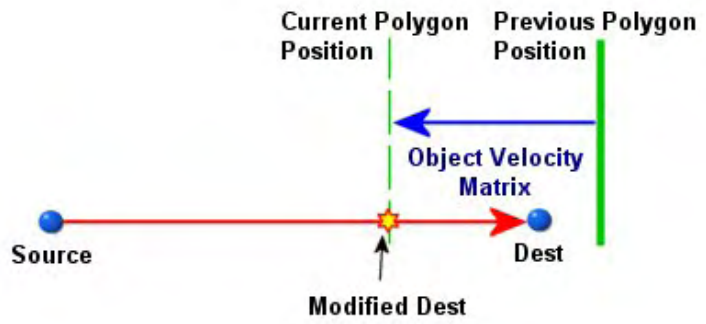

Figure 12.44

The process we are about to discuss will be used to alter the swept sphere's velocity vector for a given dynamic object. Once we have discussed these intricacies, we will then examine the complete modified EllipsoidIntersectScene function with dynamic object support.

As the EllipsoidIntersectScene function is working with eSpace variables, we have to temporarily undo this to calculate the amount of shift we have to apply to the velocity.

```
vecEndPoint = (Vec3VecScale(eCenter, Radius) + Vec3VecScale(eVelocity, Radius));
```

All we are doing here is calculating Dest in the above diagram in world space. By scaling the eSpace sphere center position and the eSpace velocity vector by the radius of the ellipsoid, we scale these back into world space. We then add the world space velocity vector that was input into the function to the world space sphere center position to get the position that our ellipsoid would like to move to in the world (if no collisions block its path). We store this desired destination position in the local variable vecEndPoint. This is the world space position that the application (or the previous response step) would like to move to the ellipsoid to.

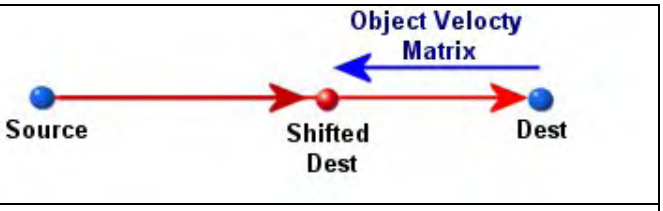

Figure 12.45

Our next step will be to take this world space destination position and transform it by the velocity matrix of the current dynamic object we are testing. In the case of our example shown in Figure 12.44, the velocity matrix describes the movement illustrated by the blue arrow. By transforming the destination position by this matrix we will shift the destination back along the ray. This shifted destination is illustrated in Figure 12.45. Notice how we are ultimately subtracting the movement of the object currently being tested from the end of our ray even though the position of the triangle in its previous location is past the end of the ray. This shifted destination position does not tell us anything quite yet, but bear with us. Below we show the code that shifts the ray end point back along the ray using the objects velocity matrix.

```
// Transform the end point
D3DXVec3TransformCoord( &eAdjust, &vecEndPoint, &pObject->VelocityMatrix );
```

At this point, Shifted Dest in Figure 12.45 is stored in the local variable eAdjust. We will now subtract the original end point of the ray from this shifted dest.

```
// Translate back so we have the difference
eAdjust -= vecEndPoint;
```

What we have a this point is a vector pointing in the opposite direction to the original velocity vector of our sphere whose length is equal to the distance moved by the dynamic object between its previous and current positions. We illustrate this in Figure 12.46. **Source** shows the original start point of the ray (the center of the ellipsoid) and **Shifted Dest** describes the position stored in eAdjust prior to the above line being executed. When we subtract the original ray end position from eAdjust we are subtracting the entire length of the original velocity vector from the shifted ray end point. This gives us an adjustment vector pointing in the opposite direction to the ray. This is shown in Figure 12.46 as the short blue arrow pointing from the ray origin (Source) to the left.

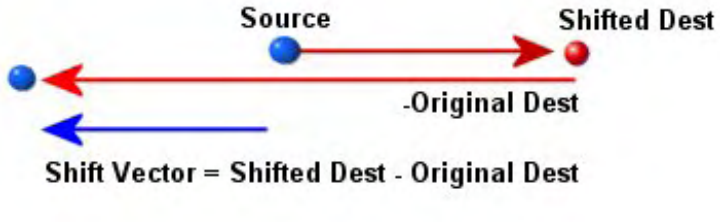

Figure 12.46

The next phase is the trick. We take this adjustment vector, transform it back into eSpace and then subtract it from the original velocity vector. Since the velocity vector and the adjustment vector are facing in opposite directions, subtracting the adjustment vector actually *adds it* to the original velocity vector. This extends the velocity vector of our swept sphere by the distance and direction the object has moved since the last collision test. Although we are illustrating just translational movement here this also works with rotations of the dynamic object.

```
// Scale back into ellipsoid space
eAdjust  = Vec3VecScale( eAdjust, InvRadius );

// Add to velocity
eVelocity-=eAdjust;
```

Figure 12.47 shows what our new velocity vector looks like. As we can see, it does indeed intersect the triangle in its previous position. We have altered the direction and length of velocity vector so that we can extrude it in the direction the object has moved since the last update and perform collision tests in its previous position.

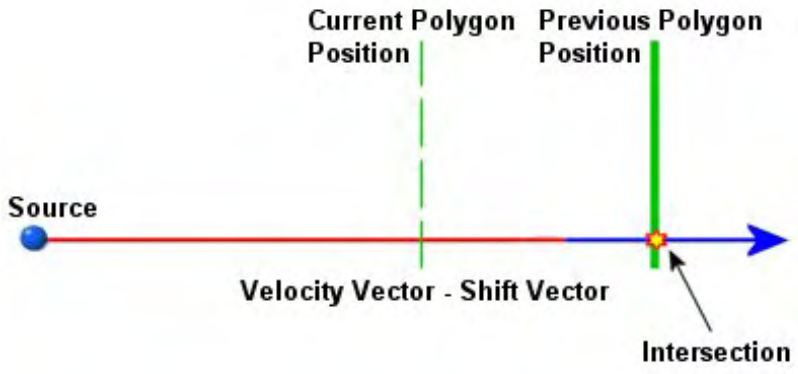

Figure 12.47

Now that we have the modified velocity vector, we can pass it into the SphereIntersectTriangle function for every triangle in the dynamic object. We do this for each dynamic object, searching for the intersection with the smallest interval. Once we have this new center position, what we actually have is the new center position of the unit sphere such that its surface is touching but not penetrating the closest intersecting triangle in the current dynamic object being tested. Of course, this is the position of the sphere resting against the triangle in its previous position and not its current position. All we have to do to correct this is take the resulting sphere center position and subtract from it the adjustment vector we initially added on. Remember, the adjustment vector is facing in the opposite direction from the velocity vector (in this example), so we actually add the adjustment vector to the resulting sphere center position to subtract it back.

```
// Translate back
Intersections[i].NewCenter      += eAdjust;
Intersections[i].IntersectPoint += eAdjust;
```

Above you can see that after we have added the new center position and the actual intersection point on the surface of the sphere to an intersection structure (to send back to the response step), we transform them back along the ray by the adjustment vector. Since this is the distance the triangle has moved from its previous position (the one we tested against), this shifts the sphere center position back so that it is now positioned on the shifted plane of the triangle in its current position instead of on the shifted plane of the triangle in its previous position. This gives us our final sphere center position (Modified Dest in Figure 12.47). As you can see, by calculating the adjustment vector, performing the intersection in the object's previous space, and then subtracting that adjustment vector from the intersection point, we essentially find out how much the sphere has to be moved back out of the way if a collision does occur.

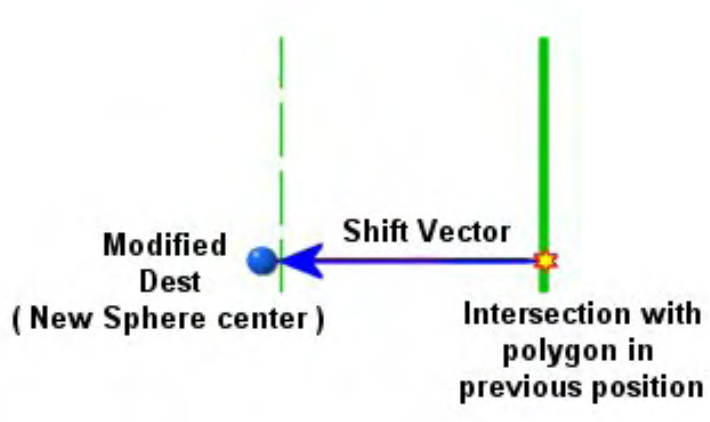

Figure 12.47

Once we have performed these same steps for every dynamic object and have found the closest intersecting triangle (or not), we then move on and test the original swept sphere against the static collision geometry using the methods explained earlier in the chapter. At the end of doing both the dynamic and static geometry tests, we will have a new ellipsoid position that we can return to the response step.

12.12.2 Integrating Dynamic Objects

In this final part of the textbook we will examine the code to the modified collision detection and response phases. The utility functions that add objects to the collision database and the way in which the application intersects with the collision system will all be discussed in the workbook. In this section, we will focus on updating the CollideEllipsoid and EllipsoidIntersectScene functions to handle both dynamic and static objects. Couple this knowledge with the fact that we have already discussed how the ObjectSetUpdated function works, and you should be able to understand everything in the workbook with very little trouble.

The first thing we will do is add a new generic function to our CCollision class that will remove the redundancy that would otherwise creep into the EllipsoidIntersectScene function now that we have many vertex and triangle buffers to process. The vertex and triangle data for each static triangle will all be stored in two STL vectors within the class namespace. These are the arrays that the EllipsoidIntersectScene function will need to extract geometry from when sweeping the sphere against

the static scene geometry. However, each dynamic object will also have its own buffers of triangle and vertex data and each of these will have to be tested too. Therefore, instead of repeating this code in the EllipsoidIntersectScene function, we will write a generic function called EllipsoidIntersectBuffers. This function can then be passed the buffer of information that needs to be processed by the EllipsoidIntersectScene function. For example, we will call this function for each dynamic object in turn, passing in a pointer to its vertex and triangle buffers. The function will loop through each triangle in the buffer and call our SphereIntersectTriangle function. It will return the new position of the sphere based on the closest collision interval. The function can be called once for each dynamic object, each time being passed the vertex and triangle buffers of the dynamic object for testing. All the while it will be keeping track of the closest intersection. Once this function has been called to process the buffer for each dynamic object, it can be called one final time and passed the vertex and triangle buffers containing all the static collision geometry.

The CCollision class has many helper functions to make registering objects with the collision database fast and easy. Below, we will look at just the member variables in the CCollision class so you get a feel for how it all works. Note that all the structures we have discussed so far are defined in the class.

```
class CCollision
{
public:

    //-----------------------------------------------------------------------
    // Public, class specific, Typedefs, structures & enumerators
    //-----------------------------------------------------------------------
    struct CollTriangle
    {
        ULONG       Indices[3];           // Indices referencing the triangle
                                          // vertices from our vertex buffer
        D3DXVECTOR3 Normal;               // The cached triangle normal.
        USHORT      SurfaceMaterial;      // The surface material index
                                          // assigned to this triangle.
    };

    // Vectors (STL Arrays) to contain triangle and vertex collision structures.
    typedef std::vector<CollTriangle>   CollTriVector;
    typedef std::vector<D3DXVECTOR3>    CollVertVector;

    struct DynamicObject
    {
        CollTriVector  *pCollTriangles;   // The triangle data referencing
                                          // the vertices below.
        CollVertVector *pCollVertices;    // The vertices defining
                                          // the level geometry.
        D3DXMATRIX     *pCurrentMatrix;   // A pointer to the actual matrix,
                                          // updated by external sources
        D3DXMATRIX      LastMatrix;       // The matrix recorded on the latest test
        D3DXMATRIX      VelocityMatrix;   // The difference for this frame
                                          // between our two matrices.
        D3DXMATRIX      CollisionMatrix;  // The space in which the collision
                                          // against this object will be performed.
        long            ObjectSetIndex;   // The index of the set of objects
                                          // this belongs to.
        bool            IsReference;      // Is this a reference object?
```

```
    };

    // Vector of a type to contain dynamic objects
    typedef std::vector<DynamicObject*> DynamicObjectVector;

    struct CollIntersect
    {
        D3DXVECTOR3     NewCenter;
        D3DXVECTOR3     IntersectPoint;
        D3DXVECTOR3     IntersectNormal;
        float           Interval;
        ULONG           TriangleIndex;  // The index of the triangle
                                        // we are intersecting
        DynamicObject * pObject;        // If we hit a dynamic object,
                                        // it will be stored here.
    };

private:
    CollTriVector       m_CollTriangles;        // The triangle data referencing
                                                // the vertices below.
    CollVertVector      m_CollVertices;         // The vertices defining
                                                // the level geometry.
    DynamicObjectVector m_DynamicObjects;       // The dynamic object structures.
    USHORT              m_nMaxIntersections;    // The total number of
                                                // intersections we should record
    USHORT              m_nMaxIterations;       // The maximum number of collision
                                                // test iterations we bail
    CollIntersect      *m_pIntersections;       // Internal buffer for storing
                                                // intersection information
    D3DXMATRIX          m_mtxWorldTransform;    // When adding primitives, this
                                                // transform will be applied.
    long                m_nLastObjectSet;       // The last object set index used.
};
```

As you can see, the member variables are declared at the bottom. Let us quickly discuss them.

CollTriVector m_CollTriangles
CollVertVector m_CollVertices

These two STL vectors store the static triangle and vertex data. Every object that is registered with the collision system that is not flagged as a dynamic object will have its triangle and vertex data added to these two vectors. The first of the two shown above is a vector containing CollTriangle structures and the second contains the D3DXVECTOR3 structures. Feeding these two vectors into our EllipsoidIntersectBuffers function (which we will write in a moment) will test the swept sphere against every triangle in the static scene geometry database.

DynamicObjectVector m_DynamicObjects

This is an STL vector that contains DynamicObject structures. Every object that is registered with the collision system as a dynamic object will be added to this vector. Each dynamic object structure contains its own triangle and vertex arrays (STL vectors). When a frame hierarchy (an actor) is registered with the collision system as a dynamic object, a dynamic object structure will be created and added to this vector for every mesh in the frame hierarchy. Each dynamic object added in this way will belong to the same object set and will be assigned the same object set index number.

USHORT m_nMaxIntersections
CollIntersect *m_pIntersections
These two variables control the size of an array of CollIntersect structures that are used temporarily by the detection phase to return information back to the response step about the closest intersecting triangles.

USHORT m_nMaxIterations
This member contains the maximum number of iterations of detection/response we wish to execute before we settle on the closest intersection and forcibly spend the remaining velocity. There are occasions when the ellipsoid could get stuck in a sliding loop chewing up CPU cycles as it bounces between surfaces. When this number of iterations is reached, we admit defeat and settle for pushing the ellipsoid to the closest intersect point.

D3DXMATRIX m_mtxWorldTransform
This matrix will describe a world transform to the collision system that should be used to transform one or more model space static meshes we are registering. The system will use this matrix as it is filling its vertex array with data from that model space mesh. This can be useful when loading referenced mesh from a file for example. You should be mindful to set this back to its default state of identity after you have finished using it since all future objects you register will also be transformed by this same matrix (i.e., it is a system level matrix).

long m_nLastObjectSet
This variable contains the number of the last object set index that was issued to a dynamic object. Every time a new object set is added, this value is incremented and assigned to the object as a means of identification. This does not necessarily describe the number of dynamic objects currently registered with the collision system. It can also apply to groups of dynamic objects that should be updated together.

As you can see, for such a complex system, it really does not have many variables to manage. Let us now see the code that has been modified to facilitate dynamic object integration. Luckily, our core intersection routines are exactly the same. The SphereIntersectTriangle function and all the sub-intersection routines it calls are unchanged. From their point of view, we are still just sweeping the sphere against a triangle, even when dealing with dynamic objects. The functions that have changed are the CollideEllipsoid and the EllipsoidIntersectScene functions. We have added an additional helper function which we will look a first. It is called EllipsoidIntersectBuffers.

12.13 The EllipsoidIntersectBuffers Function

The EllipsoidIntersectBuffers function will handle the intersection determination between a swept sphere and an arbitrary buffer of triangle data. Most of this code will be instantly recognizable as it existed in the previous EllipsoidIntersectScene function that we covered earlier. All we have done is extract the inner workings of that function into a separate function that can be used to sweep the sphere against triangles in the static scene database and the triangle buffers of each dynamic object. This

function will be called by the EllipsoidIntersectScene function, so let us first take a look at its parameter list. Most of these parameters will be familiar to us as they are simply the values that were passed into the EllipsoidIntersectScene function.

```
ULONG CCollision::EllipsoidIntersectBuffers( CollVertVector& VertBuffer,
                                             CollTriVector& TriBuffer,
                                             const D3DXVECTOR3& eCenter,
                                             const D3DXVECTOR3& Radius,
                                             const D3DXVECTOR3& InvRadius,
                                             const D3DXVECTOR3& eVelocity,
                                             float& eInterval,
                                             CollIntersect Intersections[],
                                             ULONG & IntersectionCount,
                                             D3DXMATRIX * pTransform /*= NULL*/ )
```

The first two parameters are new. They allow us to pass in the vertex and triangle buffers (STL vectors) we would like to sweep the sphere against. In our collision system, these parameters will be used either to pass the vertex and triangle buffers of the static scene geometry or the vertex and triangle buffers of a given dynamic object. The eCenter parameter is the current eSpace position of the ellipsoid that is about to be moved. The Radius and InvRadius vectors contain the radii and inverse radii of this ellipsoid. The InvRadius vector will be used to scale the vertex positions of each triangle into eSpace while the Radius vector will be used to scale the normal of each triangle into eSpace (remember the transform into eSpace works the opposite way for direction vectors). We also pass in the eSpace velocity vector describing the direction and distance we would like to move the sphere. We pass by reference the current *t* value of intersection. This will be passed to each of the intersection routines and collisions will only be considered if they have a smaller *t* value than what is currently stored. When the function returns, if a closer intersection was found than the one already stored in this variable, it will be overwritten with the new *t* value for the intersection.

As the eighth and ninth parameters we pass in the CollIntersect array which intersection results will be stored in and an output variable for a count of those items. As we have seen, this is the transport mechanism for returning the information back to the response phase. As discussed earlier, we must be mindful of the fact that this array may already hold intersection information. Recall that as soon as we find a closer intersection, we add this to the first element in the array and reset the counter to 1.

The final parameter is a pointer to a matrix that is used when processing the buffers of dynamic objects. The vertices in a dynamic object's vertex list are in model space, so before this function performs sphere/triangle tests on dynamic object geometry buffers, it must transform the triangle vertices into world space. When this function is called to perform collision testing against the static arrays, this parameter will be set to NULL. For dynamic object intersection testing, we will pass in the object's CollisionMatrix. As previously discussed, this is a world space transformation matrix that will transform the vertices of the dynamic object into their previous state.

Finally, this function will return an integer that describes the index into the intersection array where the intersection structures added by this function begin. For example, if this function was passed a CollIntersect array that contained five elements and another three were added, this function would return 5 to the caller and increment the intersection count to 8 (5 is the index of the first element in the array that was added by this function assuming zero-based offsets). If this function finds an intersection that is

smaller than the interval values of the intersections currently stored in the array, the function will return 0 since the array will be completely overwritten from the beginning with the new closer intersection information.

Let us now have a look at this function a few sections at a time.

The first thing we do is store the current intersection count that was passed in (FirstIndex). This contains the current end of the list and the index where any additional structures will be added by this function, assuming that a closer intersection time is not found. It is the value of FirstIntersect that will be returned from this function. It will be set to zero later in the function if we determine a closer intersection and start building the list from the beginning again.

```
{
    D3DXVECTOR3 ePoints[3], eNormal;
    D3DXVECTOR3 eIntersectNormal, eNewCenter;
    ULONG       Counter, NewIndex, FirstIndex;
    bool        AddToList;

    // FirstIndex tracks the first item to be added the intersection list.
    FirstIndex = IntersectionCount;

    // Iterate through our triangle database
    CollTriVector::iterator Iterator = TriBuffer.begin();
    for ( Counter = 0; Iterator != TriBuffer.end(); ++Iterator, ++Counter )
    {
        // Get the triangle descriptor
        CollTriangle * pTriangle = &(*Iterator);
        if ( !pTriangle ) continue;

        // Requires transformation?
        if ( pTransform )
        {
            // Get transformed points
            D3DXVec3TransformCoord(&ePoints[0], &VertBuffer[pTriangle->Indices[0]],
                                   pTransform );
            D3DXVec3TransformCoord(&ePoints[1], &VertBuffer[pTriangle->Indices[1]],
                                   pTransform );
            D3DXVec3TransformCoord(&ePoints[2], &VertBuffer[pTriangle->Indices[2]],
                                   pTransform );

            // Get points and transform into ellipsoid space
            ePoints[0] = Vec3VecScale( ePoints[0], InvRadius );
            ePoints[1] = Vec3VecScale( ePoints[1], InvRadius );
            ePoints[2] = Vec3VecScale( ePoints[2], InvRadius );

            // Transform normal and normalize
            // (Note how we do not use InvRadius for the normal)
            D3DXVec3TransformNormal( &eNormal, &pTriangle->Normal, pTransform );
            eNormal = Vec3VecScale( eNormal, Radius );
            D3DXVec3Normalize( &eNormal, &eNormal );

        } // End if requires transformation
```

Looking at the above code you can see that we create an iterator to access the elements of the STL vector and begin to loop through every triangle in the passed buffer. We then store a pointer to the current triangle in the local pTriangle pointer for ease of access. If for some reason this is not a valid triangle, we continue to the next iteration of the loop (a simple safety test).

We then test to see if the pTransform parameter is not NULL. If it is not, then it means that a matrix has been passed and the vertices of each triangle will need to be transformed by it prior to being intersection tested against the sphere. As you can see, we fetch the three vertices of the current triangle from the passed vertex buffer and transform them by this matrix. This code will only be executed if we are calling this function to process a dynamic object's geometry buffer. We store the transformed results of each world space vertex in the ePoints local array.

Next we scale each of the triangle vertices by the inverse radius of the ellipsoid, transforming these three vertices into eSpace. We then fetch the normal of the triangle and scale it from model space into world space using the passed transformation matrix (the CollisionMatrix of the dynamic object). Once we have the normal in world space, we scale it by the radius of the ellipsoid, transforming it into eSpace as well. We finally normalize the result.

If a valid transformation matrix was not passed, such as when processing the static geometry buffers, the triangles in those buffers are assumed to already be in world space and thus require only the transformation into eSpace.

```
        else
        {
            // Get points and transform into ellipsoid space
            ePoints[0] = Vec3VecScale( VertBuffer[ pTriangle->Indices[0] ],
                                       InvRadius );
            ePoints[1] = Vec3VecScale( VertBuffer[ pTriangle->Indices[1] ],
                                       InvRadius );
            ePoints[2] = Vec3VecScale( VertBuffer[ pTriangle->Indices[2] ],
                                       InvRadius );

            // Transform normal and normalize
            // (Note how we do not use InvRadius for the normal)
            eNormal = Vec3VecScale( pTriangle->Normal, Radius );
            D3DXVec3Normalize( &eNormal, &eNormal );

        } // End if no transformation
```

At this point we have the triangle in eSpace, so we use our SphereIntersectTriangle function to perform the intersection test. If the function returns true, an intersection was found and we are returned the collision normal in eSpace (eIntersectNormal) and the new *t* value (eInterval).

```
        // Test for intersection between unit sphere and ellipsoid space triangle
        if ( SphereIntersectTriangle( eCenter, 1.0f, eVelocity,
                                      ePoints[0], ePoints[1], ePoints[2],
                                      eNormal, eInterval, eIntersectNormal ) )
        {
            // Calculate our new sphere center at the point of intersection
            if ( eInterval > 0 )
```

```
            eNewCenter = eCenter + (eVelocity * eInterval);
        else
            eNewCenter = eCenter - (eIntersectNormal * eInterval);
```

If the function returns true we calculate the new sphere center in eSpace. If eInterval is larger than zero then it means the intersection happened along the ray and the position can be calculated by scaling the velocity vector by the interval and adding the resulting vector to the original sphere center. If the collision interval is negative, then the sphere was embedded in the triangle and needs to be moved backwards such that this is no longer the case. Under these circumstances, the actual (negative) distance to the shifted plane is stored in eInterval and we can move the sphere center position back on to the shifted plane by moving along the plane normal by that distance.

In the next section of code we test to see if the interval is smaller than the intervals of the collision structures currently stored in the array. If so, it means we have found a triangle that intersects the ray closer to the origin than any currently stored in the array. When this is the case we set NewIndex to zero (which contains the index of the element in the array where the information about this intersection will be stored). As we have just invalidated all the information currently stored in the array, we store this in element zero and reset the intersection count back to 1. We also set FirstIndex to zero. Remember, this will be returned from the function as the index of the first structure added by this function to this array.

```
        // Where in the array should it go?
        AddToList = false;
        if ( IntersectionCount == 0 || eInterval < Intersections[0].Interval )
        {
            // We either have nothing in the array yet,
            // or the new intersection is closer to us
            AddToList         = true;
            NewIndex          = 0;
            IntersectionCount = 1;

            // Reset, we've cleared the list
            FirstIndex        = 0;

        } // End if overwrite existing intersections
```

If the interval is equal (with tolerance) to the intervals of the structures already stored in the array, we will add this new intersection information to the back of the array.

```
        else if ( fabsf( eInterval - Intersections[0].Interval ) < 1e-5f )
        {
            // It has the same interval as those in our list already, append to
            // the end unless we've already reached our limit
            if ( IntersectionCount < m_nMaxIntersections )
            {
                AddToList         = true;
                NewIndex          = IntersectionCount;
                IntersectionCount++;

            } // End if we have room to store more

        } // End if the same interval
```

If the collision interval for the current triangle was either smaller or the same as the intervals currently stored, the AddToList boolean would have been set to true; otherwise, it will still be false, nothing will happen, and the following code block will be skipped. This is the code block that adds the collision information to the array (explained earlier in the EllipsoidIntersectScene discussion).

```
            // Add to the list?
            if ( AddToList )
            {
                Intersections[ NewIndex ].Interval = eInterval;
                Intersections[ NewIndex ].NewCenter = eNewCenter +
                                                      (eIntersectNormal * 1e-3f);
                Intersections[ NewIndex ].IntersectPoint = eNewCenter –
                                                           eIntersectNormal;
                Intersections[ NewIndex ].IntersectNormal = eIntersectNormal;
                Intersections[ NewIndex ].TriangleIndex = Counter;
                Intersections[ NewIndex ].pObject = NULL;

            } // End if we are inserting in our list

        } // End if collided

    } // Next Triangle

    // Return hit.
    return FirstIndex;
}
```

12.14 The Revised EllipsoidIntersectScene Function

We will now examine the code to the modified EllipsoidIntersectScene function that adds support for dynamic objects and uses the previous function to perform the intersection with the various geometry buffers. This function is essentially the detection phase of our collision system. It is called by CollideEllipsoid for each movement of the ellipsoid along the initial or slide vectors. Our CollideEllipsoid function first converts the sphere center and velocity into eSpace before passing them in.

While the detection function will stay pretty constant as its job is fairly generic, the CollideEllipsoid function is very application specific. You may wish to add different response handling functions to the CCollision class to make the ellipsoid act in a different way. Further, you may not even be using ellipsoids at all; instead you might be using a sphere of arbitrary size to bound your objects. In such a case, you would not want to needlessly perform the eSpace transformation code. Additionally you might not wish to use the CCollision system's response phase at all, but instead allow your application to make direct calls to EllipsoidIntersectScene and handle you own responses. When this is the case, you would not want to have to concern your application with feeding in eSpace values for the ellipsoid center and velocity. Preferably, you could use the EllipsoidIntersectScene function as a black box that does this for you. The same is true for output. You are not likely to want to get back eSpace values for the

intersection point, integration velocity, and the new sphere position. Ideally you would to feed EllipsoidIntersectScene world space values and get back world space values. So to make the function a little more generic, we will add two Boolean parameters that express whether the function is being passed eSpace input values and whether it should return eSpace values or perform the transformation back into world space prior to returning the information. Here is the new parameter list:

```
bool CCollision::EllipsoidIntersectScene(const D3DXVECTOR3& Center,
                                         const D3DXVECTOR3& Radius,
                                         const D3DXVECTOR3& Velocity,
                                         CollIntersect Intersections[],
                                         ULONG& IntersectionCount,
                                         bool bInputEllipsoidSpace /* = false */,
                                         bool bReturnEllipsoidSpace /* = false */ )
```

The final two parameters default to false, where the function will assume that it is being passed world space values and perform the transformation into eSpace using the passed radius vector. Because the final parameter is also set to false, this means the function will also convert the intersection information (stored in the passed CollIntersect array) back into world space prior to the function returning. While this makes the function a nice black box for third party calls, it should be noted that our CollideEllipsoid function (the function that calls this one) will transform the input values into eSpace and also requires eSpace values to be returned exactly as it did before. Therefore, when our CollideEllipsoid function calls this function, it will pass true for the final two parameters (the Center and Velocity vectors passed in will already be in eSpace).

The fourth and fifth parameters are the array and count of the CCollision object's CollIntersect array. It may seem strange to pass this array as a parameter to a CCollision function when it is already a class variable that the function would automatically have access to. We do this so that the caller can get back the results in their own array, should they wish not to use the complete collision detection and response system, but rather just the EllipsoidIntersectScene function.

Let us now talk about the new version of this function. The first thing we do is create the inverse radius vector that will be used to scale the passed center position and velocity into eSpace. If the bInputEllipsoidSpace parameter is set to false, the input variables are in world space and need to be transformed before we can continue. We copy the eSpace results into the local variables eCenter and eVelocity. If the bInputEllipsoidSpace parameter is set to true, the input variables are already in ellipsoid space and we simply copy them into the eCenter and eVelocity variables.

```
{
    D3DXVECTOR3 eCenter, eVelocity, eAdjust, vecEndPoint, InvRadius;
    float       eInterval;
    ULONG       i;

    // Calculate the reciprocal radius to prevent the many
    // divides we would need otherwise
    InvRadius = D3DXVECTOR3( 1.0f / Radius.x, 1.0f / Radius.y, 1.0f / Radius.z );

    // Convert the values specified into ellipsoid space if required
    if ( !bInputEllipsoidSpace )
    {
        eCenter   = Vec3VecScale( Center, InvRadius );
```

```
        eVelocity = Vec3VecScale( Velocity, InvRadius );
    } // End if the input values were not in ellipsoid space
    else
    {
        eCenter   = Center;
        eVelocity = Velocity;

    } // End if the input values are already in ellipsoid space
```

At this point we have our sphere center position and the velocity vector in eSpace. Next we set the eInterval variable to its maximum intersection interval of 1.0. This local variable will be fed into the EllipsoidIntersectBuffers function and will always contain the *t* value of the closest intersection we have found so far. When a closer intersection is found, the EllipsoidIntersectBuffers function will overwrite it. The initial value of 1.0 basically describes a *t* value at the end of the ray. If this is not altered by any of the collision tests, this means the velocity vector is free from obstruction. We also set the initial intersection count to zero as we have not identified any collisions yet.

```
    // Reset ellipsoid space interval to maximum
    eInterval = 1.0f;

    // Reset initial intersection count to 0 to save the caller having to do this.
    IntersectionCount = 0;
```

Now we will loop through each dynamic object in the m_DynamicObjects vector. For each one we will use its velocity vector to create the shift vector that is used to extend the length and direction of the velocity vector. This is the exact code we saw earlier when first discussing dynamic intersections. This process is also illustrated in Figures 12.43 through 12.47.

```
    // Iterate through our triangle database
    DynamicObjectVector::iterator ObjIterator = m_DynamicObjects.begin();
    for ( ; ObjIterator != m_DynamicObjects.end(); ++ObjIterator )
    {
        DynamicObject * pObject = *ObjIterator;

        // Calculate our adjustment vector in world space.
        // This is our velocity adjustment for objects
        // so we have to work in the original world space.
        vecEndPoint = ( Vec3VecScale( eCenter, Radius ) +
                        Vec3VecScale( eVelocity, Radius ));

        // Transform the end point
        D3DXVec3TransformCoord( &eAdjust, &vecEndPoint, &pObject->VelocityMatrix );

        // Translate back so we have the difference
        eAdjust -= vecEndPoint;

        // Scale back into ellipsoid space
        eAdjust  = Vec3VecScale( eAdjust, InvRadius );

        // Perform the ellipsoid intersect test against this object
        ULONG StartIntersection = EllipsoidIntersectBuffers(
                                                *pObject->pCollVertices,
                                                *pObject->pCollTriangles,
```

```
                                                    eCenter,
                                                    Radius,
                                                    InvRadius,
                                                    eVelocity - eAdjust,
                                                    eInterval,
                                                    Intersections,
                                                    IntersectionCount,
                                                    &pObject->CollisionMatrix );
```

Notice how once we have calculated the shift vector (eAdjust), we subtract it from the end of the velocity vector to extend the ray in the opposite direction of the dynamic object's movement. We do this while passing the velocity vector into the EllipsoidIntersectBuffers function as the sixth parameter. Note also that for the first two parameters we pass in the vertex and triangle arrays of the current dynamic object being processed for collision. The function will return the index of the first intersection structure that the call added to the CollIntersect array. Remember, this function will be called for each dynamic object and therefore, many different calls to the function may result in intersection information being cumulatively added to the CollIntersect array. If the function found no additional intersections, StartIntersect will be equal to IntersectionCount on function return.

Now it is time to loop through any structures that were added by the above function call and translate them back by the adjustment vector. By doing this little trick, we are sure to catch the sphere if it is between the previous and current position of the moving triangle. We can then translate the sphere back by the movement of the triangle so it is pushed out of the way by the dynamic object.

```
        // Loop through the intersections returned
        for ( i = StartIntersection; i < IntersectionCount; ++i )
        {
            // Move us to the correct point (including the objects velocity)
            // if we were not embedded.
            if ( Intersections[i].Interval > 0 )
            {
                // Translate back
                Intersections[i].NewCenter      += eAdjust;
                Intersections[i].IntersectPoint += eAdjust;

            } // End if not embedded

            // Store object
            Intersections[i].pObject = pObject;

        } // Next Intersection

    } // Next Dynamic Object
```

Notice that at the bottom of the dynamic object loop, if an intersection has occurred with the object's buffers, we also store a pointer to the dynamic object in each CollIntersect structure. This might be useful if the calling function would like to know more information about which object was actually hit.

With all the dynamic objects tested for intersection and the closest intersection recorded in eInterval, we now have to test the static scene geometry for intersection with the swept sphere. We do this by simply calling the EllipsoidIntersectBuffers function one more time. This time we pass in the vertex and

triangle buffers containing the static scene geometry along with the CCollision object's m_CollVertices and m_CollTriangles members.

```
    // Perform the ellipsoid intersect test against our static scene
    EllipsoidIntersectBuffers(
                         m_CollVertices,
                         m_CollTriangles,
                         eCenter,
                         Radius,
                         InvRadius,
                         eVelocity,
                         eInterval,
                         Intersections,
                         IntersectionCount );
```

At this point, if any intersections have occurred with any geometry, the CollIntersect array will contain information about the closest intersection. The array may contain multiple entries if collisions occurred with multiple triangles at the exact same time. Either way, the first structure in this array will contain the new center position of the sphere. It is automatically returned to the response phase in CollideEllipsoid.

Before we return there is one final step that we will take. If bReturnEllipsoidSpace is set to false, then the function should transform all the eSpace values stored in the CollIntersect array into world space before returning. If this is the case, we loop through each intersection structure and apply the ellipsoid radius scale to make that so. Notice once again how we transform a positional vector from eSpace to world space by scaling it by the radii of the ellipsoid, but we transform a direction vector from eSpace to world space by scaling it by the inverse radii of the ellipsoid.

```
    // If we were requested to return the values in normal space
    // then we must take the values back out of ellipsoid space here
    if ( !bReturnEllipsoidSpace )
    {
        // For each intersection found
        for ( i = 0; i < IntersectionCount; ++i )
        {
            // Transform the new center position and intersection point
            Intersections[ i ].NewCenter =
                             Vec3VecScale( Intersections[ i ].NewCenter, Radius );
            Intersections[ i ].IntersectPoint =
                             Vec3VecScale( Intersections[ i ].IntersectPoint,
                                           Radius );

            // Transform the normal
            // (again we do this in the opposite way to a coordinate)
            D3DXVECTOR3 Normal =
                     Vec3VecScale( Intersections[ i ].IntersectNormal, InvRadius );
            D3DXVec3Normalize( &Normal, &Normal );

            // Store the transformed normal
            Intersections[ i ].IntersectNormal = Normal;

        } // Next Intersection

    } // End if !bReturnEllipsoidSpace
```

```
    // Return hit.
    return (IntersectionCount > 0);
}
```

The function simply returns true if the number of intersections found is greater than zero.

12.15 The Revised CollideEllipsoid Function

The CollideEllipsoid has also received a minor upgrade due to the integration of dynamic objects. The only major change involves the calculation of the integration vector that is returned back to the application.

As discussed earlier, the integration velocity vector parameter is an output parameter that will contain the new direction and speed of the object on function return. If no collisions have occurred, this will be a straight copy of the velocity vector passed in. However, while the input velocity vector is continually split at intersection planes and recalculated by projecting any remaining velocity past the point of intersection onto the slide plane, we do not wish the integration velocity to be diminished in this way. We should retain as much of its length as possible so that we can more accurately communicate the new direction and speed of the moving entity back to the application on function return.

Now we will have to take collisions with dynamic objects into account when calculating this vector. When the slide plane is on a dynamic object, we must once again calculate the adjustment vector in order to extend the integration velocity vector so that it can be projected onto the slide plane. However, remember that the intersection was performed between our velocity vector and the triangle of the dynamic object by adjusting the length of the ray to compensate for object movement. Since we now wish to project our integration velocity onto this same plane, we must also extend that vector in the same manner. Recall that we returned the intersection normal based on the dynamic object's previous position instead of its current one. The velocity matrix that describes the transition from the dynamic object's previous position to its current one may contain rotation as well. In short, we need to know that when we project the integration velocity vector onto the slide plane that the velocity vector is in the same *space* as the slide plane; otherwise the projection of the velocity vector onto this slide plane will be incorrect. This probably all sounds very complicated, but when you see the code you will realize that this is the exact same code we used to extend the velocity vector when testing for intersection against dynamic objects.

We have also added another feature to our CollideEllipsoid function. As we know, the CollIntersect array that is returned from the EllipsoidIntersectScene function contains the information about the closest collisions. If this array contains more than one element, then it means the ellipsoid intersected multiple geometry constructs at the same time. We also know that each CollIntersect structure contains within it, a vector describing the point of intersection on the surface of the ellipsoid. It is sometimes handy to have two vectors returned that describe the maximum and minimum collision extents on the surface of the ellipsoid. For example, our application will know that if the player is walking on the ground, then we should always have at least of one collision (the collision between the bottom of the ellipsoid and the floor polygon). We know that if the minimum y component of all the intersection

points that occurred on the surface of the ellipsoid is very near to -Radius.y, the height of this point places it at the ground level with respect to the ellipsoid. Our application uses this to set a state that indicates that the player is on the ground and friction should be applied to diminish the velocity of the player.

This state is also tested during user input when the user presses the CTRL key to see whether the player should be allowed to jump -- a player that is in mid-air and currently falling should not be able to jump. Remember that an intersection point with a y component of zero would describe a point that is aligned with the center of the ellipsoid along the y axis. The top and bottom of the ellipsoid is described by +Radius.y and –Radius.y from the center of the ellipsoid, respectively.

Similarly, we know that if the y component of the lowest intersection point on the surface of the ellipsoid is zero, then the intersection point is aligned vertically with the center of the ellipsoid. This would mean that the player is currently in the air, and if gravity is being applied, the player will be falling. The collision point would also suggest to the application that an object has collided into a wall as the player is falling.

Finally, we know that when we have an intersection point nearing a y value of zero, the intersection point is aligned with the center of the sphere along the y axis. If you think about this for a moment, you will see that this means the player is hitting something almost head on, and its velocity should be set to zero. In fact, as we walk our ellipsoid into steeper inclines, we will find intersection points that are near the center of the ellipsoid vertically. Our application will use this information to slow the velocity of the player so that the steeper the hill, the slower the speed of the player as it ascends.

How these minimum and maximum collision extents are used by the application will be discussed in the workbook since it is not part of the collision detection system proper. However, the CollideEllipsoid function will record the minimum and maximum extents of the intersection points and return them via two output vectors that are passed as parameters.

Let us have a look at the new parameter list to this function. The only difference is that we have added these two new parameters to the end. These two vectors will be filled by the function with the minimum and maximum x, y, and z components of all intersection points. Thus these two vectors describe a bounding box within which all the intersection points are contained.

```
bool CCollision::CollideEllipsoid( const D3DXVECTOR3& Center,
                                   const D3DXVECTOR3& Radius,
                                   const D3DXVECTOR3& Velocity,
                                   D3DXVECTOR3& NewCenter,
                                   D3DXVECTOR3& NewIntegrationVelocity,
                                   D3DXVECTOR3& CollExtentsMin,
                                   D3DXVECTOR3& CollExtentsMax )
{
```

This is the function that is called by the application to calculate a movement update for an entity. The first parameter is the world space position of the center of the ellipsoid and the second is its radius vector. The Velocity vector describes the direction and distance the application would like to move the ellipsoid. On function return, NewCenter will describe the new world space position of the ellipsoid that

is free from obstruction. It can be used by the application to update the position of the entity which the ellipsoid is approximating. On function return, the NewIntegrationVelocity parameter will contain the new direction and speed which the object should be heading after collisions and their responses have been taken into account. The final two parameters will contain two vectors describing the bounding box of intersection points.

We will look at the function a bit at a time, although most of this code will be familiar from the earlier version. First we add the passed velocity to the passed sphere center point to describe the world space position we would like to move the sphere to. We store the resulting position in the local variable vecOutputPos. We also take the passed velocity and store it in the local variable vecOutputVelocity. It is this output velocity that will contain the integration velocity we wish to return to the application. At the moment we set it to the current velocity because if no intersections occur, the velocity should not be changed.

```
    D3DXVECTOR3 vecOutputPos, vecOutputVelocity, InvRadius, vecNormal, vecExtents;
    D3DXVECTOR3 eVelocity, eInputVelocity, eFrom, eTo;
    D3DXVECTOR3 vecNewCenter, vecIntersectPoint;
    D3DXVECTOR3 vecFrom, vecEndPoint, vecAdjust;
    ULONG       IntersectionCount, i;
    float       fDistance, fDot;
    bool        bHit = false;

    vecOutputPos        = Center + Velocity;
    vecOutputVelocity   = Velocity;
```

Next we initialize the minimum and maximum extents vectors to the initial extremes. That is, we set the minimum vector to the maximum extents of the ellipsoid and set the maximum vector to the minimum extents of the ellipsoid. This will make sure that minimum extent starts as large as possible and will be set to the first intersection point we initially find, and vice versa. We have seen code like this when initializing bounding boxes in the past.

```
    // Default our intersection extents
    CollExtentsMin.x  = Radius.x;
    CollExtentsMin.y  = Radius.y;
    CollExtentsMin.z  = Radius.z;
    CollExtentsMax.x  = -Radius.x;
    CollExtentsMax.y  = -Radius.y;
    CollExtentsMax.z  = -Radius.z;
```

Now we create the inverse radius vector and scale the sphere center position and the velocity vector into eSpace. We store the current eSpace sphere position in eFrom, the eSpace velocity in eVelocity, and the eSpace desired destination position in eTo.

```
    // Store ellipsoid transformation values
    InvRadius = D3DXVECTOR3( 1.0f / Radius.x, 1.0f / Radius.y, 1.0f / Radius.z );

    // Calculate values in ellipsoid space
    eVelocity = Vec3VecScale( Velocity, InvRadius );
    eFrom     = Vec3VecScale( Center, InvRadius );
    eTo       = eFrom + eVelocity;
```

```
    // Store the input velocity for jump testing
    eInputVelocity = eVelocity;
```

Notice that we copy the eSpace velocity passed into the function into the eInputVelocity local variable. As discussed earlier, we may need this later if, after the maximum number of collision iterations, we still cannot resolve a final position. When this is the case, we will just use the initial velocity vector passed in to run the detection phase one last time to get a position which we will settle for (no sliding).

We now loop through the maximum number of iterations we wish to spend finding the correct position. Inside the loop, we see that if the current length of our velocity vector is zero (with tolerance) we have no more sliding left to do and can exit. Otherwise, we call the EllipsoidIntersectScene function to test for collisions along the current velocity vector. Notice how we pass true for the two boolean parameters, indicating that we will be passing in eSpace values and would like to have eSpace values returned.

```
    // Keep testing until we hit our max iteration limit
    for ( i = 0; i < m_nMaxIterations; ++i )
    {
        // Break out if our velocity is too small
        // (optional but sometimes beneficial)
        //if ( D3DXVec3Length( &eVelocity ) < 1e-5f ) break;

        if ( EllipsoidIntersectScene( eFrom, Radius, eVelocity,
                                m_pIntersections, IntersectionCount, true, true ) )
        {
            // Retrieve the first collision intersections
            CollIntersect & FirstIntersect = m_pIntersections[0];

            // Calculate the WORLD space sliding normal
            D3DXVec3Normalize( &vecNormal,
                               &Vec3VecScale( FirstIntersect.IntersectNormal,
                                              InvRadius )
                             );
```

If the function returns true then the sphere collided with something along the velocity vector and we should access the new position of the sphere from the first CollIntersect structure in the array. We also transform the returned eSpace collision normal into world space and normalize the result. We will need to do some work with this when projecting the integration vector.

In the next section of code we would usually just project the current integration velocity vector onto the slide plane, but if this collision has occurred with a dynamic object, then we have to calculate the force and direction at which the dynamic object struck the ellipsoid so that we can add that to the current integration velocity. As it happens, we already know how to do this. When we performed intersection tests between the sphere and triangles of a dynamic object, you will recall how we create an adjustment vector that allows us to extend the ray and collide with the previous position of the object. This adjustment vector described the direction the object has moved since the previous update. If we calculate this adjustment vector in the same way, we have a vector that describes the speed and distance of movement the dynamic object has moved as shown below.

```
            // Did we collide with a dynamic object
            if ( FirstIntersect.pObject )
```

```
            {
                DynamicObject *pObject = FirstIntersect.pObject;

                // Calculate our adjustment vector in world space. This is for our
                // velocity adjustment for objects so we have to work in the
                // original world space.
                vecFrom     = Vec3VecScale( eFrom, Radius );
                vecEndPoint = vecFrom + vecOutputVelocity;

                // Transform the end point
                D3DXVec3TransformCoord( &vecAdjust, &vecEndPoint,
                                        &pObject->VelocityMatrix );

                // Translate back so we only get the distance.
                 vecAdjust -= vecEndPoint;
```

The code above is not new to us -- we created a shift vector (eAdjust) in exactly the same way when performing the intersection tests. The adjustment vector describes the movement of the dynamic object from its previous state to its current state; the period in which the collision with the sphere happened. This vector tells us the speed which the dynamic object was traveling from its previous position to its new position and we can use this to approximate an applied force on our sphere as a result of the impact. After we have projected the current integration velocity vector onto the slide plane, we have a new integration vector facing in the slide direction:

```
                // Flatten out to slide velocity
                fDistance = D3DXVec3Dot( &vecOutputVelocity, &vecNormal );
                vecOutputVelocity -= vecNormal * fDistance;
```

We will then calculate the angle between the adjustment vector and the slide plane normal. Since the slide plane normal describes the orientation of the point of impact on the triangle, and the adjustment vector describes the speed and direction of the movement of the triangle when it hit the sphere, performing the dot product between them will give us with a distance value that gets larger the more head-on the collision between the two objects. We will use this distance value to add a force to the integration velocity that pushes the object away from the triangle in the direction of the triangle normal.

```
                // Apply the object's momentum to our velocity along the
                // intersection normal
                fDot = D3DXVec3Dot( &vecAdjust, &vecNormal );
                vecOutputVelocity += vecNormal * fDot;

            } // End if colliding with dynamic object
```

Remember, even before we calculate the integration vector, the sphere has been correctly repositioned so that it has moved back with the colliding triangle and thus is not intersecting. By adding this force to the integration velocity that is returned to the application, it means that our application will continue to move the sphere back away from the point of impact for the next several frames. This is certainly not state of the art physics here, but it certainly provides a convincing enough effect to be suitable for our purposes in this demo.

The next code block is executed if the intersection information does not relate to a dynamic object. In this case we just project the current integration velocity onto the side plane, just as we did in the previous version of the function.

```
            else
            {
                // Generate slide velocity
                fDistance = D3DXVec3Dot( &vecOutputVelocity, &vecNormal );
                vecOutputVelocity -= vecNormal * fDistance;

            } // End if colliding with static scene
```

We have now modified the integration velocity vector and accounted for collisions with a static or scene triangle. The application can now be informed of the new direction the object should be heading when the function returns.

In the next section of code we grab the new eSpace position of the sphere and store it in the eFrom local variable. This is the new position of the sphere as suggested by the collision detection phase. We then calculate the slide vector that will become the velocity vector passed into the EllipsoidIntersectScene function in the next iteration of the collision loop. We subtract the actual position we were allowed to move to from the previous desired destination position which provides us with the remaining velocity vector after the point of intersection. This is then dotted with the plane normal, giving us the distance from the original desired destination position to the slide plane. We then subtract this distance from the original intended destination along the direction of the plane normal, thus flattening the remaining velocity onto the slide plane. This is stored in the eTo local variable which will be used in a moment to calculate the new slide velocity that will be one of the inputs for the next collision detection loop.

```
            // Set the sphere position to the collision position
            // for the next iteration of testing
            eFrom = FirstIntersect.NewCenter;

            // Project the end of the velocity vector onto the collision plane
            // (at the sphere centre)
            fDistance = D3DXVec3Dot( &( eTo - FirstIntersect.NewCenter ),
                                     &FirstIntersect.IntersectNormal );
            eTo -= FirstIntersect.IntersectNormal * fDistance;
```

We will now get the new sphere position and the intersection point on the surface of the sphere and transform them into world space. This will be done for the purpose of testing the intersection point against the minimum and maximum extents currently recorded. We adjust the relevant extents vector if the intersection point is found to outside the bounding box (i.e., we will grow the box to fit). To calculate the new world space sphere center position, we just transform the new eSpace sphere position returned from the collision detection function using the ellipsoid radius vector. To calculate the intersection point on the surface of the ellipsoid we simply scale the slide plane normal into world space by the radius vector and subtract the world space sphere position from it.

```
            // Transform the sphere position back into world space,
            // and recalculate the intersect point
            vecNewCenter       = Vec3VecScale( FirstIntersect.NewCenter, Radius );
```

```
            vecIntersectPoint  = vecNewCenter - Vec3VecScale( vecNormal, Radius );
```

If the calculation of the intersection point is bothering you, remember that in eSpace the sphere has a radius of one. Since a unit vector also has a length of one we know that in eSpace, the intersection point on the sphere can be found simply by subtracting the slide plane normal from the sphere center position. This will always generate a vector at a distance of 1.0 unit from the sphere center in the direction of the intersection point. Because we are transforming the unit normal by the radius vector, we also scale its length as well. The resulting vector will have a length equal to the world space distance from the center of the ellipsoid to the point on the surface of the ellipsoid. If we subtract this from the world space ellipsoid position, we have the intersection point in world space on the surface of the ellipsoid.

In the next section of code we subtract the ellipsoid center position to leave us with an intersection point that is relative to its center. We can now test the x, y, and z components of the intersection point against the corresponding components in the extents vectors and grow those vectors if we find a component of the intersection point vector that is outside the box. The result is a bounding box where there ellipsoid center is assumed to be at its center.

```
            // Calculate the min/max collision extents around the ellipsoid center
            vecExtents = vecIntersectPoint - vecNewCenter;
            if ( vecExtents.x > CollExtentsMax.x ) CollExtentsMax.x = vecExtents.x;
            if ( vecExtents.y > CollExtentsMax.y ) CollExtentsMax.y = vecExtents.y;
            if ( vecExtents.z > CollExtentsMax.z ) CollExtentsMax.z = vecExtents.z;
            if ( vecExtents.x < CollExtentsMin.x ) CollExtentsMin.x = vecExtents.x;
            if ( vecExtents.y < CollExtentsMin.y ) CollExtentsMin.y = vecExtents.y;
            if ( vecExtents.z < CollExtentsMin.z ) CollExtentsMin.z = vecExtents.z;
```

Next we create the slide vector that will become the velocity vector for the next iteration of the collision detection phase. In the eTo vector, we currently have the original desired destination point projected onto the slide plane. This describes the location we want to travel to in the next iteration. In eFrom we also have the new non-interpenetrating position of the ellipsoid returned from the previous call to EllipsoidIntersectScene. Therefore, by subtracting eFrom from eTo, we have our new velocity vector.

```
            // Update the velocity value
            eVelocity = eTo - eFrom;

            // We hit something
            bHit = true;

            // Filter 'Impulse' jumps (described in earlier version of function)
            if ( D3DXVec3Dot( &eVelocity, &eInputVelocity ) < 0 )
            { eTo = eFrom; break; }

        } // End if we got some intersections
        else
        {
            // We found no collisions, so break out of the loop
            break;

        } // End if no collision

    } // Next Iteration
```

Above we see the final section of code in the inner loop. Hopefully, we will have found a collision and broken from the above loop before the maximum number of iterations. Notice how we use the additional dot product to filter out back and forth vibration. Now you see why we made that additional copy of the initial velocity vector that was input into the function. We would need it later to test if we ever generate a slide vector in the response phase that is bouncing the ellipsoid back in the opposite direction than was initially intended. If we find this is the case, we set eTo equal to eFrom, making the slide vector zero length so that no more sliding is performed.

The next section of code is executed if an intersection occurred. If at any point in the detection loop above EllipsoidIntersectScene returned true, the local boolean variable bHit will have been set to true. Inside this conditional is another one that tests whether the number of loop iterations we executed is equal to the maximum number of iterations. If not, then it means we successfully resolved the response to our satisfaction and simply have to scale the new position of the sphere into world space.

```
    // Did we register any intersection at all?
    if ( bHit )
    {
        // Did we finish neatly or not?
        if ( i < m_nMaxIterations )
        {
            // Return our final position in world space
            vecOutputPos = Vec3VecScale( eTo, Radius );

        } // End if in clear space
```

However, if the loop variable *i* is equal to the maximum number of iterations allowed, it means we could not find a satisfactory position to slide to in the given number of iterations. When this is the case we simply call EllipsoidIntersectScene again with the original input values to get the closest non-intersecting position and store this in vecOutputPos after transforming it into world space. As you can see, if this section of code is executed, we have encountered the undesirable situation where the response step was repeatedly bouncing the sphere between two triangles. When this is the case, we forget about the slide step and just move the sphere along the velocity vector as much as possible and discard any remaining velocity.

```
        else
        {
            // Just find the closest intersection
            eFrom = Vec3VecScale( Center, InvRadius );

            // Attempt to intersect the scene
            IntersectionCount = 0;
            if ( EllipsoidIntersectScene( eFrom, Radius, eInputVelocity,
                                          m_pIntersections, IntersectionCount,
                                          true, true ) )
            {
                // Retrieve the intersection point in clear space,
                // but ensure that we undo the epsilon
                // shift we apply during the above call.
                // This ensures that when we are stuck between two
                // planes, we don't slowly push our way through.
                vecOutputPos = m_pIntersections[0].NewCenter –
```

```
                                    (m_pIntersections[0].IntersectNormal * 1e-3f);

                // Scale back into world space
                vecOutputPos = Vec3VecScale( vecOutputPos, Radius );

            } // End if collision
            else
            {
                // Don't move at all, stay where we were
                vecOutputPos = Center;
            } // End if no collision

        } // End if bad situation

    } // End if intersection found

    // Store the resulting output values
    NewCenter             = vecOutputPos;
    NewIntegrationVelocity = vecOutputVelocity;

    // Return hit code
    return bHit;
}
```

The final few lines of code simply store the new world space ellipsoid position in the NewCenter variable and store the integration velocity in the NewIntegrationVelocity vector. Since both of these vectors were passed by reference, the application will be able to access these values when the function returns. We conclude by returning the value of bHit, which will be set to either true or false depending on whether EllipsoidIntersectScene call ever returned true.

Conclusion

This has probably been a very challenging lesson for many of you as it was certainly one of our most complicated and most mathematically intense systems to date in the series. Do not be concerned if you find that you need to re-read parts of this chapter again in order to fully grasp what is happening. It is recommended that you take your time with the material and try to keep the actual source code in hand.

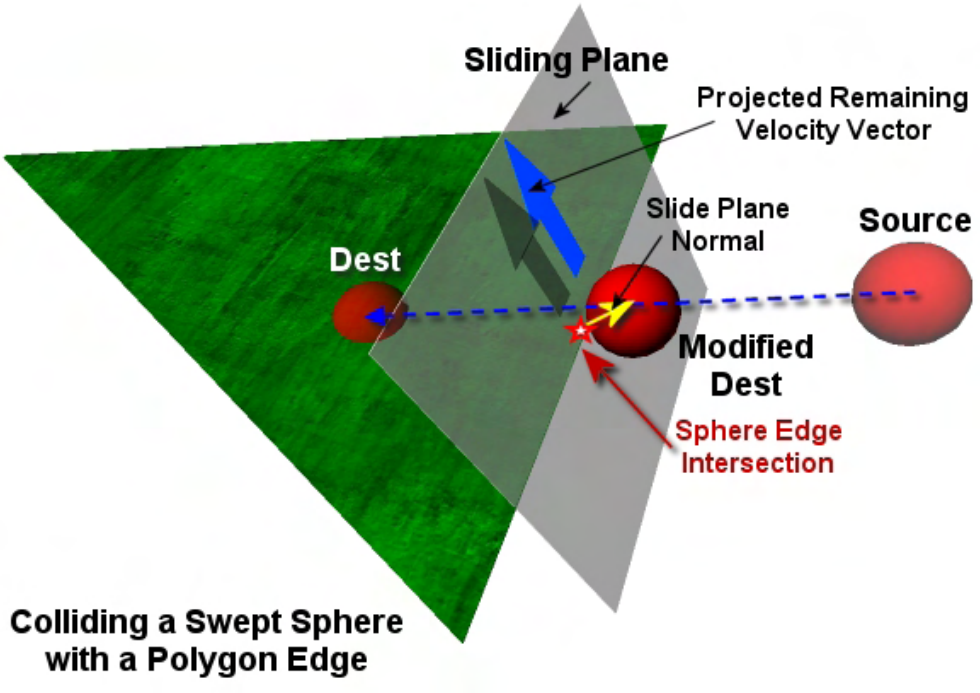
On the bright side, we have developed a collision system that can be easily plugged into our future applications. We will expand the coverage of our CCollision class in the accompanying workbook, where the changes to the application and the CPlayer class will be discussed. We will also discuss all of the CCollision utility member functions, such as those responsible for registering terrains, dynamic objects, and static meshes with the collision database.

The core runtime query functions of the collision system have all been discussed in this chapter, so they will not be covered again. The final EllipsoidIntersectScene, EllipsoidIntersectBuffers and CollideEllipsoid functions just examined are almost identical to the ones used by the CCollision class in Lab Project 12.1. In the lab project we add a few extra lines to efficiently deal with terrains, but this will be explained in the workbook. The SphereIntersectTriangle, SphereIntersectPlane, SphereIntersectPoint,

and SphereIntersectLineSegment intersection routines (called from SphereIntersectTriangle) are also the exact implementations used in Lab Project 12.1. With all the intersection routines covered, this leaves us with a workbook that can concentrate on how geometry is registered with the system and how the collision system is used by our framework.

Your next course of action should be to read the workbook that accompanies this chapter so that you will finally have a full understanding of every aspect of the collision system. As we will be using this collision system in all future lab projects, it is a good idea to make sure you understand it very well.

Workbook Thirteen:
Collision Detection and Response



Lab Project 13.1: The CollisionSystem

In this workbook we will discuss the remaining code in Lab Project 13.1 which was not discussed in the accompanying textbook. It is very important that you read the accompanying textbook before reading this workbook because the intersection routines in the CCollision class will not be discussed again in detail here.

This workbook will focus on the utility functions exposed by the CCollision class which allow an application to easily register various types of static and dynamic objects with the collision system. We will discuss the functions that allow the application to register static meshes with the collision geometry database as well as how to register complete frame hierarchies (contained in a CActor) with the collision system. Furthermore, we will cover the functions that allow the application to register single mesh constructs and entire frame hierarchies as dynamic scene collision objects. This will allow an application to register fully animated actors with the collision system such that collision determination and response between moving entities and animated scene geometry can happen in real time.

Figure 13.1

We will also add a special method tailored for the registration of terrain data that will help keep the memory overhead of the collision geometry database minimized. This will ensure that our CTerrain objects too can benefit from the collision system. The process will involve our collision system building triangle data on the fly using the terrains height map whenever that terrain is queried for collision. This allows us to completely eliminate the need for us to make a copy of every triangle comprising the terrain in order to add it to the static geometry database. Whenever a terrain is queried for intersection, the swept ellipsoid will be transformed into the image space of the terrain's height map. The starting location and the desired destination location of the ellipsoid will then be used to construct an image space bounding box on the height map describing the region of the terrain that could possibly be collided with in this update. This will then be used to build temporary vertex and triangle lists containing only triangles in the area of the terrain that fall within that box (see Figure 13.1). These buffers will then be tested for intersection using our standard tests. The end result is that our collision system will provide detection and response for our CTerrain objects without the need to store copies of every terrain triangle. This makes collision detection against height map based terrains very memory efficient as only a handful of triangles will need to be temporarily stored, and only for the lifetime of the collision test. These triangles will then be discarded.

Our collision system will also be extended to deal with the registration of referenced actors. This means that dynamic objects inside the collision system will not always have their own vertex and triangle lists. We may, for example, have a frame hierarchy loaded into a CActor object that contains 20 meshes. This actor might even be used to model a geometric construct that appears many times in our scene; a street lamp for example. We already know that from a rendering perspective, rather than having to load 20 separate actors into memory, all with the same geometric detail, we can just create 20 CObjects that all point to the same actor but have different world matrices (and possibly animation controllers). As long as we inform the actor of the objects world matrix so that it can update itself before it is rendered, we can have just one actor in memory and render it from in 20 different places in our scene.

We also took this concept a step further earlier in the course when we added support for referenced *animated* actors. To do this we expanded the CObject structure to store both a pointer to the actor it is referencing and a pointer to the animation controller for that reference. Before we render the object, we pass its world matrix into the actor so that it can update all its frame matrices correctly for that reference. We also attach the object's controller to the actor. Attaching the instance controller allowed the actor to update its frame matrices so that they reflect the positions and orientations described by the animation controller for that reference.

We have to consider this idea with respect to our collision database. When we add an actor to our collision database, the CCollision class will traverse the hierarchy and add a new dynamic object to the internal list of dynamic objects for every mesh container found in the hierarchy. For each mesh container we find, we will copy over its vertex and index data into a new dynamic object. Clearly, if we have a single actor that contained 10 meshes and we would like to place it in the scene 100 times in different world space locations, we would not want to create 1000 dynamic objects in our collision system (100*10) that all had their own copies of the same vertex data. To address this, we will allow an actor to be added as a reference to an actor that has previously been registered with the collision system. We know from the textbook discussion that when an actor is registered with the collision system, every mesh in that hierarchy will have a dynamic object created for it and each will be assigned the same object set index. Using the previous example of a 10 mesh hierarchy, when the actor is added for the first time, 10 dynamic objects would be created and added to the collision database. However, each of these dynamic objects would be assigned the same object set ID. This is how the collision system knows that all these objects belong to the same hierarchy or group and need to be updated together.

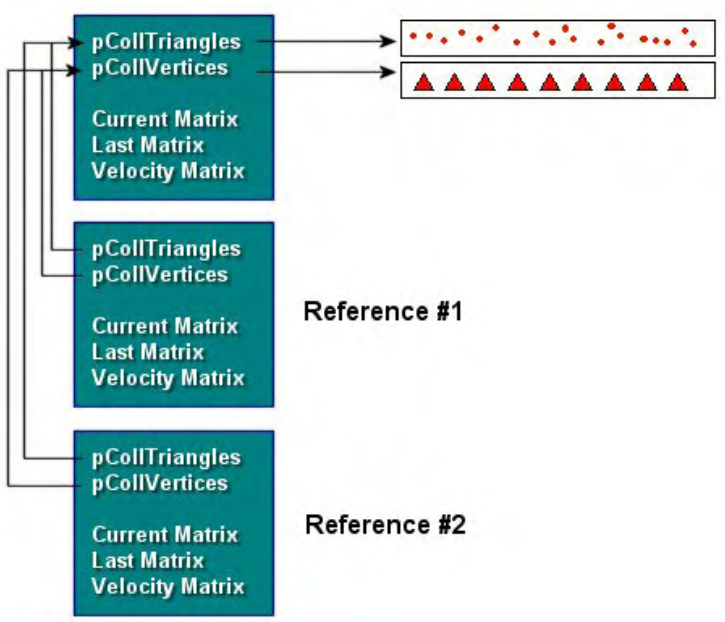


Figure 13.2

The next time we wish to register the same actor with the collision system we can use the CCollision::AddActorReference function. This function will be passed the object set index that was returned by the collision system when the initial actor was added. This function will then loop through the collision systems dynamic object array searching for all dynamic objects that have a matching object set index. It knows that each one it finds belongs to the original actor that is now being referenced. As such, it can just make a new copy of each dynamic object and have the vertex and triangle buffer pointers point to the original dynamic objects buffers.

For example, if we initially add an actor that contains 20 meshes to the collision system, 20 dynamic objects will be created. Each will contain actual vertex and index information from the original meshes in the hierarchy that was registered with the collision system. The registration of this actor would cause

the collision system to issue an object set index back to the application that will have been assigned to each dynamic object created from that actor. If the application subsequently passed this object set index into the CCollision::AddActorReference method, the 20 dynamic objects would be duplicated such that there would now be 40 dynamic objects registered with the collision system. However, the vertex and triangle buffers of the second 20 objects would be pointers to the buffers of the original 20 objects from which they were cloned. Remember from the textbook that a non-referenced dynamic object will contain its geometry data in model space. Since each dynamic object (normal or referenced) contains its own world matrix, the collision system has everything it needs to take that geometry and transform it into world space prior to performing any intersection tests on that dynamic object

We will also examine how the CScene IWF loading functions (e.g., ProcessMeshes and ProcessReference) have been altered so that they can register each mesh, actor, and terrain they create with the collision system. The CScene class owns the CCollision object as a member variable.

Finally, we will discuss how the application (and especially the CPlayer object) uses the collision system in a real-time situation. We will add a better physics model to the movement of our CPlayer so that now concepts like friction and gravity are factored when computing its velocity. The velocity of the CPlayer will ultimately be controlled by how much force is being applied to it. The CGameApp::ProcessInput function will also be altered slightly so that instead of moving the player directly in response to key presses, these now cause an application of force to the player. We then let our simple physics model determine the velocity of the player based on the force being applied, taking into account other factors such as resistant forces (aerodynamic drag, for example).

In this workbook will cover the following:

- Adding geometry registration functions to CCollision
- Adding referenced data to the collision system
- Adding memory efficient terrain registration and collision testing functions for height-map based terrains
- Modifying our IWF and X file loading functions to automate geometry registration with the collision system
- Interfacing the application with our collision system
- Applying a simple Newtonian physics model to our player to accommodate movement that accounts for forces (friction, drag, gravity, etc.)

The CCollision Class

The CCollision class will be a member of our CScene class. It will be charged with the task of determining collisions with scene geometry and generating appropriate responses. The CCollision class has its core intersection functions declared as static members so that they can be used directly by external sources in the event that the full suite of functionality offered by this class is not required by the user. All of the query functions have been discussed in detail in the textbook, but there will be a minor upgrade to the EllipsoidIntersectScene function presented in the textbook to accommodate CTerrain objects that may have been registered with the collision system. So we will have to look at that later.

The CCollision class is declared in CCollision.h and its implementation is in CCollision.cpp. Below we see the CCollision class declaration. We have removed the list of member functions to improve readability, so check the source code for a full list of methods. All we are interested in at the moment are the member variables and structures declared within the class scope. If you have read the textbook, then all of these structures and nearly all of the member variables will be familiar to you. We have added one or two (in bold below) that were not shown in the textbook version of the class to facilitate support for height mapped terrains.

```
class CCollision
{
public:

    //-----------------------------------------------------------------------
    // Public, class specific, Typedefs, structures & enumerators
    //-----------------------------------------------------------------------
    struct CollTriangle
    {
        ULONG       Indices[3];         // Triangle Indices
        D3DXVECTOR3 Normal;             // The cached triangle normal.
        USHORT      SurfaceMaterial;    // The material index of this triangle.
    };

    // Vectors
    typedef std::vector<CollTriangle>   CollTriVector;
    typedef std::vector<D3DXVECTOR3>    CollVertVector;

    struct DynamicObject
    {
        CollTriVector  *pCollTriangles;   // Triangle List
        CollVertVector *pCollVertices;    // vertex List
        D3DXMATRIX     *pCurrentMatrix;   // Pointer to dynamic objects
                                          // application owned external matrix
        D3DXMATRIX      LastMatrix;       // The matrix recorded on the last test
        D3DXMATRIX      VelocityMatrix;   // Describes movement from previous
                                          // position to current position.
        D3DXMATRIX      CollisionMatrix;  // Space in which collision is performed
        long            ObjectSetIndex;   // The index of the set of objects this
                                          // belongs to inside the collision
                                          // systems geometry database.
        bool            IsReference;      // Is this a reference object?
    };

    // Vectors
    typedef std::vector<DynamicObject*> DynamicObjectVector;

    struct CollIntersect
    {
        D3DXVECTOR3     NewCenter;      // The new sphere/ellipsoid centre point
        D3DXVECTOR3     IntersectPoint; // Collision point on surface of ellipsoid
        D3DXVECTOR3     IntersectNormal;// The intersection normal (sliding plane)
        float           Interval;       // The Time of intersection (t value)
        ULONG           TriangleIndex;  // The index of the intersecting triangle
        DynamicObject * pObject;        // A pointer to the dynamic object that has
                                        // been collided with.
    };
```

```
    // Vectors
    typedef std::vector<CTerrain*>      TerrainVector;

    // Constructors & Destructors for This Class.
             CCollision();
    virtual ~CCollision();

 private;

    // Private Variables for This Class.
    CollTriVector       m_CollTriangles;
    CollVertVector      m_CollVertices;
    DynamicObjectVector m_DynamicObjects;

    TerrainVector       m_TerrainObjects;
    USHORT              m_nTriGrowCount;
    USHORT              m_nVertGrowCount;

    USHORT              m_nMaxIntersections;
    USHORT              m_nMaxIterations;
    CollIntersect      *m_pIntersections;

    D3DXMATRIX          m_mtxWorldTransform;
    long                m_nLastObjectSet;
};
```

We have added only three new member variables beyond the version covered in the textbook. Let us briefly discuss them.

TerrainVector m_TerrainObjects
In the last lesson we introduced our CTerrain class, which encapsulated the creation of terrain geometry from height maps. We also added support in our IWF loading code for the GILES™ terrain entity. We can use GILES™ to place terrain entities in our IWF level and have those terrains created and positioned by our CTerrain class at load time. Each CTerrain object contains a height map and the actual geometric data created from that height map.

We will develop a memory efficient way for these terrain objects to be registered with the collision system by using the terrain height map to build only a temporary list of triangles in the region of the swept sphere as and when they are needed. As terrains are usually quite large and are comprised of many triangles, we certainly want to avoid storing a copy of every terrain triangle in the static geometry database. All our collision system will need is an array where it can store CTerrain pointers. The CCollision interface will expose an AddTerrain method which will essentially just add the passed CTerrain pointer to this internal list of terrain objects. That is all it does. No geometry is added to the collision system. When the EllipsoidIntersectScene function is called in the detection step, these CTerrain pointers will be used to access the height map of each terrain. These height maps will then be used to build only triangles that are within the same region as the swept sphere.

This member variable will be used to store any pointers to CTerrain objects that are registered with the collision system. It is of type TerrainVector, which is a typedef for an STL vector of CTerrain pointers.

typedef std::vector<CTerrain*> TerrainVector;

USHORT m_nTriGrowCount
USHORT m_nVertGrowCount
STL vectors are used throughout the collision system for storing vector and triangle data. As you know, STL vectors encapsulate the idea of a dynamic array. The STL vector has methods to easily add and delete elements to/from an array as well as methods to resize an array if we have added elements up to its maximum capacity.

The collision system has a vector for storing static triangle structures and a vector for storing static vertices. Additionally, each dynamic object we create will also have its own vectors to store its model space triangle and vertex data. Finally, with our dynamic terrain mechanism, we will be building triangle data on the fly and adding that triangle and vertex data to temporary vectors so that they can be passed into the intersection methods of the collision system. Suffice to say, that during the registration stages especially, we will be adding a lot of triangles and vertices to these vectors. This is especially true of the collision systems static triangle and vertex buffers, since they will have geometry data cumulatively added to them as multiple files are loaded and multiple meshes registered with the static database.

We never know how much space we are going to need in these vectors until we have loaded and registered all the geometry, so we usually set the initial capacity of these buffers to some initial small value. If we wish to add a vertex or a triangle to one of these vectors but find that it is full, we can simply resize the array and add an additional element on the end to place our new data. While the STL vector has methods to allow us to do that easily, we must remember that underneath the hood an array resize is still happening and they can be quite costly. Usually an array resize results in a totally new memory block being allocated that is large enough to store the new capacity before the data from the old memory block is copied into it. The memory of the original array is then deleted and the variable adjusted to point at the new memory block. Of course, all of this happens behind the scenes, but if we imagine that we wish to add 50,000 vertices to the collision databases static vertex vector, as each one is added, the array would have to be resized so that in the worst case there is only enough space for that new vertex. In this worst case, that would mean that while registering those 50,000 vertices, we have also performed 50,000 memory allocations, 50,000 block memory copies and 50,000 memory de-allocations. Again, that is a worst case scenario as most STL vector implementations are far more efficient than this. Still, we wish to avoid slowing down our registration of geometry too much and would like to try to avoid excessive memory fragmentation.

The solution is simple if we are prepared to spare a little memory. We can instead make the decision that when a vector is full and we wish to add another element to it, we can increase its capacity by a fixed size (e.g., 500). We can now add another 500 vertices before we fill it up and have to increase its capacity again. This would cut down our (worst case) 50,000 resize example down to 100. To be sure, at the end of the loading process, this vector could have a few hundred unused elements at the end of its array. But even this can be corrected after the loading process is complete by resizing the vector so that the capacity of the vector matches its number of contained elements.

The m_nTriGrowCount and m_nVertGrowCount variables contain the resize amount for times when vertices are triangles are being added to a data buffer that is currently full. If you set m_nTriGrowCount to 250, when the m_nCollTriangles vector reaches capacity and more space is needed, it will be resized to accommodate another 250 triangles (even though we might only be adding just one). We have seen all of this logic many times before, so it should be quite familiar to you.

D3DXMATRIX m_mtxWorldTransform

The m_mtxWorldMatrix member is used when adding of triangle data to the static database. When we load meshes from a file, those meshes will typically be defined in model space and accompanied by a world transformation matrix that describes the location of that mesh within the scene. When we are adding such mesh data to our static collision geometry database, we are only interested in the world space vertex positions. Therefore, the vertices of the mesh should be transformed by that matrix prior to being stored in the static collision database. The CCollision class exposes a SetWorldTransform method to set this matrix member to the world transform for the mesh that is about to have its vertex data registered. When the vertices of that mesh are passed into the CCollision::AddIndexedPrimitive method to register them with the static database, the vertices will be transformed by this matrix into world space prior to being added to the static collision geometry list. Thus, application registration of three static model space meshes with the collision system would take on the following form:

```
pCollision->SetWorldTransform(…);
pCollision->AddIndexedPrimitive(…);

pCollision->SetWorldTransform(…);
pCollision->AddIndexedPrimitive(…);

pCollision->SetWorldTransform(…);
pCollision->AddIndexedPrimitive(…);
```

Let us now discuss the functions to the CCollision class that we have not yet seen. We will start by looking at the simple initialization functions (the constructor, etc.) and will then discuss the geometry registration functions over several sections. We will then look at the upgraded EllipsoidIntersectScene function and see how we have added intersection testing for registered CTerrain objects.

CCollision::CCollision()

In our application, we will only need to use one instance of a CCollsion object. To keep things simple, this object will be a member of the CScene class. The only constructor is the default one, which simply initializes the member variables of the collision system at application startup.

```
CCollision::CCollision()
{
    // Setup any required values
    m_nTriGrowCount     = 100;
    m_nVertGrowCount    = 100;
    m_nMaxIntersections = 100;
    m_nMaxIterations    = 30;
    m_nLastObjectSet     = -1;

    // Reset the internal transformation matrix
    D3DXMatrixIdentity( &m_mtxWorldTransform );

    // Allocate memory for intersections
    m_pIntersections    = new CollIntersect[ m_nMaxIntersections ];
}
```

The default STL vector resize quantity is set to 100 for both vertex and triangle buffers. Every time our collision system tries to add another triangle or another vertex to an STL vector that is currently filled to capacity, the vector will have its capacity increased by 100. We also set the size of the intersection buffer to 100. This is the CollIntersect buffer that is used by the EllipsoidIntersectScene function to return collision information back to the response phase. We use a default value of 100 as it is unlikely a moving entity will collide with 100 triangles in a single update. Either way, the collision system is really only interested in the first intersection, so even if the buffer is not large enough to return all intersection information structures back to the response step, it will not adversely effect the collision detection or the response phase. The remaining intersection information is only used to compile a bounding box that is returned to the application. Feel free to change this value if needed.

We also set the maximum number of iterations that will be executed by the collision system to a default of 30 loops. If our CollideEllipsoid cannot deplete the slide vector and calculate the final resting place the of the ellipsoid after 30 tries, the collision detection phase will be called one more time and the first non-intersecting position returned will be used. This should rarely happen, but it allows us to cover ourselves when it does.

There is also a member variable called m_nLastObjectSet which is used by the system to store the last object set index that was issued. This is set to -1 initially because we have not yet added any dynamic objects and our collision system has not yet issued any object set indexes. Every time a new group of dynamic objects is registered with the collision system, this value will be incremented and assigned to each dynamic object in that group.

We also set the collision object's world transformation matrix to an identity matrix. The application can set this to a mesh world matrix when it wishes to register a mesh with collision database.

Finally we allocate the array of CollIntersect structures that will be used as the transport mechanism to return triangle intersection information from the detection phase (the EllipsoidIntersectScene function) back to the response phase (the CollideEllipsoid function).

CCollision::SetTriBufferGrow / SetVertBufferGrow

These two functions are simple utility functions that allow you to alter the amount that the capacity of either a vertex or triangle STL vector is expanded when it becomes full and new data is about to be added.

```
void CCollision::SetTriBufferGrow( USHORT nGrowCount )
{
    // Store grow count
    m_nTriGrowCount = max( 1, nGrowCount );
}
```

```
void CCollision::SetVertBufferGrow( USHORT nGrowCount )
{
    // Store grow count
    m_nTriGrowCount = max( 1, nGrowCount );
}
```

Notice that in each function we do not simply store the passed nGrowCount value in the respective CCollision member variables because we must not ever allow these values to be set to zero. If we did, it would break our collision system. We use these values to make room for the extra elements that are about to be added, so it must be set to at least 1.

CCollision::SetMaxIntersections

This function allows you to alter the size of the buffer that is used to transport triangle collision information from the detection phase to the response phase. It essentially defines how many intersections in a given update we are interested in recording information for. This must be set to a size of at least 1 since the response phase uses the first element in this buffer to extract the new ellipsoid position, intersection point, and collision normal. Any additional elements in this array are collisions with other triangles at the exact same *t* value. The application may or may not wish to know which other triangles were hit and as such, we can adjust the size of this array to fit our needs. The default size is 100, but the application can change this default value by calling this function.

```
void CCollision::SetMaxIntersections( USHORT nMaxIntersections )
{
    // Store max intersections
    m_nMaxIntersections = max( 1, nMaxIntersections );

    // Delete our old buffer
    if ( m_pIntersections ) delete []m_pIntersections;
    m_pIntersections = NULL;

    // Allocate a new buffer
    m_pIntersections = new CollIntersect[ m_nMaxIntersections ];
}
```

Notice how the function will not allow the value of m_nMaxIntersections to be set to a value of less than 1 because the system needs to record at least one collision in order to employ the response step. The function then deletes the previous array and allocates a new array of the requested size to replace it.

Collision::SetMaxIterations

This function allows the application to tailor the maximum number of response iterations that will be executed while trying to resolve the final position of the ellipsoid in a collision update (see earlier discussions). The default is 30 iterations (see constructor).

```
void CCollision::SetMaxIterations( USHORT nMaxIterations )
{
    // Store max iterations
    m_nMaxIterations = max( 1, nMaxIterations );
}
```

Once again, we must have at least a single iteration or our collision detection and response code would never be called at all.

CCollision::SetWorldTranform

This simple function can be used by the application to send a world transformation matrix to the collision system before registering any vertex and triangle data for a mesh that needs to be converted into world space.

```
void CCollision::SetWorldTransform( const D3DXMATRIX& mtxWorld )
{
    // Store the world matrix
    m_mtxWorldTransform = mtxWorld;
}
```

When we load internal meshes exported from GILES™, the vertices are already defined in world space, so we can pass them straight into the AddIndexedPrimtive function and leave this matrix set at identity (default). When this is not the case, we must set this matrix prior to registering each model space mesh.

Geometry Registration Methods

This section will discuss the geometry registration methods exposed by the CCollision interface. These are the functions an application will use to register pre-loaded or procedurally generated geometry with the collision system prior to entering the main game loop.

CCollision::AddBufferData

Many of the registration functions that are exposed to the application by the CCollision class will typically involve adding vertex data and triangle data to STL vectors. Whether these vectors are the ones that store the static vertex and triangle geometry buffers or whether they represent the vertex and triangle geometry buffers for a single dynamic object, we will wrap this functionality in a private generic function that can be called to perform this core task for all registration functions. Now that we are adding specialized terrain support to our collision system, we will need to build triangle data for that terrain on the fly when the terrain is queried for collision. These terrain triangles and vertices will also need to be added to temporary STL vectors so that they too can be passed into the EllipsoidIntersectBuffers function which performs the core intersection processes.

Before we discuss the geometry registration functions exposed by the CCollision class, we will first examine the code to the CCollision::AddBufferData method. This is a generic function that is passed two STL vectors (one stores vertices and another stores triangles) and arrays of vertex and index data that should be added to these STL vectors. This function is called from many places in the collision system to take vertex and index data, create triangle information from it, and then add the triangle data to the two passed buffers. By placing this code in a generic function like this, we can use the same code to add geometry to the static geometry STL vectors, the STL vector of each dynamic object, and the temporary STL vectors that are used at runtime to collect relevant terrain data in response to a collision query.

This function will convert the input data into the format that our vertex and triangle STL vectors require. This will involve constructing triangles from the passed indices and generating the triangle normals. This information can then be stored in a CollTriangle structure and added to the passed triangle buffer. The function is also responsible for recognizing when an STL vector is full and expanding its capacity by the values stored in the m_nTriGrowCount and the m_nVertGrowCount member variables.

Finally, remember that an application will never directly call this function; it is private. It is simply a helper function that is used internally by the collision system to cut down on the amount of redundant code that would otherwise have to be added to each registration function. All of these registration functions need to add geometry to buffers, so there would be no sense in duplicating such code in every function.

Let us look at this function a few sections at a time, starting first with its parameter list.

```
bool CCollision::AddBufferData( CollVertVector& VertBuffer,
                                CollTriVector& TriBuffer,
                                LPVOID Vertices,
                                LPVOID Indices,
                                ULONG VertexCount,
                                ULONG TriCount,
                                ULONG VertexStride,
                                ULONG IndexStride,
                                const D3DXMATRIX& mtxWorld )
{
    ULONG        i, Index1, Index2, Index3, BaseVertex;
    UCHAR       *pVertices = (UCHAR*)Vertices;
    UCHAR       *pIndices  = (UCHAR*)Indices;
    CollTriangle Triangle;
    D3DXVECTOR3  Edge1, Edge2;

    // Validate parameters
    if ( !Vertices || !Indices || !VertexCount || !TriCount ||
          !VertexStride || (IndexStride != 2 && IndexStride != 4) )
       return false;
```

The first two parameters are the STL vectors that are going to receive the vertex and triangle data passed into this function. These buffers may be the static scene buffers or the buffers of a single dynamic object. In this function, we are not concerned with who owns these buffers or what they are for, only with filling them with the passed data.

The third and fourth parameters are void pointers to the vertex and index data that we would like to format into triangle data that our collision system understands. These might be the void pointers returned to the application when it locked the vertex and index buffers of an ID3DXMesh, or just pointers to blocks of system memory that contain vertex and index data. The VertexCount and TriCount parameters instruct the function as to how many vertices and indices are contained in these passed arrays. For example, the VertexCount parameter tells us how many vertices are in the Vertices array and the TriCount parameter tells us how many triplets of indices exist in the Indices array.

The VertexStride parameter tells the function about the size of each vertex (in bytes) in the passed vertex array. Although our function will only be interested in the positional X, Y and Z components of each vertex stored in the first 12 bytes of each vertex structure, each vertex may contain other data that our collision system is not interested (e.g., texture coordinates or a vertex normal). We will need to know the size of each vertex in the function so that we can iterate though each vertex in the array and extract only the information we need.

The IndexStride parameter should contain a value describing the size (in bytes) of each index in the indices array. As an index will be either a WORD or DWORD in size, this value will be either 2 or 4 respectively. We need to know this so that we know how to traverse the array.

The final parameter is a matrix that should be used to transform the vertices in the vertex array (into world space) prior to adding them to the STL vector.

Notice how we cast the vertex and index arrays pointers to local unsigned char pointers (pVertices and pIndices). These pointers will allow us to step through those memory blocks one byte at a time so that we can extract the information we need. We also allocate a single CollTriangle structure that will be used to temporarily build each triangle we are going to add to the CollTriangle STL vector.

Our first real task is to test the current maximum capacity of the passed STL vector that will receive the vertex data. If it is not large enough to contain all the vertices it currently contains (VertBuffer.Size) plus the number of vertices we are about to add (VertexCount) then we will have to grow the vector. We grow the vector by the number of elements stored in the m_nVertGrowCount variable (by default set to 100). Since even this may not be enough, we execute this code in a while loop so the vector will continually have its capacity increased until such a time as it is large enough to accept all the vertices we intend to add.

```
    // Catch template exceptions
    try
    {
        // Grow the vertex buffer if required
        while ( VertBuffer.capacity() < VertBuffer.size() + VertexCount )
        {
            // Reserve extra space
            VertBuffer.reserve( VertBuffer.capacity() + m_nVertGrowCount );

        } // Keep growing until we have enough
```

We also do exactly the same thing for the STL vector that is going to receive the triangle information. We resize its capacity until it is large enough to contain the triangles it already contains plus the ones we wish to add to it in this function.

```
        // Grow the triangle buffer if required
        while ( TriBuffer.capacity() < TriBuffer.size() + TriCount )
        {
            // Reserve extra space
            TriBuffer.reserve( TriBuffer.capacity() + m_nTriGrowCount );

        } // Keep growing until we have enough
```

Before we add any vertices to the vertex vector, we must record the current number of vertices that are stored there. We will need to offset the indices we are about to add by this amount so that when the are placed into the CollTriangle structure and added to the triangle vector, they still reference the (original) vertices that were passed in the accompanying vertex array.

We store the current number of vertices in the vector in a local variable called BaseVertex. When we store the indices in the triangle structure, we will add BaseVertex to each index. This will ensure that the triangle indices we add index into the correct portion of the vertex vector and maintain their relationship with their associated vertices.

```
        // Store the original vertex count before we copy
        BaseVertex = VertBuffer.size();
```

Now we will loop through each vertex in the passed vertex array using the vertex stride to move our byte pointer from the start of a vertex to the next. Our byte pointer pVertices will always point to the start of a vertex in this array. Since we are only interested in the positional 3D vector stored in the first 12 bytes, we can cast this pointer to a D3DXVECTOR3 structure to extract the values into a temporary D3DXVECTOR3. We will then transform this vertex position by the input world transformation matrix before adding the transformed position to the vertex vector (using the vector::push_back method).

```
        // For each vertex passed
        for ( i = 0; i < VertexCount; ++i, pVertices += VertexStride )
        {
            // Transform the vertex
            D3DXVECTOR3 Vertex = *(D3DXVECTOR3*)pVertices;
            D3DXVec3TransformCoord( &Vertex, &Vertex, &mtxWorld );

            // Copy over the vertices
            VertBuffer.push_back( Vertex );

        } // Next Vertex
```

At this point we have successfully transformed all the vertices in the passed array into world space and added them to the passed vertex STL vector. Now we must add the triangles to the passed CollTriangle vector.

We set up a loop to count up to the value of TriCount. Since the data is assumed to represent an indexed triangle list, we know that there should be 3*TriCount indices in the passed array. For each iteration of the loop, we will extract the next three indices in the array and make a triangle out of them. We will also generate the triangle normal before adding the triangle structure to the CollTriangle vector. Our collision system will need to know the triangle normal if the triangle has its interior collided with as this will be used as the slide plane normal.

First we will examine the section of code that extracts the three indices from the array. This may initially look a little strange, but we will explain how it works in a moment.

```
        // Build the triangle data
        for ( i = 0; i < TriCount; ++i )
        {
```

```
            // Retrieve the three indices
            Index1 = ( IndexStride == 2 ? (ULONG)*((USHORT*)pIndices)
                                        : *((ULONG*)pIndices) );
            pIndices += IndexStride;

            Index2 = ( IndexStride == 2 ? (ULONG)*((USHORT*)pIndices)
                                        : *((ULONG*)pIndices) );
            pIndices += IndexStride;

            Index3 = ( IndexStride == 2 ? (ULONG)*((USHORT*)pIndices)
                                        : *((ULONG*)pIndices) );
            pIndices += IndexStride;
```

We currently have a byte sized pointer to the index array, so we know that we are going to have to cast the index pointer to either a USHORT or a ULONG (WORD or DWORD) pointer in order to dereference that pointer and grab a copy of the actual index in the correct format (depending on whether we have been passed 16 or 32-bit indices). However, our CollTriangle structures *always* store indices as ULONGs (32-bit values), so in the case where we have a byte pointer to 16-bit indices, a double cast is necessary.

To clarify, if the index stride is 2, then we have an array of 16-bit (USHORT) indices. When this is the case we must first cast the byte pointer (pIndices) to a pointer of the correct type (USHORT):

```
(USHORT*) pIndices
```

We then want to dereference this pointer to get the actual value of the index pointed to:

```
*((USHORT*)pIndices)
```

We now have a 16-bit value, but our collision system wants it as a 32-bit value so we do an additional cast to a ULONG on the de-referenced 16 bit value.

```
(ULONG)*((USHORT*)pIndices)
```

If the index stride parameter is not set to 2, we have a byte pointer to an array of 32-bit (ULONG) values. When this is the case, we can simply cast the byte pointer to a ULONG pointer and deference the result.

```
*((ULONG*)pIndices)
```

Notice that as we extract the information for each index into the local variables (Index1, Index2, and Index3), we increment the byte pointer by the stride of each index (IndexStride) so that it moves the correct number of bytes forward to be pointing at the start of the next index in the array.

In the next section of code we start to fill out the local CollTriangle structure with the information about the current triangle we are about to add. In this function, we set the surface material index of each triangle to zero as this can be set by a higher level function. The surface material index allows you to assign some arbitrary numerical value to a collision triangle so that your application can determine what it should do if a collision with a triangle using that material occurs. For example, if the triangle has a

toxic material or texture applied, the application may wish to degrade the health of the player after contact is made.

In the following code, we also add the three indices we have fetched from the indices array to the indices array of the CollTriangle structure. As we add each index, we remember to add on BaseVertex to account for the fact that the original indices were relative to the start of the passed vertex array and not necessarily the start of the vertex STL vector.

```
            // Store the details
            Triangle.SurfaceMaterial = 0;
            Triangle.Indices[0]      = Index1 + BaseVertex;
            Triangle.Indices[1]      = Index2 + BaseVertex;
            Triangle.Indices[2]      = Index3 + BaseVertex;
```

We now need to generate a normal for this triangle. This will be used by the collision detection phase as the collision (slide plane) normal when direct hits with the interior of the triangle occur.

In order to calculate the normal of a triangle we need to take the cross product of its two edge vectors. In order to calculate the edge vectors we use our new indices to fetch the triangles vertices from the vertex vector.

```
            // Retrieve the vertices themselves
            D3DXVECTOR3 &v1 = VertBuffer[ Triangle.Indices[0] ];
            D3DXVECTOR3 &v2 = VertBuffer[ Triangle.Indices[1] ];
            D3DXVECTOR3 &v3 = VertBuffer[ Triangle.Indices[2] ];
```

We now create an edge vector from the first vertex to the second vertex and another from the first vertex to the third vertex and normalize the result.

```
            // Calculate and store edge values
            D3DXVec3Normalize( &Edge1, &(v2 - v1) );
            D3DXVec3Normalize( &Edge2, &(v3 - v1) );
```

We then perform a safety check to make sure that we have not been passed a degenerate triangle. We take the dot product of the two edge vectors we just calculated. If the absolute result is equal to 1.0 (with tolerance) we know that the three vertices of the triangle exist on the same line. This triangle will provide no benefit in our collision system as it has zero volume and cannot be collided with. When this is the case, we skip to the next iteration of the triangle generation loop and avoid adding the current triangle to the triangle vector.

```
            // Skip if this is a degenerate triangle, we don't want it in our set
            float fDot = D3DXVec3Dot( &Edge1, &Edge2 );
            if ( fabsf(fDot) >= (1.0f - 1e-5f) ) continue;
```

We now take the cross product of the two edge vectors and normalize the result to get our triangle normal. We store the result in the CollTriangle structure before finally adding the triangle structure to the back of the CollTriangle vector.

```
            // Generate the triangle normal
            D3DXVec3Cross( &Triangle.Normal, &Edge1, &Edge2 );
            D3DXVec3Normalize( &Triangle.Normal, &Triangle.Normal );

            // Store the triangle in our database
            TriBuffer.push_back( Triangle );

        } // Next Triangle

    } // End Try Block

    catch ( ... )
    {
        // Just fail on any exception.
        return false;

    } // End Catch Block

    // Success!
    return true;
}
```

CCollision::AddIndexedPrimitive

This is a public method that can be used to register mesh vertex and index data with the collision system. Lab Project 13.1 uses this function when loading the internal meshes from an IWF file. It will take the loaded vertex and index lists and pass them in along with information about the size of the vertex and index structures. This function is used to register mesh data with the **static** scene geometry database.

AddIndexedPrimitive is just a wrapper around the previous function. You should take note of the variables that are passed by this function to the AddBufferData method. For the first and second parameters it passes in the m_CollVertices and m_CollTriangles member variables. These are the STL vectors used by the CCollision class to contain all its static vertex and triangle geometry. In other words, the AddBufferData function will add the passed geometry data to the static buffers of the collision system. Notice also that the member variable m_mtxWorldTranform is passed in as the final parameter. This is the collision system's current world transformation matrix that will be applied to the static geometry being registered. Now you can see how setting this matrix (via the SetWorldTransform method) before registering a mesh with the collision system transforms the vertices of that mesh into world space before adding them to the static database.

```
bool CCollision::AddIndexedPrimitive( LPVOID Vertices,
                                      LPVOID Indices,
                                      ULONG VertexCount,
                                      ULONG TriCount,
                                      ULONG VertexStride,
                                      ULONG IndexStride )
{
    // Add to the standard buffer
    return AddBufferData(     m_CollVertices,
                              m_CollTriangles,
```

```
                                Vertices,
                                Indices,
                                VertexCount,
                                TriCount,
                                VertexStride,
                                IndexStride,
                                m_mtxWorldTransform );
}
```

CCollision::AddIndexedPrimitive (Overloaded)

This next method overloads the previous one and allows you to specify a numerical material index that will be assigned to each triangle. For example, if you wanted every triangle of this a mesh that was registered with the collision system to have a material index that matches its subset ID in the original D3DX mesh, you would call this AddIndexedPrimitive version multiple times for the mesh, once for each subset. In each call, you would pass only the vertices and indices of the current subset you are rendering and the subset ID as the material index.

```
bool CCollision::AddIndexedPrimitive( LPVOID Vertices,
                                      LPVOID Indices,
                                      ULONG VertexCount,
                                      ULONG TriCount,
                                      ULONG VertexStride,
                                      ULONG IndexStride,
                                      USHORT MaterialIndex )
{
    ULONG i, BaseTriCount;

    // Store the previous triangle count
    BaseTriCount = m_CollTriangles.size();

    // Add to the standard buffer
    if ( !AddBufferData( m_CollVertices,
                         m_CollTriangles,
                         Vertices,
                         Indices,
                         VertexCount,
                         TriCount,
                         VertexStride,
                         IndexStride,
                         m_mtxWorldTransform ) ) return false;

    // Loop through and assign the specified material ID to all triangles
    for ( i = BaseTriCount; i < m_CollTriangles.size(); ++i )
    {
        // Assign to triangle
        m_CollTriangles[i].SurfaceMaterial = MaterialIndex;
    }

    // Success
    return true;
}
```

The above function first records how many triangles are in the scene's static triangle vector before it adds the new buffer data, and stores the result in the BaseTriCount local variable. The AddBufferData function is then called as before to add the vertex and triangle data to the collision system's static geometry database. When the function returns, BaseTriCount will contain the index of the first triangle that was added to the buffer in this call. We can then start a loop through every triangle from the first new one that was added to the end of the triangle buffer. This is the range of triangles that were just added. We set the SurfaceMaterial member of each triangle in this range to the material index passed into the function by the caller.

Collision::AddTerrain

Although we have not yet explained exactly how our collision detection system will dynamically generate triangle data from terrain height maps for collision purposes, we know that it will need access to the CTerrain objects which the application intends to use as collision geometry. The CCollision class stores its registered terrains as a simple vector of CTerrain pointers.

This function is used by application to register CTerrain objects with the static collision database. This function is extremely simple since the collision system will use the CTerrain object pointer to generate the actual collision geometry during the intersection tests. All we need to do in this function is add a pointer to the passed terrain to the collision system's CTerrain pointer vector. We must also call the CTerrain->AddRef method to let the terrain object know that another object has a pointer to its interface. Remember, we recently added the COM reference counting mechanism to the CTerrain class and it must be used (otherwise the terrain object could delete itself from memory prematurely).

```
bool CCollision::AddTerrain( CTerrain * pTerrain )
{
    // Validate parameters
    if ( !pTerrain ) return false;

    // Catch Exceptions
    try
    {
        // We own a reference, make sure it's not deleted.
        pTerrain->AddRef();

        // Store the terrain object
        m_TerrainObjects.push_back( pTerrain );

    } // End Try Block

    catch ( ... )
    {
        // Simply bail
        return false;

    } // End Catch Block

    // Success!
    return true;
}
```

CCollision::AddDynamicObject

In the textbook we discussed how dynamic objects would be integrated into the collision system. In terms of our collision system, a dynamic object is a scene object that cannot be stored in the usual static database because its world space position/orientation can change at any moment. A simple example is the mesh of a sliding door. We would want the player to be able to collide with this door so that he/she is not allowed access to a certain area when the door is closed. The door mesh cannot be transformed into world space during registration because the application may wish to alter its world matrix in response to a game event.

When we register a dynamic object with the collision system, a new DynamicObject structure is allocated and added to the collision system's dynamic object STL vector. A dynamic object stores its own model space vertex and triangle data and a pointer to the matrix that the application can update. Whenever the application updates the world matrix for a dynamic object, it should call the CCollision::ObjectSetUpdated method to allow the collision system to recalculate the velocity matrix and collision matrix used by the intersection functions. This was all discussed in the textbook, so we will not review that material here.

This particular function should be used if the caller would like to register a single mesh as a dynamic object. We will not be using this function in Lab Project 13.1 as all the dynamic objects we register will be actors containing complete frame hierarchies of meshes. There are separate functions to aid in the registration of actors.

An application that would like to register a single mesh object with the collision system as a dynamic object should pass this function the model space vertex and index data and a pointer to the application owned world matrix for the dynamic object. A copy if this pointer will be cached in the dynamic object structure so that both the collision system and the application have direct access to it. The application will be responsible for updating the world matrix and the collision system will be able to work with those updates.

Before we look at the code remember that whenever a dynamic object is added to the collision database, it is assigned a collision ID which is referred to as an object set index. This is like the handle for the object within the collision system and is the means by which the application can inform the collision system that the matrix of that object has been updated. Because we may want to add multiple dynamic objects as part of the same object group (they share the same object set index) we have a final boolean parameter to this function. If set to true, the CCollision::m_nLastObjectSet member will be increased, thus creating a new object group assigned to the dynamic object. If this boolean is set to false then the m_nLastObjectSet index will not be increased and the object will be assigned the same index as a previous object that has been registered. This allows us to assign multiple dynamic objects the same ID, much like when an actor is registered with the collision system. If we assigned multiple objects the same ID, we can reference and update all those dynamic objects as a single group using a single collision index. If you want each dynamic object you register to have its own object set index (most often the case) then you should pass true as this parameter.

When this function is called to add the first dynamic object to the collision system, the current value of m_nLastObjectSet will be set to -1, which is not a valid object set index. So you should never pass false

to this function when registering the first dynamic object. Essentially, you are stating that you would like the dynamic object to be added to a previously created group, which makes no sense in the case of the first dynamic object when no groups have yet been created. Just in case, the function will force this boolean to true if this is the first dynamic object that is being added to the system.

The first section of code creates an identity matrix. You will why this is the case in a moment. The function tests to see if the current value of m_nLastObjectSet is smaller than zero and if so, then we know this is the first dynamic object that has been added to the system and the NewObjectSet Boolean is forced to true. The value of the Boolean parameter is then checked and if set to true, the current value of the member variable m_nLastObjectSet is incremented to provide a new object set index for this object. The function then allocates a new DynamicObject structure and initializes it to zero for safety. We then allocate the vertex and triangle STL vectors which will be pointed at by the dynamic object structure and used to contain the model space geometry of the dynamic object's mesh

```
long CCollision::AddDynamicObject(  LPVOID Vertices,
                                    LPVOID Indices,
                                    ULONG VertexCount,
                                    ULONG TriCount,
                                    ULONG VertexStride,
                                    ULONG IndexStride,
                                    D3DXMATRIX * pMatrix,
                                    bool bNewObjectSet /* = true */ )
{
    D3DXMATRIX      mtxIdentity;
    DynamicObject * pObject = NULL;

    // Reset identity matrix
    D3DXMatrixIdentity( &mtxIdentity );

    // Ensure that they aren't doing something naughty
    if ( m_nLastObjectSet < 0 ) bNewObjectSet = true;

    // We have used another object set index.
    if ( !bNewObjectSet ) m_nLastObjectSet++;

    try
    {
        // Allocate a new dynamic object instance
        pObject = new DynamicObject;
        if ( !pObject ) throw 0;

        // Clear the structure
        ZeroMemory( pObject, sizeof(DynamicObject) );

        // Allocate an empty vector for the buffer data
        pObject->pCollVertices  = new CollVertVector;
        if ( !pObject->pCollVertices ) throw 0;

       pObject->pCollTriangles = new CollTriVector;
        if ( !pObject->pCollTriangles ) throw 0;
```

At this point we have a new dynamic object which also has pointers to two new (currently empty) STL vectors for the model space the vertices and triangles of the mesh. We set the dynamic object's matrix

pointer to point at the matrix passed by the application. This will describe the current world space transformation of the dynamic object at all times. We also copy the values of this matrix into the LastMatrix and CollisionMatrix members of the structure since the object is currently stationary. These values will be set correctly the first time the CCollision::ObjectSetUpdated method is called prior to any collision tests.

```
        // Store the matrices well need for
        pObject->pCurrentMatrix  = pMatrix;
        pObject->LastMatrix      = *pMatrix;
        pObject->CollisionMatrix = *pMatrix;
        pObject->ObjectSetIndex  = m_nLastObjectSet;
        pObject->IsReference     = false;
```

Notice in the above code that we then assign the value of the m_nLastObjectSet member variable as the dynamic object's ID. If the Boolean parameter was set to false, this will not have been incremented and the object will be assigned the same ID as the last dynamic object that was created (i.e., adding this dynamic object to a pre-existing object set). If the Boolean parameter was set to true, then the value would have been incremented, creating a new and currently unique ID, making this object the first to be added to this new object set. We also set the reference member of the structure to false since this is not a referenced dynamic object (it has its own vertex and triangle data).

Our next task is to format the passed model space vertices and indices of the dynamic object's mesh and add them to its STL geometry vectors. This is no problem since we can once again use our AddBufferData function for this task.

```
        // Add to the dynamic objects database
        if ( !AddBufferData(  *pObject->pCollVertices,
                              *pObject->pCollTriangles,
                              Vertices,
                              Indices,
                              VertexCount,
                              TriCount,
                              VertexStride,
                              IndexStride,
                              mtxIdentity ) ) throw 0;

        // Store the dynamic object
        m_DynamicObjects.push_back( pObject );

    } // End try block
```

The first and second parameters are the dynamic object's geometry vectors to be filled with the formatted data. The final parameter is the identity matrix we created at the head of the function. We do this because we know that the AddBufferData function will transform all the vertices we pass it by this matrix to transform them into world space. In the case of a dynamic object, we want the vertices to remain in model space since they will be transformed into world space on fly by the collision detection routines. After the AddBufferData function returns, our dynamic object structure will be fully populated and its geometry vectors will contain all the relevant model space vertices and triangles. As a final step, we then add this dynamic object structure to the collision system's dynamic object array.

If anything went wrong in the process and an exception was thrown, we free any memory we may have allocated in the catch block before returning an error value of -1.

```
    catch (...)
    {
        // Release the object if it got created
        if ( pObject )
        {
            if ( pObject->pCollVertices  ) delete pObject->pCollVertices;
            if ( pObject->pCollTriangles ) delete pObject->pCollTriangles;
            delete pObject;

        } // End if object exists

        // Return failure
        return -1;

    } // End Catch Block
```

If we get this far then everything worked and we return the object set index that was assigned to the dynamic object. Our application will store the object set indices of each dynamic object we register in the CObject structure that owns the mesh. When we update the matrix of a CObject, we can then use this object set index to notify the collision system that the matrices of the dynamic object need to be re-cached using the CCollision::ObjectSetUpated method. This was discussed in the textbook.

```
    // Return the object index
    return m_nLastObjectSet;
}
```

CCollision::AddActor

Adding single meshes as dynamic objects is certainly useful, but most of our previous demos have used our CActor class. As we are by now intimately aware, our CActor class encapsulates the loading, rendering and animation of complete frame hierarchies that may contain multiple meshes. We will definitely want our collision system to expose a way to also register these multi-mesh constructs with our collision system.

An actor that has no animation data or that is not intended to be moved throughout the scene is essentially a static actor. Registering it with the collision system will mean storing the triangles of each mesh in that hierarchy in the static collision database. This is not very difficult. We just have to traverse the hierarchy searching for mesh containers and for each one container we find, we will lock its vertex and index buffers and transform the vertices into world space using the mesh container's absolute frame matrix (not the parent relative matrix). This does mean that we will also need to be passed the current world matrix for the entire actor as it will influence the world matrices stored at each frame in the hierarchy. We will need to update the hierarchy's absolute matrices using the passed world matrix as we traverse the hierarchy. This is so we know that all absolute frame matrices in the hierarchy are correctly set to contain the world space transforms for each mesh container before using it to transform their

vertices. For each mesh container, we will transform the vertices into world space and then use the AddBufferData function to add this geometry to the static database.

If the actor contains animation or if the application intends to animate the position of the actor within the scene, then we will also need a means to register an actor as a dynamic object, or more correctly, a dynamic object set. Once again, this is not so difficult. If the actor is to be added as a dynamic object set, we will need a function that will traverse the hierarchy searching for mesh containers. For each mesh container it finds it will allocate a new DynamicObject structure and add it to the collision system's dynamic object array. We will lock the vertex and index buffers of each mesh and copy the *model space* vertex and index data into the dynamic object's geometry arrays (using AddBufferData). We will assign each dynamic object we create from a given actor the same object set ID. We know when the actor is animated and all its frame matrices are updated, calling the ObjectSetUpdated method and passing this single ID will result in all dynamic objects created from that actor having their matrices re-cached. Each dynamic object that is created from an actor will also store (as its matrix pointer), a pointer to the absolute matrix in the mesh container's owner frame. This will always store the world space transformation of the mesh whether an animation is playing or not.

So we need two strategies for registering actors. We will wrap both techniques in a single function that uses its parameters to decide whether the actor should be added as a dynamic object set or as static geometry. We pass a Boolean parameter to this function called Static which, if set to true, will cause the meshes contained inside the actor to be registered statically after having been transformed into world space. Otherwise, each mesh in the hierarchy will have a dynamic object created for it and added to the collision system's dynamic object array. The functions used to actually perform the registration process are private functions called AddStaticFrameHierarchy and AddDynamicFrameHierarchy and are for the registration of static and dynamic actors, respectively.

The wrapper function that our application calls is called AddActor and accepts three parameters. The first is a pointer to the CActor that we would like to register. The second is a matrix describing the placement of the actor within the scene (i.e., the root frame world matrix). The third parameter is the Boolean that was previously discussed that indicates whether the actor's geometry should be registered as static or dynamic triangle data.

```
long CCollision::AddActor(    const CActor * pActor,
                              const D3DXMATRIX& mtxWorld,
                              bool Static /*= true*/ )
{
    // Validate parameters
    if ( !pActor ) return -1;

    // Retrieve the root frame
    D3DXFRAME * pFrame = pActor->GetRootFrame();

    // If there is no root frame, return.
    if ( !pFrame ) return -1;

    // Add as static or dynamic geometry?
    if ( Static )
    {
        if ( !AddStaticFrameHierarchy( pFrame, mtxWorld ) ) return -1;
```

```
    } // End if static
    else
    {
        if ( !AddDynamicFrameHierarchy( pFrame, mtxWorld ) ) return -1;

    } // End if dynamic

    // We have used another object set index.
    m_nLastObjectSet++;

    // Return the object index
    return m_nLastObjectSet;

}
```

Notice that before we call the AddStaticFrameHierarchy or AddDynamicFrameHierarchy functions, we fetch the root frame of the actor to pass in as a parameter. These functions are recursive and will start at the root frame of the hierarchy and traverse to the very bottom searching for mesh containers.

It may seem odd that we increment the m_nLastObjectSet member variable at the end of the function rather than before the recursive functions are called. This is because in the actual recursive functions, this value will be incremented by assigning an object set index of m_nLastObjectSet+1 to each dynamic object we create. In other words, if the last dynamic object we added was issued an ID of 10, all the dynamic objects created by these recursive functions would be assigned an ID of 10+1=11. Remember, every dynamic object created from an actor will be assigned the same object set index and are therefore considered to belong to the same object group/set. When the recursive functions return and the dynamic objects have all been created, we then increment the m_nLastObjectSet variable so it now correctly describes the last object set index that was used. In this example, that would be a value of 11.

Of course, this function does not really do a whole lot by itself since the registration processes for both dynamic and static actors are buried away in the helper functions AddStaticFrameHierarchy and AddDynamicFrameHierarchy. Let us now have a look at these functions, starting first with the function that adds a non-animating actor to the static geometry database.

CCollision::AddStaticFrameHierarchy

This function is called by the AddActor method to register a frame hierarchy and all its contained mesh data with the static geometry database. The function recurses until all mesh containers have been found and their geometry added.

The first parameter is a pointer to the current frame that is being visited. When first called by the AddActor method, this will be a pointer to the root frame of the hierarchy. The second parameter is the world matrix that this frame's parent relative matrix is relative to. When this matrix is combined with the parent relative matrix stored at the frame, we will have the absolute world transformation matrix for the frame and the world matrix for any mesh container that it may contain. This same matrix is also passed along to each sibling frame if any should exist since all sibling frames share the same frame of reference. We can think of this matrix as being the absolute world matrix of the parent frame which,

when combined with the parent relative matrix, will provide the absolute matrix of the current frame. This matrix, once used to transform the vertices of any child mesh containers of this frame, is then passed down to the children of this frame. The matrix parameter passed into this function, when called for the root frame (from AddActor), will be the world matrix of the actor itself.

```
bool CCollision::AddStaticFrameHierarchy( D3DXFRAME * pFrame,
                                          const D3DXMATRIX& mtxWorld )
{
    D3DXMESHCONTAINER * pMeshContainer = NULL;
    LPD3DXBASEMESH      pMesh          = NULL;
    LPVOID              pVertices      = NULL;
    LPVOID              pIndices       = NULL;
    ULONG               nVertexStride, nIndexStride;
    D3DXMATRIX          mtxFrame;

    // Validate parameters (just skip)
    if ( !pFrame ) return true;

    // Combine the matrix for this frame
    D3DXMatrixMultiply( &mtxFrame, &pFrame->TransformationMatrix, &mtxWorld );

    // Retrieve the mesh container
    pMeshContainer = pFrame->pMeshContainer;
```

In the first section of the code (shown above) we first test that the frame pointer passed into the function is valid; if not, we return immediately. We then combine the passed matrix with the parent relative matrix of the current frame to generate the absolute world matrix for this frame. This is the world matrix that describes the world space placement of any meshes that are owned by this frame.

We then grab a copy of the frame's pMeshContainer pointer and store it in a local variable (pMeshContainer) for ease of access. If this pointer is NULL then there are no meshes attached to this frame and we have no geometry to add. We can just jump straight to the bottom of the function where we traverse into the child and sibling frames.

> **Note:** We are not interested in storing skinned meshes since our collision system will not directly support skinned geometry. To use skinned meshes as colliders, a good approach is to register either a geometric bounding volume that encapsulates the skinned structure or a series of low polygon meshes that bound the object and animate with it. This produces very good results with little overhead.

The next section of code loops through each mesh container attached to this frame (remember that a frame may have multiple mesh containers arranged in a linked list). Each iteration of the loop will process a single mesh in the list. If the mesh container pointer is NULL, then there are no meshes attached to this frame and the loop is never executed. Once inside the loop, if the mesh container does not have a NULL ID3DXSkinInfo pointer, then we know it contains skinning information and we skip to the next mesh in the list (see note above).

```
    // Keep going until we run out of containers (or there were none to begin with)
    for ( ; pMeshContainer != NULL;
```

```
            pMeshContainer = pMeshContainer->pNextMeshContainer )
    {
        // Skip if this is a skin container
        if ( pMeshContainer->pSkinInfo ) continue;

        // Attempt to retrieve standard mesh
        pMesh = (LPD3DXBASEMESH)pMeshContainer->MeshData.pMesh;

        // Attempt to retrieve progressive mesh if standard mesh is unavailable
        if ( !pMesh ) pMesh = (LPD3DXBASEMESH)pMeshContainer->MeshData.pPMesh;
```

After we have made sure that the current mesh container does not contain skinning information, we then retrieve a pointer to the ID3DXMesh stored in the mesh container (via the D3DXMESHDATA member pMesh field). If this pointer is NULL then it may mean that a progressive mesh is stored here instead of a regular ID3DXMesh. When this is the case, we assign the local pMesh pointer to the pPMesh member of the container's D3DXMESHDATA structure instead. At this point, we hopefully have either a pointer to a progressive mesh or a regular mesh and we can continue. If pMesh is still NULL, then it contains a mesh data format that our system does not currently support (e.g., a patch mesh).

Now that we have a pointer to the mesh, we can use its interface to inquire about the stride of the vertices contained within. We can also use the ID3DXMesh->GetOptions method to determine whether the indices of the mesh are 16 or 32-bits wide. Notice in the following code that if the D3DXMESH_32BIT flag is set, we set the nIndexStride variable to 4 (bytes); otherwise we set it to 2. We need these pieces of information when we feed the vertices and indices of the mesh into the AddBufferData function.

```
        // If we have a mesh to process
        if ( pMesh )
        {
            try
            {
                // Retrieve the stride values
                nVertexStride = pMesh->GetNumBytesPerVertex();
                nIndexStride  = (pMesh->GetOptions() & D3DXMESH_32BIT) ? 4 : 2;
```

Now that we know how big each vertex and index is, we lock the vertex and index buffers of the mesh. The pointers to the vertex and index data are returned in the pVertices and pIndices local variables. Once we have these pointers, we can pass them straight into the AddBufferData function along with the vertex stride and index stride information, as shown below.

```
                // Retrieve the vertex buffer
                if ( FAILED(pMesh->LockVertexBuffer
                                    ( D3DLOCK_READONLY, &pVertices ) ) )
                  throw 0;

                if ( FAILED(pMesh->LockIndexBuffer
                                    ( D3DLOCK_READONLY, &pIndices ) ) )
                  throw 0;

                // Add to static database
```

```
                if ( !AddBufferData(      m_CollVertices,
                                          m_CollTriangles,
                                          pVertices,
                                          pIndices,
                                          pMesh->GetNumVertices(),
                                          pMesh->GetNumFaces(),
                                          nVertexStride,
                                          nIndexStride,
                                          mtxFrame ) ) throw 0;

                // Unlock resources
                pMesh->UnlockVertexBuffer();
                pVertices = NULL;
                pMesh->UnlockIndexBuffer();
                pIndices = NULL;

            } // End try block
```

There are a few important things to note about the AddBufferData call. First, the first two parameters we are passing in are the STL vectors of the CCollision class that contain the static vertex and geometry data. We are also using the methods of the ID3DXMesh interface to pass in the number of vertices and triangles pointed at by the pVertices and pIndices pointers, respectively. Perhaps most important is the matrix we pass in as the final parameter. This is the combined matrix of the current frame which describes the world space transformation of any meshes attached directly to this frame. The AddBufferData function will use this matrix to transform the vertices of the mesh into world space prior to adding them to the static geometry database.

After the AddBufferData function returns, the current mesh has been added to the static geometry database and we can unlock the vertex and index buffers. Our task is complete for this particular mesh.

If an exception is raised for whatever reason, the catch block below will be executed. It simply forces the unlocking of the vertex and index buffers if they were locked when the exception occurred.

```
            catch (...)
            {
                // Unlock resources
                if ( pVertices ) pMesh->UnlockVertexBuffer();
                if ( pIndices  ) pMesh->UnlockIndexBuffer();

                // Return fatal error
                return false;

            } // End catch block

        } // End if mesh exists

    } // Next Container
```

That concludes the mesh loop of this function. The above sections of code will be executed for every mesh container that is a child of the current frame being visited by our recursive function. Notice at the

top of the loop, we move along the linked list of the mesh container by setting the mesh container pointer to point at its pNextMeshContainer member with each iteration.

If we get to this point, we have processed all the meshes attached to this frame and have added them to the static geometry database. We are now ready to continue our recursive journey down the hierarchy. First we test to see if the current frame has a sibling list. If it has, then we will traverse into that list. Notice that when the function recursively calls itself in order to visit the sibling(s), it is passed the same matrix that was passed into this instance of the function. Remember, this is the combined absolute world matrix of the parent frame. Since all siblings share the same parent frame of reference, this same matrix must be passed along to each of them so that they too can combine it with their parent-relative matrices to generate their own world transforms.

```
    // Process children and siblings
    if ( pFrame->pFrameSibling )
    {
        if ( !AddStaticFrameHierarchy( pFrame->pFrameSibling, mtxWorld ) )
            return false;

    } // End if there is a sibling
```

We have now visited our sibling frames and entered their meshes into the static database. Now we must continue down to the next level of the hierarchy and visit any child frames. When the function steps into the child frame, it passes the absolute world matrix of the current frame as the matrix parameter, not the matrix that was passed into this instance of the function. We have had enough exposure to hierarchy traversals at this point to know why this is the case.

```
    if ( pFrame->pFrameFirstChild )
    {
        if ( !AddStaticFrameHierarchy( pFrame->pFrameFirstChild, mtxFrame ) )
             return false;

    } // End if there is a child

    // Success!
    return true;
}
```

That is all there is to adding an entire frame hierarchy to our static database. It is a simple recursive procedure that searches a hierarchy for meshes and adds them to the static geometry vectors.

CCollision::AddDynamicFrameHierarchy

This function is called by the AddActor method if its Boolean parameter was set to false, indicating that this is not a static actor. When this is the case a recursive procedure will be executed, much like the AddStaticFrameHierarchy function (and identical in many respects). The differences between this function and previous function occur when a mesh container is found. This time, its geometry is not transformed into world space and added to the static geometry array. Instead, a new dynamic object is created and the model space vertices are copied into the geometry arrays of the dynamic object. Also, a

pointer to the absolute matrix of the parent frame is stored inside the dynamic object also so that any changes to the hierarchy (via an animation update or an update of the position of the actor by the application), is immediately available to the collision system via this pointer. Each dynamic object is also assigned the same object set index. As the ID issued to the last dynamic object group added to the collision system will be currently stored in m_nObjectSetIndex, we can add one to this value and assign this new index to each dynamic object created from this hierarchy. As we saw when we discussed the AddActor method, the actual value of m_nObjectSetIndex in incremented when the AddDynamicFrameHierarchy function returns so that m_nObjectSetIndex is updated to store the ID we have just assigned to each dynamic object in the hierarchy.

Let us look at the code a section at a time. Note that a lot of this code is duplicated from the previous function we have just discussed, so we will move a little faster.

This function is called from AddActor and is passed the root frame of the hierarchy and the world matrix of the actor. This is the matrix describing the current position of the actor in the scene. We combine it with the parent relative matrix of the current frame being visited (initially the root) to generate the absolute world transformation matrix of the frame we are visiting. This is the world matrix of any meshes assigned to this frame.

```
bool CCollision::AddDynamicFrameHierarchy( D3DXFRAME * pFrame,
                                           const D3DXMATRIX& mtxWorld )
{
    D3DXMESHCONTAINER * pMeshContainer = NULL;
    LPD3DXBASEMESH      pMesh          = NULL;
    LPVOID              pVertices      = NULL;
    LPVOID              pIndices       = NULL;
    ULONG               nVertexStride, nIndexStride;
    D3DXMATRIX          mtxFrame, mtxIdentity;

    // Validate parameters (just skip)
    if ( !pFrame ) return true;

    // Combine the matrix for this frame
    D3DXMatrixMultiply( &mtxFrame, &pFrame->TransformationMatrix, &mtxWorld );

    // Store identity
    D3DXMatrixIdentity( &mtxIdentity );
```

Notice how we also set up an identity matrix. This will be passed into the AddBufferData function so that it does not transform the vertices of the mesh and instead copies the model space vertices straight into the geometry arrays of the dynamic object.

The next section of code is the same as the last. We set up a loop to traverse the linked list of mesh containers that may exist at this frame and skip any meshes in the list that are skins.

```
    // Retrieve the mesh container
    pMeshContainer = pFrame->pMeshContainer;

    // Keep going until we run out of containers (
    // or there were none to begin with)
```

```
    for( ;  pMeshContainer != NULL;
            pMeshContainer = pMeshContainer->pNextMeshContainer )
    {
        // Skip if this is a skin container
        if ( pMeshContainer->pSkinInfo ) continue;

        // Attempt to retrieve standard mesh
        pMesh = (LPD3DXBASEMESH)pMeshContainer->MeshData.pMesh;

        // Attempt to retrieve progressive mesh if standard mesh is unavailable
        if ( !pMesh ) pMesh = (LPD3DXBASEMESH)pMeshContainer->MeshData.pPMesh;
```

The next section of code is executed if we have a valid mesh object. It once again retrieves the stride of both the indices and the vertices and locks the vertex and index buffers.

```
        // If we have a mesh to process
        if ( pMesh )
        {
            DynamicObject * pObject = NULL;

            try
            {
                // Retrieve the stride values
                nVertexStride = pMesh->GetNumBytesPerVertex();
                nIndexStride  = (pMesh->GetOptions() & D3DXMESH_32BIT) ? 4 : 2;

                // Retrieve the vertex buffer
                if ( FAILED(pMesh->LockVertexBuffer(  D3DLOCK_READONLY,
                                                      &pVertices ) ) ) throw 0;

                if ( FAILED(pMesh->LockIndexBuffer( D3DLOCK_READONLY,
                                                    &pIndices ) ) ) throw 0;
```

We do not wish to add this geometry to the static arrays of the collision system but instead want to create a new dynamic object from this mesh. Thus, we first allocate a new dynamic object, initialize its memory to zero, and then allocate the two STL vectors that the dynamic object will use for its vertex and triangle data.

```
                // Allocate a new dynamic object instance
                pObject = new DynamicObject;
                if ( !pObject ) throw 0;

                // Clear the structure
                ZeroMemory( pObject, sizeof(DynamicObject) );

                // Allocate an empty vector for the buffer data
                pObject->pCollVertices  = new CollVertVector;
                if ( !pObject->pCollVertices ) throw 0;

                pObject->pCollTriangles = new CollTriVector;
                if ( !pObject->pCollTriangles ) throw 0;
```

At this point, our dynamic object has its pCollVertices and pCollTriangles members pointed at the newly allocated empty vectors.

In the next section of code we will assign the pCurrentMatrix member of the dynamic object to point at the frame's combined matrix. This is the matrix that will contain the world space transform for this frame (and any of its attached meshes) when the actor is updated. We do not care what is currently stored in this matrix as we will not use it until the ObjectSetUpdated method is called to signify to the collision system that this matrix has been updated (either explicitly by the application or via an animation update). We also assign the current world space transformation of this frame (calculated above) to the LastMatrix and CollisionMatrix members. We are saying that the current position of the dynamic object in the world (described by the passed world matrix) will also be the previous position when the collision update it first called. In other words, the object has not moved yet.

We do not want to assign LastMatrix an arbitrary position even if it will be overwritten the first time ObjectSetUpdated is called; we should set it to the current position of the parent frame. If we did not do that, then for the first update we might have large values in our velocity matrix calculated between the last matrix and the current matrix which could really throw off our response system. Furthermore, our terrain collision system could end up testing thousands of triangles unnecessarily purely because the swept ellipsoid would span a great distance in its first update forcing the collision system to think that the object has moved a great distance between the last and current updates. You should remember from the textbook that it is actually the previous matrix of the dynamic object (cached in CollisionMatrix) that is used for intersection testing.

```
                // Store the matrices well need for
                pObject->pCurrentMatrix=
                                        &((D3DXFRAME_MATRIX*)pFrame)->mtxCombined;

                pObject->LastMatrix      = mtxFrame;
                pObject->CollisionMatrix = mtxFrame;
                pObject->ObjectSetIndex  = m_nLastObjectSet + 1;
                pObject->IsReference     = false;
```

As the m_nLastObjectSet will contain the last ID assigned to an actor/object that was registered, we can add one to this amount to generate the new group ID for every dynamic object created from this hierarchy. Remember, the value of m_nLastObjectSet is never altered or incremented in this function; we are assigning the same ID to every dynamic object we create from this actor. The ID of every object in this group will be one greater than the ID of the previous group that was added. We also set the IsReference member to false as this is not a reference (we will discuss adding references in a moment).

We will now add the model space vertices of the mesh to the dynamic object vectors using the AddBufferData member. Take note of the first two parameters where we are passing the dynamic object's geometry arrays and not the static scene geometry arrays as before. Also notice that as the final parameter we pass an identity matrix so that the model space vertices are not transformed into world space. We want them to be stored in the dynamic object in model space because (as we saw in the textbook), the geometry will be transformed into world space on the fly during the EllipsoidIntersectScene call.

```
                // Add to the dynamic objects database
                if ( !AddBufferData(      *pObject->pCollVertices,
                                          *pObject->pCollTriangles,
                                          pVertices,
                                          pIndices,
                                          pMesh->GetNumVertices(),
                                          pMesh->GetNumFaces(),
                                          nVertexStride,
                                          nIndexStride,
                                          mtxIdentity ) ) throw 0;
```

Now that our dynamic object structure contains all the data it needs, let us add it to the collision system's dynamic object array and unlock the vertex and index buffers of the D3DX mesh.

```
                // Store the dynamic object
                m_DynamicObjects.push_back( pObject );

                // Unlock resources
                pMesh->UnlockVertexBuffer();
                pVertices = NULL;
                pMesh->UnlockIndexBuffer();
                pIndices = NULL;

            } // End try block
```

If anything went wrong in the above code and an exception is thrown, the following catch code block will be triggered. It releases the dynamic object structure and the STL vectors we allocated to contain its geometry. We also unlock the vertex and index buffers.

```
            catch (...)
            {
                // Is there an object already?
                if ( pObject )
                {
                    if ( pObject->pCollVertices  ) delete pObject->pCollVertices;
                    if ( pObject->pCollTriangles ) delete pObject->pCollTriangles;
                    delete pObject;

                } // End if object created

                // Unlock resources
                if ( pVertices ) pMesh->UnlockVertexBuffer();
                if ( pIndices  ) pMesh->UnlockIndexBuffer();

                // Return fatal error
                return false;

            }
        }
    }
```

If we reach this point in the code then every mesh container that was attached to the current frame has had a dynamic object created and has had its model space geometry arrays created. We now traverse into

the sibling and child lists as before, causing a cascade effect that allows this function to recursively visit the entire hierarchy and create dynamic objects from any meshes found. Each mesh is assigned the same object set ID and as such, all the dynamic objects in the actor will belong to the same object group in the collision system.

```
    // Process children and siblings
    if ( pFrame->pFrameSibling )
    {
        if ( !AddDynamicFrameHierarchy( pFrame->pFrameSibling, mtxWorld ) )
            return false;

    } // End if there is a sibling

    if ( pFrame->pFrameFirstChild )
    {
        if ( !AddDynamicFrameHierarchy( pFrame->pFrameFirstChild, mtxFrame ) )
            return false;

    } // End if there is a child

    // Success!
    return true;
}
```

We have now covered not only how to add dynamic objects to the collision system, but have also discussed how to add entire hierarchies of dynamic objects. There is one more dynamic object registration function that we must cover which allows an actor to be registered with the collision system by referencing an actor that has previous been registered.

CCollision::AddActorReference

A referenced dynamic object shares its geometry data with the dynamic object from which it was instanced. When an actor is added to the system, multiple dynamic objects will be created. To reference an actor, we simply call the AddActorReference function passing in the object set index of the actor that was originally added. We want this function to make a copy of every dynamic object with a matching object set index. We do not need to traverse the frame hierarchy of the actor to do this. We can simply loop though the collision system's dynamic object array searching for all dynamic objects that currently exist which match the object set index passed into the function. For each one that is found, we will create a new dynamic object. However, unlike the normal creation of dynamic objects, we will not allocate these dynamic objects their own vertex and triangle vectors. Instead, we will assign their pointers to the geometry buffers of the original dynamic object we are referencing. This makes the system more memory efficient.

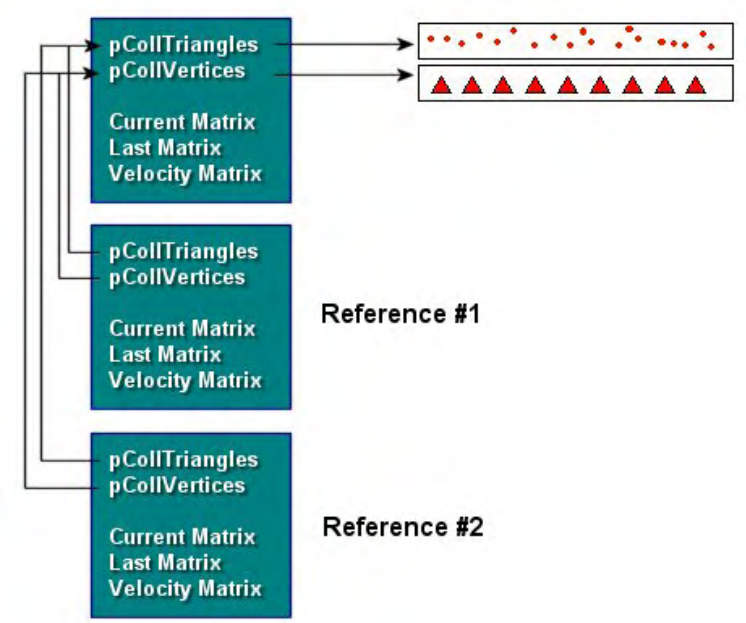

Figure 13.3

In Figure 13.3 we see how three dynamic objects might look in the collision system's dynamic object array. The topmost dynamic object was not created as a reference and therefore it has its own geometry buffers. The following two dynamic objects were registered using the AddActorReference function, passing in the object set index of the original dynamic object. As you can see, while these are dynamic objects in their own right (with their own object set index and matrix pointers), their geometry buffer pointers point at the buffers owned by the original dynamic object.

Although this makes sense, some confusion may be caused by the fact that the dynamic object's matrix pointer will be pointing to the same absolute frame matrix. The whole idea of references is to be able to place the same actor in the world in different locations and orientations without having to duplicate the geometry data. However, if each of our referenced dynamic objects points to the same world matrix (the absolute frame matrix in the actor's hierarchy) as the original dynamic object, would this not mean that all of our references will have to be in the same position in the world (negating the whole point of using references to begin with)?

While this is certainly a worthwhile observation to make, remember that the dynamic objects added to the system for the referenced actors will have different object set indices than the dynamic objects added to the system for the original actor. In the textbook we also discussed that when the application updates the position of an actor in any way (or applies an animation), it should immediately instruct the actor to update itself. This will cause the absolute frame matrices of the actor to be regenerated. If we have multiple CObjects using the same actor, we can see that this would cause the single actor to be updated many times in a given scene animation update, once for each CObject that stores a pointer to it. As we perform each update on the actor for each object that uses it (CScene::AnimateObjects), we also call the CCollision::ObjectSetUpdated function. This will update all the matrices of dynamic objects that were created from that actor or actor reference that was assigned that object set index. This function will use the matrix pointer to get the current position of the parent frame in the hierarchy which it will then use to build its LastMatrix, CollisionMatrix and VelocityMatrix members. The matrix pointer which points directly into the hierarchy is not needed by that group of dynamic objects any further in this update because its values have been cached. The frame matrix can therefore be updated by other objects in the scene after this point. The general pattern of actor updating is described below.

Imagine we have three CObjects in our scene and each one's actor pointer points to the same CActor. At the scene level, we know this actor is being referenced by three objects. That is, one set of geometry, and three instances of it. We would also want to register the same actor with the collision system as one real actor and two actor references. Assume that when we first register the actor with the collision

system we get back an object set index of 1. When we register the second actor as a reference, we get an object set index of 2. Finally, when we register the third actor (as our second reference) we get back an object set index of 3. If we also imagine that the original actor contained 10 meshes, we would now have 30 dynamic objects in our collision system. But there would only be 10 sets of geometry buffers (those from the original non-referenced actor).

We also know that each corresponding dynamic object from each of the three object groups in the collision system will store a pCurrentMatrix pointer pointing to the exact same frame matrix. However, as long as we update the position of each object separately, we will not have a problem. We just update the frames of that actor to reflect the pose of the object and then notify the collision system of a change so that it can grab a snapshot of the current values for each dynamic object's matrix at that point. The update strategy should be as follows:

1. For each CObject in CScene
    a. Apply animation to actor using this CObject's animation controller
    b. Set actor's world matrix to the CObject matrix and instruct actor to update its absolute matrices.
    c. Now that the actor is in its correct position for the reference, inform the collision system that it has been updated using CCollision::UpdateSetUpdated. We pass in the object set ID of this object reference. This function will extract the current state of each absolute matrix in the hierarchy that is being pointed at by each dynamic object and use it to generate its collision matrix, last matrix and its velocity matrix members. These will be used later in the current game loop to transform the dynamic object into world space for intersection testing.

As you can see, the fact that referenced and non-referenced dynamic objects with the same mesh point to the same physical frame matrix is not a problem, as long as we update each object group one at a time. This gives the CCollision::ObjectSetUpdated function a chance to generate its internal matrices based on a snapshot of the actor in the reference pose. From the collision system's perspective, it is almost as if we are posing the hierarchy in different poses for each object reference and recording the matrix information for each pose so that it can be used for intersection testing later.

Now that we know how the application deals with references both inside and outside the collision system, let us look at the code that allows us to add an actor reference to the collision system.

When an application calls this function it does not have to pass a pointer to an actor since this function has no need for the frame hierarchy. Every dynamic object that belongs to the original actor's object set will be duplicated in the collision system. Therefore, we just have to pass the object set index of the group we wish to reference and a world matrix describing where we would like the referenced actor to be placed in the scene. We must also pass the original world matrix that was used when we added the original actor (non-referenced) to the collision database. We will discuss why this is needed in a moment. Let us look at the first snippet of code.

```
long CCollision::AddActorReference( long ObjectSet,
                                    const D3DXMATRIX& mtxOriginalWorld,
                                    const D3DXMATRIX& mtxWorld )
{
```

```
    D3DXMATRIX      mtxInv;
    bool            bAddedData = false;

    // Generate the inverse of the original world matrix
    D3DXMatrixInverse( &mtxInv, NULL, &mtxOriginalWorld );
```

As you can see, the parameters to the function from left to right are the object set index of the group we wish to reference, the original world matrix that was used when the original group of objects was added to the collision system (the actor that was not added as a reference), and the world matrix for this reference.

Why do we need the world matrix of the original actor? In short, because we need to invert it so that we can undo the current world transform that is applied to the objects we are referencing. We will discuss this further in just a moment.

The next section of code sets up a loop to iterate through every dynamic object currently contained in the collision system's dynamic object array. It then compares the object set index assigned to each dynamic object in the array to see if it matches the object set index passed into the function. If there is no match we simply skip the dynamic object as it does not belong to the group we wish to reference. For each object that we do find that has an object set index that matches the one passed into the function, we know that it is one that we wish to reference, so we create a new dynamic object structure.

```
    // Iterate through our object database
    DynamicObjectVector::iterator ObjIterator = m_DynamicObjects.begin();
    for ( ; ObjIterator != m_DynamicObjects.end(); ++ObjIterator )
    {
        DynamicObject * pObject = *ObjIterator;
        if ( !pObject ) continue;

        // We only reference if the set indices match
        if ( pObject->ObjectSetIndex == ObjectSet )
        {
            DynamicObject * pNewObject = NULL;

            // Catch Exceptions
            try
            {
                // Allocate a new dynamic object instance
                pNewObject = new DynamicObject;
                if ( !pNewObject ) throw 0;

                // Clear the structure
                ZeroMemory( pNewObject, sizeof(DynamicObject) );
```

Unlike non-referenced dynamic objects, we do not allocate the new object its own vertex and triangle arrays. Instead, we assign its pCollVertices and pCollTriangles members to point at the geometry buffers of the object being referenced. We also set the new objects IsReference Boolean member to true.

```
                // Setup referenced data
                pNewObject->IsReference    = true;
                pNewObject->pCollTriangles = pObject->pCollTriangles;
```

```
                pNewObject->pCollVertices  = pObject->pCollVertices;
                pNewObject->pCurrentMatrix = pObject->pCurrentMatrix;

                // Store the new object set index
                pNewObject->ObjectSetIndex = m_nLastObjectSet + 1;
```

Just as in the non-referenced case, we assign the new object's matrix pointer to point to the same matrix as the dynamic object it is instancing. That is, in the case of an actor, both the dynamic object and the referenced dynamic object point to the same absolute matrix stored in the mesh's owner frame. As just discussed, this does not cause a problem because the ObjectSetUpdated function will be called when each object is individually updated, allowing the collision system to take a snapshot of the frame matrix in the correct pose for that instance.

At the bottom of the above code, we also assign the new object a new object set ID which is NOT the same as the dynamic object we are referencing. We calculate this object set ID just as before; by adding one to the ID last issued by the collision registration functions. Note that if we are referencing an actor that has multiple meshes in its hierarchy, multiple dynamic object references will be created in the collision system, but each will have the same object set ID and belong to the same group, as we would expect. After all, when an object is updated in the collision system (CCollision::ObjectSetUpdated), we wish the matrix data for each dynamic object that belongs to that group to be re-calculated.

The next step is where we use that inverted matrix we calculated earlier and stored in the mtxInv local variable. This matrix contains the inverted world space transform of the original dynamic object we are referencing (the original actor). More accurately, it is the inverted world space transformation of the root frame of the actor we are referencing. So why do we need it?

As discussed in the previous function, we want to assign the LastMatrix and CollisionMatrix members of the dynamic object to a value that has legitimate meaning when we first call our collision update function. However, we cannot really set these members to the object's previous position as it has none; it is only just being created now. We also do not want to give these matrices arbitrary values because they will be used to create the velocity matrix of the dynamic object when the ObjectSetUpdated function is first called for this object group. If we assign these matrices a position in the world that is nowhere near the current position of the object in the first collision update, we will get a huge velocity vector which will wreak havoc in our response code. Furthermore, we do not want our terrain collision system thinking that the object has moved in the first update across a huge expanse of terrain since this would mean hundreds, perhaps thousands, of triangles would need to be temporarily built and tested for intersection.

So it makes sense to assign to the dynamic object's LastMatrix and CollisionMatrix members the current transform of the frame in the hierarchy which owns this mesh. However, unlike the AddDynamicFrameHierarchy function, which traversed the hierarchy and always had access to the absolute frame matrix, in this function we are not traversing the hierarchy and we are not combining matrices. Therefore, we do not know the world space position of the dynamic objects. That is, we do not know what the absolute matrix should contain in the reference pose. We are simply looping through the dynamic objects of the collision system. Although this function was passed a world matrix for this reference, it only describes the world matrix of the root frame in the reference position. Of course, the mesh in the actor will likely be offset from the root frame by several levels of transforms. What we need

to know is not the world matrix of the root frame of the actor in the reference pose (the mtxWorld parameter), but the world matrix of the owner frame in the reference position.

Although we do not have this information at hand, we do know the current world space position of the dynamic object we are *referencing* since this information is stored in its LastMatrix parameter. We also have the original world matrix that was assigned to that actor's root frame when it was registered with the collision system since we have passed it as the second parameter to this function (mtxOriginalMatrix). Finally, we have the inverse of this matrix which undoes the transformation that was applied to the root frame of the non-referenced actor when it was registered. Therefore, if we multiply this inverse matrix with the non-referenced dynamic object's LastMatrix pointer (the dynamic object we are copying), we are essentially subtracting the position and rotation of its root frame from the world space position of the non-referenced dynamic object. This transforms the actor and all its meshes into model space (the reference pose). In other words, we are left with a matrix for that object that describes its position and orientation relative to <0,0,0> in actor space.

```
                // Transform the matrices to ensure it starts in the correct place
                D3DXMatrixMultiply( &pNewObject->LastMatrix,
                                    &pObject->LastMatrix,
                                    &mtxInv );
```

Now that we have undone the transformation that was originally applied to the non-referenced object, we can transform it back out into world space using the world space matrix of the referenced object. The result is the current world space position of the corresponding frame in the hierarchy, positioned by the reference matrix (instead of the original matrix used to position the non-referenced actor).

```
                D3DXMatrixMultiply( &pNewObject->LastMatrix,
                                    &pNewObject->LastMatrix,
                                    &mtxWorld );
                pNewObject->CollisionMatrix = pNewObject->LastMatrix;
```

At this point, both the CollisionMatrix and the LastMatrix members of the new dynamic object store the current world space position of the dynamic object using the reference's own world transform.

With our dynamic object reference now created, we finally add it to the collision system's dynamic object array. If an exception was thrown in the above code, the catch block simply deletes the dynamic object structure.

```
                // Store the dynamic object
                m_DynamicObjects.push_back( pNewObject );

                // We've added, ensure we don't release
                pNewObject = NULL;

                // We successfully added some data
                bAddedData = true;

            } // End Try Block
```

```
            catch (...)
            {
                // Release new memory
                if ( pNewObject ) delete pNewObject;

                // Return failure.
                return -1;

            } // End Catch Block

        } // End if from matching set

    } // Next object
```

At this point, if the local Boolean variable bAddedData is set to true, we know that at least one of the currently existing dynamic objects was referenced and we have added a new object group. Therefore, we increment the m_nLastObjectSet and return the new group index to the caller. Otherwise, we return -1 indicating that the requested object group could not be referenced because it seemed not to exist.

```
    // Did we find anything to reference?
    if ( bAddedData )
    {
        // We have used another object set index.
        m_nLastObjectSet++;

        // Return the object index
        return m_nLastObjectSet;

    } // End if added references
    else
    {
        return -1;

    } // End if nothing added
}
```

Thankfully, we have covered all the geometry registration functions of the CCollision class and you should have a good understanding of where the static and dynamic objects live in the collision system and how they are accessed.

CCollision::Optimize

The optimize method can optionally be called after your application has registered all static and dynamic objects with the collision system. It simply compacts the STL vectors used by both the static database and each dynamic object to their actual size, eliminating wasted space introduced during registration.

This function will test the current size and the capacity of each STL vector used by the system. This includes the two vectors that contain the static vertices and triangles and the vectors of each dynamic object used to contain its geometry. Since the size of the vector describes how many elements have been added to it, and the capacity of the vector describes how many elements can be added to it, we just have

to change the capacity of the vector to equal to its current size. This is done using the vector::reserve method which removes the wasted space from the end of each vector.

```
bool CCollision::Optimize( )
{
    // For now, we simply remove any slack from our vectors, but you could
    // (for instance) weld all the vertices here too.
    try
    {
        // Remove array slack
        m_CollTriangles.reserve( m_CollTriangles.size() );
        m_CollVertices.reserve( m_CollVertices.size() );

        // Iterate through our object database
        DynamicObjectVector::iterator ObjIterator = m_DynamicObjects.begin();
        for ( ; ObjIterator != m_DynamicObjects.end(); ++ObjIterator )
        {
            DynamicObject * pObject = *ObjIterator;
            if ( !pObject ) continue;

            // If there is a database, remove slack
            if ( pObject->pCollTriangles )
            pObject->pCollTriangles->reserve(pObject->pCollTriangles->size());

            if ( pObject->pCollVertices  )
            pObject->pCollVertices->reserve( pObject->pCollVertices->size() );

        } // Next object

    } // End Try Block

    catch ( ... )
    {
        // Simply bail
        return false;

    } // End Catch Block

    // Success!
    return true;
}
```

While this function is not vital to proper system functioning, it is recommended that your application call it after geometry registration to keep memory requirements as minimal as possible.

Updating Collision Querying with a CTerrain Handler

In the accompanying textbook we discovered that the CCollision::EllipsoidIntersectScene function is the heart of the collision detection process. It uses the EllipsoidIntersectBuffers method to perform collision determination on both the static geometry buffers and the geometry buffers of each dynamic object registered with the system. The code was already discussed in great detail, so we will not spend a great deal of time on it (or its helper functions) in this section. However, we will discuss the special case code we will add to allow us to perform intersection tests against any CTerrain objects that have been registered with the system.

We will first look at the updates to the EllipsoidIntersectScene function where we will discover that an additional collision phase has been added. In our textbook discussion, this function performed intersection testing in two phases. It would first loop through each dynamic object and perform intersection tests on each object's geometry buffers. Then it would perform intersection testing against the collision system's static geometry buffers. We will now add a third step (which will actually turn out to be performed as the first step in our revised implementation) which will process collisions against CTerrain objects. When we examined the CCollision::AddTerrain method earlier, we saw that it simply added the passed CTerrain pointer to an internal vector of terrain object pointers. No geometry from the terrain was added to the static or dynamic geometry buffers.

While adding terrain geometry to the collision system could be done simply by registering the terrain geometry with the static database just like we do with any other static geometry (using AddIndexedPrimitive), this is obviously not the most memory efficient design. Terrains are usually quite vast and are often comprised of many thousands of triangles. As programmers, we usually have a hard enough time as it is fitting such huge terrains in memory for the purposes of rendering. If we were to store a copy of each terrain triangle in the collision database, we would effectively double the memory overhead of using that terrain. Instead, we will use a procedural geometry approach at runtime that will make using terrains based on height map data very efficient. For terrains that are not built from height map data (e.g., static meshes designed in 3D Studio MAX™) these can still be registered with the collision system using the AddIndexedPrimitive methods.

For height map based terrains which can be loaded into our CTerrain class, we will store only the CTerrain pointer in the collision system. The EllipsoidIntersectScene function will now use a new function we will implement called CollectTerrainData to temporarily build the triangles of the terrain that need to be tested for intersection. This determination will be based on the position of the ellipsoid, its velocity vector, and the data contained in the height map. The ellipsoid and its velocity vector will be mapped into the image space of the terrain's height map and used to build a bounding box describing a region on the height map that contains potentially colliding triangles. In a given update, where the ellipsoid will have moved a very small distance from its previous position, this bounding box will span only a very small area of pixels in the height map. The bounded rectangular area of pixels can then be used to build quads for the terrain that falls within that box. This is exactly the same way we build the renderable terrain data from a height map. The only difference is that instead of building quads for every pixel in the height map, we are only using a very small subsection to build a temporary mini-terrain for the area we are interested in. Once this temporary buffer has been tested for collision, the data can then be released.

The CollectTerrainData function will return the vertices and triangles for a given sub-terrain in two buffers (STL vectors) that the EllipsoidIntersectScene function can then pass into the EllipsoidIntersectBuffers function for normal intersection testing. At this point, we will not concern ourselves with how the CollectTerrainData function builds its terrain data. First we will concentrate on the additions to the EllipsoidIntersectScene function. Although the entire function is shown below, we will only discuss the new code that has been added (shown in bold). The rest of the code has been discussed in detail in the accompanying textbook.

Collision::EllipsoidIntersectScene (Version 3)

In this first section of code we see two new lines that declare two local STL vectors. One will be used to hold the vertex data returned from the CollectTerrainData function and the other used to contain the triangle data. Note that these vectors are of the same type used for the static geometry in the collision system and the model space geometry of each dynamic object. We then calculate the inverse radius vector of the ellipsoid so that we can scale the vectors in and out of eSpace as required.

```
bool CCollision::EllipsoidIntersectScene( const D3DXVECTOR3 &Center,
                                          const D3DXVECTOR3& Radius,
                                          const D3DXVECTOR3& Velocity,
                                          CollIntersect Intersections[],
                                          ULONG & IntersectionCount,
                                          bool bInputEllipsoidSpace /* = false */,
                                          bool bReturnEllipsoidSpace /*= false*/ )
{
    D3DXVECTOR3 eCenter, eVelocity, eAdjust, vecEndPoint, InvRadius;
    float       eInterval;
    ULONG       i;

    // Vectors for terrain building
    CollVertVector VertBuffer;
    CollTriVector  TriBuffer;

    // Calculate the reciprocal radius
    InvRadius = D3DXVECTOR3( 1.0f / Radius.x, 1.0f / Radius.y, 1.0f / Radius.z );
```

In the next section of code we copy the passed ellipsoid position and velocity vectors into the local variables eCenter and eVelocity. If the bInputEllipsoidSpace Boolean parameter was set false it means that we would like this function to convert them into eSpace for us. In our code, the CollideEllipsoid function passes true for this parameter because it inputs both the ellipsoid position and velocity vector already in eSpace and therefore, the data is copied straight into the local variables.

```
    // Convert the values specified into ellipsoid space if required
    if ( !bInputEllipsoidSpace )
    {
        eCenter   = Vec3VecScale( Center, InvRadius );
        eVelocity = Vec3VecScale( Velocity, InvRadius );

    } // End if the input values were not in ellipsoid space
    else
    {
```

```
        eCenter   = Center;
        eVelocity = Velocity;

    } // End if the input values are already in ellipsoid space
```

Next set the initial intersection interval along the ray (the *t* value) to 1.0, meaning that the closest intersection is at the end of the velocity vector. If this is not modified to a smaller value by the intersection routines, the path of the ellipsoid along its desired velocity vector is free from obstruction and can be moved to its desired position. We also set the initial value of IntersectionCount to zero as we have not yet found any colliding triangles.

```
    // Reset ellipsoid space interval to maximum
    eInterval = 1.0f;

    // Reset initial intersection count to 0 to save the caller having to do this.
    IntersectionCount = 0;
```

Now we enter step one of the three detection steps. This is the new step that performs intersection testing against any CTerrain objects that have been registered with the collision system. This small section of code is virtually all the new code that has been added to this function. This is due to the fact that most of the new code is wrapped up in the CollectTerrainData method, which we will discuss in a moment.

We will first loop through every CTerrain object that has been registered with the collision system via the AddTerrain method. The pointers of each CTerrain object will be stored in the m_TerrainObjects member variable. This is an STL vector of type TerrainVector. In each iteration of the loop, we will extract the current CTerrain object being processed into the local pTerrain pointer for ease of access.

```
    // Iterate through our terrain database
    TerrainVector::iterator TerrainIterator = m_TerrainObjects.begin();
    for ( ; TerrainIterator != m_TerrainObjects.end(); ++TerrainIterator )
    {
        const CTerrain * pTerrain = *TerrainIterator;
```

We now have a pointer to the CTerrain object we want to test for intersections with our ellipsoid. The CollectTerrainData function will now be called to build and return the triangle data for the region of interest in the height map. The CollectTerrainData function must be passed the world space ellipsoid center position and velocity vector in order to do this. It uses these values to calculate the start and end positions of the ellipsoid in order to construct an image space bounding box on the height map. Because we currently have our ellipsoid position and velocity vector in eSpace, we must temporarily multiply them by the radius vector of the ellipsoid to put them back into world space. We then call the CollectTerrainData function, passing in the terrain object itself, the world space position and velocity vector, and the ellipsoid radius vector. As the final two parameters we pass the two local geometry buffers we allocated at the top of the function. When the function returns, these vectors will contain the triangle and vertex data needed to testing.

```
        // Get world space values
        D3DXVECTOR3 vecCenter   = Vec3VecScale( eCenter, Radius );
```

```
        D3DXVECTOR3 vecVelocity = Vec3VecScale( eVelocity, Radius );

        // Collect the terrain triangle data
        if ( !CollectTerrainData(   *pTerrain,
                                    vecCenter,
                                    Radius,
                                    vecVelocity,
                                    VertBuffer,
                                    TriBuffer ) ) continue;
```

If the function returns false, it means that the ellipsoid is not intersecting the overall terrain object and therefore no data could be collected from the height map. If the ellipsoid is not currently over the terrain, then mapping the bounding box of its start and end positions to image space would place it outside the entire height map. If the function returns false the ellipsoid could not possibly be colliding with this terrain and we just continue on to the next iteration of the loop and test any other terrain objects that may have been registered with the system.

If the CollectTerrainData function returns true, it means that some geometry was compiled from the terrain height map and should be tested for intersection. Luckily, we already have a function that performs all the intersection testing and interval recording -- the EllipsoidIntersectBuffers function. We can use it here as well to perform the tests against the temporary terrain buffers that were just built by CollectTerrainData.

```
        // Perform the ellipsoid intersect test against this set of terrain data
        EllipsoidIntersectBuffers(  VertBuffer,
                                    TriBuffer,
                                    eCenter,
                                    Radius,
                                    InvRadius,
                                    eVelocity,
                                    eInterval,
                                    Intersections,
                                    IntersectionCount );

        // Clear buffers for next terrain
        VertBuffer.clear();
        TriBuffer.clear();

    } // Next Terrain
```

The first and second parameters passed are the local temporary terrain geometry buffers that were just generated for this terrain object. This function will test every triangle in those buffers and record the closest colliding triangle's *t* value in the eIntersect variable. It will also store the triangle intersection information for this interval in the Intersections array.

After the EllipsoidIntersectBuffers function returns, we no longer need the temporary terrain geometry buffers, so we empty all the data they contain. They have served their purpose at this point and if any collision with the geometry did occur, the collision information will have been recorded in the Intersection array. Emptying the buffers lets us reuse them for any other terrain objects which need processing in future iterations of this loop.

At this point we have tested all the terrain objects and step one is complete. We now move on to step two where we test each dynamic object. This was all covered earlier.

```
    // Iterate through our triangle database
    DynamicObjectVector::iterator ObjIterator = m_DynamicObjects.begin();
    for ( ; ObjIterator != m_DynamicObjects.end(); ++ObjIterator )
    {
        DynamicObject * pObject = *ObjIterator;

        // Calculate our adjustment vector in world space.
        vecEndPoint = (Vec3VecScale(eCenter, Radius)
                       + Vec3VecScale( eVelocity, Radius ));

        // Transform the end point
        D3DXVec3TransformCoord(&eAdjust, &vecEndPoint, &pObject->VelocityMatrix);

        // Translate back so we have the difference
        eAdjust -= vecEndPoint;

        // Scale back into ellipsoid space
        eAdjust  = Vec3VecScale( eAdjust, InvRadius );
```

We now have the adjustment vector which can be added to the velocity vector to compensate for the movement of the dynamic object between collision updates. So we call the EllipsoidIntersectBuffers function to test our ellipsoid against the geometry of the dynamic object. Notice how we extend the velocity ray by the adjustment vector while passing the parameter and that the first and second parameters are the model space buffers of the dynamic object. The final parameter is the world matrix of the dynamic object in its previous position. This technique is described in the textbook.

```
        // Perform the ellipsoid intersect test against this object
        ULONG StartIntersection
               = EllipsoidIntersectBuffers(     *pObject->pCollVertices,
                                                *pObject->pCollTriangles,
                                                eCenter,
                                                Radius,
                                                InvRadius,
                                                eVelocity - eAdjust,
                                                eInterval,
                                                Intersections,
                                                IntersectionCount,
                                                &pObject->CollisionMatrix );
```

We now loop through the intersection information that was added to the array for this dynamic object in the previous function call and adjust the new eSpace position and intersection points by the adjustment vector. This gives us the new position of the ellipsoid after it has been shunted back by any dynamic object that might have collided with it. Remember, the original collision test was done using a velocity vector that was extended by the opposite amount the dynamic object has moved from its previous position.

```
        // Loop through the intersections returned
        for ( i = StartIntersection; i < IntersectionCount; ++i )
        {
            // Move us to the correct point (including the objects velocity)
            // if we were not embedded.
            if ( Intersections[i].Interval > 0 )
            {
                // Translate back
                Intersections[i].NewCenter      += eAdjust;
                Intersections[i].IntersectPoint += eAdjust;

            } // End if not embedded

            // Store object
            Intersections[i].pObject = pObject;

        } // Next Intersection

    } // Next Dynamic Object
```

At this point, step two is complete and we have performed intersection tests against all terrain objects and all dynamic objects. Step three is the simplest -- we simply call EllipsoidIntersectBuffers one more time to perform intersection tests against our static geometry buffers.

```
    // Perform the ellipsoid intersect test against our static scene
    EllipsoidIntersectBuffers(      m_CollVertices,
                                    m_CollTriangles,
                                    eCenter,
                                    Radius,
                                    InvRadius,
                                    eVelocity,
                                    eInterval,
                                    Intersections,
                                    IntersectionCount );
```

We now have a CollIntersect array containing the information of all triangles that collided simultaneously at the smallest interval (eInterval). The new ellipsoid position and collision normals stored in this structure are currently in eSpace. If the caller passed false as the bReturnEllipsoidSpace boolean parameter, then it means they would like all the information stored in this array to be returned as world space vectors. When this is the case, we simply loop though each intersection structure in the compiled array and use the radius vector of the ellipsoid to scale the values from eSpace into world space. Our CollideEllipsoid function passes true as this parameter as it wants the information returned in eSpace. Thus, this code is never utilized in Lab Project 13.1.

```
    // If we were requested to return the values in normal space
    // then we must take the values back out of ellipsoid space here
    if ( !bReturnEllipsoidSpace )
    {
        // For each intersection found
        for ( i = 0; i < IntersectionCount; ++i )
        {

            // Transform the new center position and intersection point
```

```
            Intersections[ i ].NewCenter
                              =Vec3VecScale(Intersections[i].NewCenter,
                                            Radius );

            Intersections[ i ].IntersectPoint
                              = Vec3VecScale(   Intersections[i].IntersectPoint,
                                                Radius );

            // Transform the normal
            D3DXVECTOR3 Normal
                              = Vec3VecScale(   Intersections[i].IntersectNormal,
                                                InvRadius );
            D3DXVec3Normalize( &Normal, &Normal );

            // Store the transformed normal
            Intersections[ i ].IntersectNormal = Normal;

        } // Next Intersection

    } // End if !bReturnEllipsoidSpace

    // Return hit.
    return (IntersectionCount > 0);
}
```

At the very bottom of the function we return true if the number of intersections found is greater than zero; otherwise we return false. How the CollectTerrainData function works is the final piece of the puzzle and will be discussed next.

CCollision::CollectTerrainData

The CollectTerrainData function is tasked with finding the region of the passed CTerrain object that falls within a bounding box described by the movement of the ellipsoid. It will then build the terrain data for this region and add the vertex and triangle data to the passed buffers (VertBuffer and TriBuffer). As we have seen in the previous discussion, these buffers are then returned to the EllipsoidIntersectScene function where they are tested for intersection before being discarded. Basically what we are after is a cheap and simple way to reject most of the triangles from consideration so we only have to build a very small amount of temporary triangle data.

Since upgrading our CTerrain class in the previous chapter, a CTerrain object can now have a world matrix that positions and orients it in the world. We will transform the ellipsoid (sort of) into terrain space and compile a terrain space bounding box that describes a region of potential colliding triangles. We know that the terrain object also has a scale vector that describes the scale of the terrain geometry in relation to the height map used to create it. For example, a scale vector of (1,1,1) would mean that neighboring pixels in the image map would represent a space of 1 world space unit. A scale vector of (10,7,12) would mean that each group of four pixels represent a quad in terrain space that is 10 units wide (x axis) and 12 units deep (z axis). The values stored in the height map for each vertex would also be scaled by 7 to produce its terrain space height. Notice that we are referring to the scaled image data as describing the terrain space dimensions of the terrain and not the world space dimensions. This is

because the world matrix is also used to potentially rotate and translate the terrain geometry to position it in the world. Therefore, a quad that is 10x10 in terrain local space may be rotated about the world Y axis by 45 degrees. That is why we must transform the start and end positions of the ellipsoid into terrain space first so that we are working in the model space of the terrain. In this space, the quads of the terrains are aligned with the X and Z axes of the local coordinate system. Figure 13.4 shows how the center and movement vectors of the ellipsoid will be used to generate a terrain space bounding box for a (typically very small) region of the overall terrain.

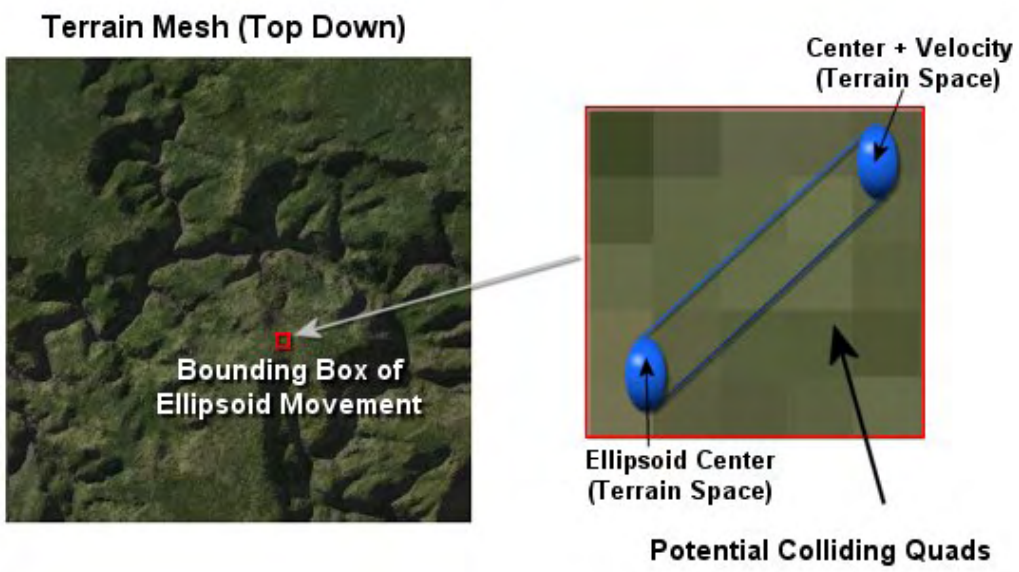

Figure 13.4

Since we know that the terrain's scale vector transforms the pixel positions in the height map into terrain space, dividing the dimensions of the terrain space bounding box by this scale vector will provide us with a bounding box in height map image space. Once we have this rectangle on the height map, we can simply loop through each row of contained pixels and build the triangle data in the exact same way we built the original terrain rendering geometry.

Let us now discuss this function a section at a time.

```
bool CCollision::CollectTerrainData(      const CTerrain& Terrain,
                                          const D3DXVECTOR3& Center,
                                          const D3DXVECTOR3& Radius,
                                          const D3DXVECTOR3& Velocity,
                                          CollVertVector& VertBuffer,
                                          CollTriVector& TriBuffer )
{
    D3DXMATRIX   mtxInverse;
    D3DXVECTOR3  tCenter, tVelocity, tvecMin, tvecMax, Vertex;
    long         nStartX, nEndX, nStartZ, nEndZ,
                 nX, nZ, nCounterX, nCounterZ, nPitch;
    float        fLargestExtent;

    // Retrieve the various pieces of information we need from the terrain
    const float *pHeightMap = Terrain.GetHeightMap();
```

```
    D3DXMATRIX   mtxWorld   = Terrain.GetWorldMatrix();
    D3DXVECTOR3  vecScale   = Terrain.GetScale();
    long         Width      = (long)Terrain.GetHeightMapWidth();
    long         Height     = (long)Terrain.GetHeightMapHeight();

    // Retrieve the inverse of the terrains matrix
    D3DXMatrixInverse( &mtxInverse, NULL, &mtxWorld );

    // Transform our sphere data, into terrain space
    D3DXVec3TransformCoord( &tCenter, &Center, &mtxInverse );
    D3DXVec3TransformNormal( &tVelocity, &Velocity, &mtxInverse );
```

In the first section of code (shown above) we retrieve all the information about the terrain we need; a pointer to its height map, the width and height of the height map, and the world matrix of the terrain object. We also fetch the terrain's scaling vector that describes the scaling that takes place to transform a pixel in the height map into a terrain space vertex position. The world space position and velocity vector of the ellipsoid have been passed into the function as parameters, but we need them in the terrain's local space. Remember that in world space, the terrain may be arbitrarily rotated or positioned by its world matrix, so we must make sure that the ellipsoid and the terrain are in the same space prior to compiling the bounding box. The obvious choice is terrain space because we can then easily transform the terrain space box into image space using the terrain's scale vector.

In order to do this, the ellipsoid center and velocity vectors will need to be multiplied by the terrain's inverse world matrix. Thus, in the above section of code we invert the terrain matrix and transform the vector into terrain space. The terrain space vectors are stored in local variables tCenter and tVelocity. If we look at Figure 13.4, we can see that tCenter represents the bottom left blue ellipsoid and tCenter + tVelocity describes the position of the top right blue ellipsoid.

Of course, we cannot just take the start and end points of the ellipsoid into account when compiling our terrain space bounding box. The vectors describe only the extents of the ellipsoid's center point as it travels along the terrain space velocity vector. As we know, an ellipsoid has a width, height and depth described by the radius vector that was also passed into the function. Therefore, if we could transform the ellipsoids radius vector into terrain space also, we would know that the extents of the bounding box along any of its three axes can be found by adding and subtracting the terrain space radius vector from the source and destination locations of the ellipsoid and recording the smallest and largest x, y and z values. This gives us the box shown in Figure 13.4 where it bounds the start and end center points and the radii of the ellipsoid surrounding those points.

So in order to compile our terrain space bounding box we must also transform the radius vector of the ellipsoid into terrain space. Then we have everything we need to start compiling our bounding box. You would be forgiven for thinking that we can transform the radius of the ellipsoid into terrain space simply by transforming the ellipsoid radius vector by the terrain's inverse matrix. Unfortunately, this is not the case, as transforming the ellipsoid radius vector in this way will produce a very different shaped ellipsoid in terrain space.

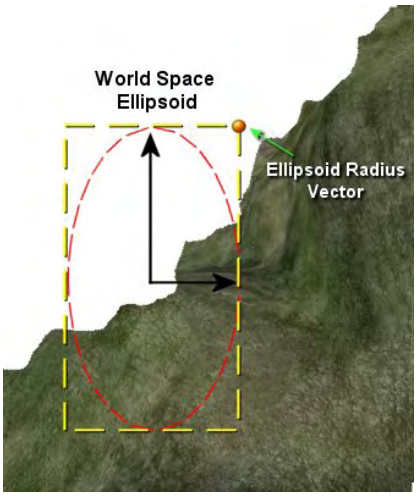

Figure 13.5

In Figure 13.5 we see both an ellipse and a terrain in world space. We will reduce the problem to 2D here for ease of explanation. The terrain's matrix has it rotated 45 degrees so that our ellipse is actually colliding into it at an angle. We know we can transform the center of the ellipsoid into terrain space using the inverse world matrix of the terrain but the ellipsoid radius is a completely different matter. If we think about the radius vector, we can see that while it is used to describe three radius values, if we think of it as a 3D vector, it actually describes a location at the tip of a bounding box that encases the ellipsoid. In Figure 13.5 the width radius is 1 and the height radius is 2 and therefore, the radius vector (1, 2) actually describes a location 1 unit along the X axis and 2 units along the Y axis. This is shown as the orange sphere at the top right corner of the bounding box. Inside the box we see the actual ellipsoid when the components of this vector are used to describe an ellipse radius.

In terrain space, the terrain will no longer be rotated; it will be perfectly aligned with the X, Y, and Z axes of the coordinate system and the ellipse shown in Figure 13.5 will be rotated forward 45 degrees. If we look at the two back arrows emanating from the center of the ellipse, we can see that they show its width and height axes. We might think that rotating the radius vector 45 degrees to the right would rotate these axes also thus providing us with a perfect terrain space bounding volume. However, this is not the case. As discussed, the world space radius vector describes only that orange sphere in Figure 13.5. When we rotate it, we are actually rotating the orange sphere by 45 degrees. In terrain space, this will now describe the top right extent of a bounding box that encloses the new terrain space ellipsoid. This is not remotely similar to the ellipsoid we were after as Figure 13.6 clearly shows.

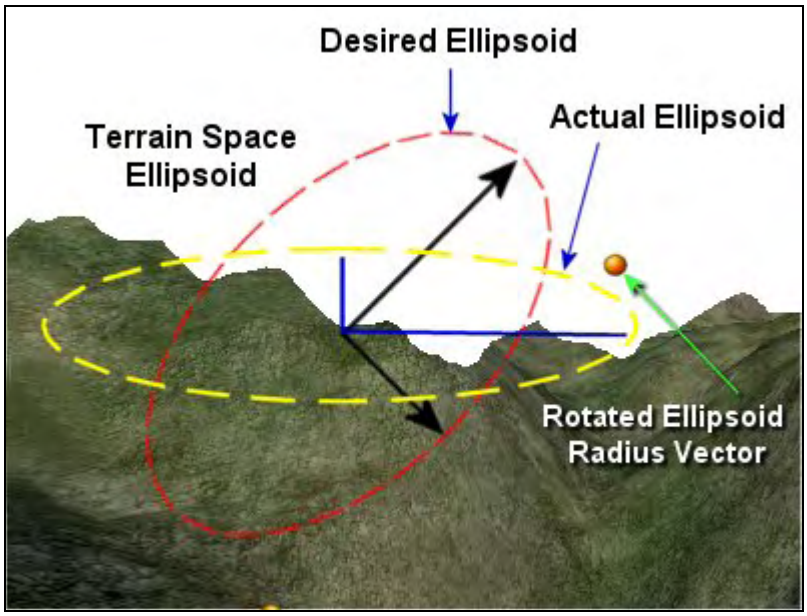

Figure 13.6

In Figure 13.6 the terrain space ellipse that we were actually hoping to get is shown as the red dashed ellipse complete with its rotated axis vectors. However, the orange sphere shows the radius vector plotted as a position describing the new top right extent of a bounding box that encases the new terrain space ellipse (post-rotation). Therefore, if we imagine this as being one corner of a box that surrounds the center of the ellipsoid, we can see the actual ellipse this describes as the yellow dashed ellipse. The ellipse has been severely squashed vertically and it is certainly not conservative. That is, the ellipsoid we ideally wanted does not fit inside the shape we actually get after rotation. Therefore, it is dangerous to use this approximation. We may reject polygons that do intersect the ellipsoid in world space but which fail to be added to the collision list because they do not intersect our terrain space ellipsoid.

The solution is simple, but comes with the cost of perhaps being a little too conservative. The problem here is the rotation of the terrain in world space and how to make sure that our ellipsoid in terrain space is at least big enough to force the compilation of a bounding box that will cause all polygons that could potentially collide with our ellipsoid to be added to the arrays. What we will do is simplify our problem by making our ellipsoid a sphere in terrain space. The rotation of the terrain in relation to a sphere is not significant as it has a radius equal in all directions. We need this sphere to be large enough to contain what our ellipsoid should like in terrain space when rotated at any angle. All we have to do then is simply take the largest component of the world space ellipsoid radius vector and essentially use a sphere that has a radius as large (see Figure 13.7).

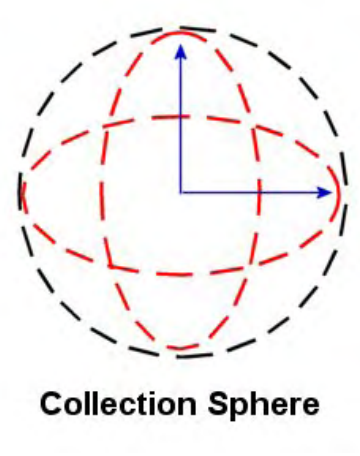

Figure 13.7

In this diagram we show two ellipsoids. The taller ellipsoid is the actual ellipsoid in world space and the wide ellipsoid shows the maximum width the ellipsoid could be in terrain space if the terrain were rotated 90 degrees. If we take the largest radius dimension of the world space ellipsoid vector and use this to build a sphere, we will have a sphere that completely encapsulates any rotation that may be applied to the original ellipsoid when transformed into terrain space.

Of course, we do not actually need to build a sphere as all we are after is the radius value. Once we have this, we can both add and subtract this value from the terrain space start and end positions of the center of the ellipsoid and record the maximum and minimum terrain space extents that we find.

The following code compiles the terrain space bounding box. It first tests each component of the world space ellipsoid radius vector to find which is the largest. This will be the radius of our hypothetical terrain space sphere.

```
    // Find the largest extent of our ellipsoid.
    fLargestExtent = Radius.x;
    if ( Radius.y > fLargestExtent ) fLargestExtent = Radius.y;
    if ( Radius.z > fLargestExtent ) fLargestExtent = Radius.z;
```

Now that we have the radius of our terrain space sphere, we will compile a bounding box by finding the minimum and maximum world space positions by adding and subtracting this radius vector from the terrain space start and end locations of the ellipsoid's center point. We start by first setting the minimum

and maximum vectors of this bounding box to values which describe an inside-out box that will be snapped to the correct size as soon as the first location tests are performed.

```
    // Reset the bounding box values
    tvecMin = D3DXVECTOR3( 9999999.0f, 9999999.0f, 9999999.0f );
    tvecMax = D3DXVECTOR3( -9999999.0f, -9999999.0f, -9999999.0f );
```

First we will add the radius of the sphere to the starting position of our ellipsoid. If this is larger than the current maximum we have recorded for that axis so far, we record the new extent. Note that this is done on a per-axis basis since we need the x, y, and z minimum and maximum extents to create a box.

```
    // Calculate the bounding box extents of where the ellipsoid currently
    // is, and the position it will be moving to.
    if ( tCenter.x + fLargestExtent > tvecMax.x )
            tvecMax.x = tCenter.x + fLargestExtent;

    if ( tCenter.y + fLargestExtent > tvecMax.y )
            tvecMax.y = tCenter.y + fLargestExtent;

    if ( tCenter.z + fLargestExtent > tvecMax.z )
            tvecMax.z = tCenter.z + fLargestExtent;
```

We next test to see if subtracting the radius of our sphere from the ellipsoid's starting position provides a new minimum extent for any of the axes.

```
    if ( tCenter.x - fLargestExtent < tvecMin.x )
            tvecMin.x = tCenter.x - fLargestExtent;

    if ( tCenter.y - fLargestExtent < tvecMin.y )
            tvecMin.y = tCenter.y - fLargestExtent;

     if ( tCenter.z - fLargestExtent < tvecMin.z )
            tvecMin.z = tCenter.z - fLargestExtent;
```

Now we test to see if adding the sphere radius to the destination location of the ellipsoid's center point (calculated as tCenter + tVelocity) provides a new maximum extent for any axis.

```
     if ( tCenter.x + tVelocity.x + fLargestExtent > tvecMax.x )
            tvecMax.x = tCenter.x + tVelocity.x + fLargestExtent;

     if ( tCenter.y + tVelocity.y + fLargestExtent > tvecMax.y )
            tvecMax.y = tCenter.y + tVelocity.y + fLargestExtent;

     if ( tCenter.z + tVelocity.z + fLargestExtent > tvecMax.z )
            tvecMax.z = tCenter.z + tVelocity.z + fLargestExtent;
```

And finally we test to see if subtracting the radius of our sphere from the destination location of the ellipsoid's center point provides us with a new minimum extent for any axis.

```
     if ( tCenter.x + tVelocity.x - fLargestExtent < tvecMin.x )
```

```
            tvecMin.x = tCenter.x + tVelocity.x - fLargestExtent;

    if ( tCenter.y + tVelocity.y - fLargestExtent < tvecMin.y )
            tvecMin.y = tCenter.y + tVelocity.y - fLargestExtent;

    if ( tCenter.z + tVelocity.z - fLargestExtent < tvecMin.z )
            tvecMin.z = tCenter.z + tVelocity.z - fLargestExtent;
```

With floating point inaccuracies being what they are, we would hate the above bounding box to miss a vertex later on just because it was outside the box by some very small epsilon value (0.000001 for example). Therefore, we will give ourselves a bit of padding by inflating the box 2 units along each axis; one unit for each axis in the positive direction and one for each axis in the negative direction.

```
    // Add Tolerance values
    tvecMin -= D3DXVECTOR3( 1.0f, 1.0f, 1.0f );
    tvecMax += D3DXVECTOR3( 1.0f, 1.0f, 1.0f );
```

We now have a bounding box in terrain space encompassing all the triangles that might intersect the movement of the ellipsoid. Any triangles outside this box cannot possibly collide, so sending them through our intersection routines would be unnecessary.

Next we need to transform our box into the image space of the height map. This is very easy to do. The terrain object's scale vector was used to transform a pixel in the height map into terrain space. All we had to do was multiply the x and y coordinate of the pixel by the scaling vector and we get the terrain space X and Z vertex coordinates generated from the pixel. The value stored in the pixel itself was also multiplied by the scale vector to create the height of the vertex (Y position) in terrain space. Thus, all we have to do to turn our terrain space 3D bounding box into a 2D rectangle on the height map, is reverse the process and divide the X and Z extents of this box by the scaling vector. We also snap the results to integer pixel locations on the height map as shown below.

```
    // Calculate the actual heightmap start and end points
    // (ensure we have enough surrounding points)
    nStartX = (long)(tvecMin.x / vecScale.x) - 1;
    nStartZ = (long)(tvecMin.z / vecScale.z) - 1;
    nEndX   = (long)(tvecMax.x / vecScale.x) + 1;
    nEndZ   = (long)(tvecMax.z / vecScale.z) + 1;
```

Notice how after generating the integer extents of the 2D box along both the X and Z axes, we subtract and add one to the minimum and maximum extents, respectively. This is to make sure that we always have at least four different corner points so that at least a single quad can be built. If we imagine for example that the ellipsoid is small and has no velocity, it is possible that the four extents of the terrain space bounding box, when transformed into image space and snapped to integer values, could all map to the same single pixel location in the height map. Remember that a pixel in the height map represents a vertex, so we need at least four unique points to build a quad. This addition and subtraction makes sure this is always the case.

In the next section of code we clamp the extents of the bounding box so that its extents are within the image of the height map. We certainly do not want to be trying to access pixel locations like x=600 if

the image is only 300 pixels wide. We also do not want to try and access pixel locations like x=-10 since there are no negative pixels in image space.

```
    // Clamp these values to prevent array overflow
    nStartX = max( 0, min( Width - 1, nStartX ) );
    nStartZ = max( 0, min( Height - 1, nStartZ ) );
    nEndX   = max( 0, min( Width - 1, nEndX ) );
    nEndZ   = max( 0, min( Height - 1, nEndZ ) );
```

At this point, we have four integer values which describe the corner points of our 2D bounding box where (nStartZ, nStartX) = Top Left and (nEndZ, nEndX) = Bottom Right. Remember at this point that nStartZ and nEndZ describe the image space Y axis, which increases top to bottom. Before we start stepping through these pixels and building vertices from each one, we should first make sure that the bounds of the box are not degenerate. That is, if the width or height of the box is zero then we just return true. We have no triangles to add from this terrain to the collision list.

```
    // Return if the bounds are degenerate (no op)
    if ( nEndX - nStartX <= 0 || nEndZ - nStartZ <= 0 ) return true;
```

Now it is time to start stepping through the rows and columns of pixels contained inside the rectangle on the image.

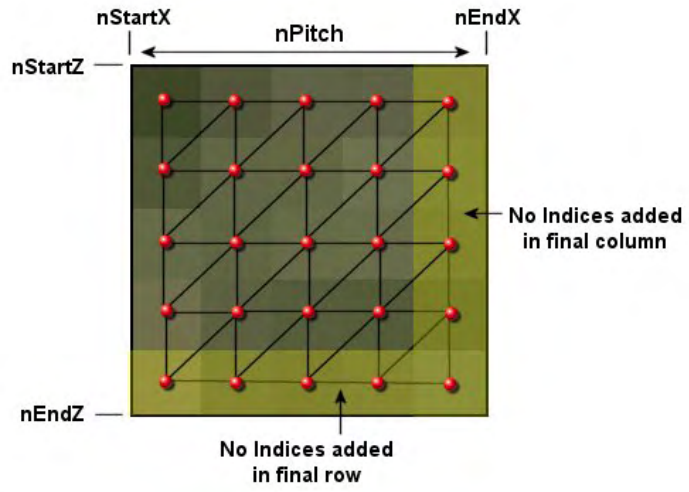

Figure 13.8

Figure 13.8 shows how we will build the vertex and triangle data for the vertices inside our box. Starting at the top left corner (nStartX , nStartY) we will work along each row and along each column. For each pixel in the height map we will add a vertex along with six indices describing the quad formed by the vertex, its right neighbor, the vertex below it and the vertex below and to the right of it. Since the top left vertex of any quad is the first to be added, when building the two triangles at the vertex, our triangles will be indexing into vertices that we have not yet added.

For example, look at the top left vertex in Figure 13.8, which shows the vertex that will be added in the first iteration of the loop. Not only will we create a vertex here, we will also create the entire top left quad (the group of four vertices in the top left corner). Although these other three vertices have not been added yet, we know where they will be positioned in the vertex buffer because we know how many vertices will be created in a given row (nPitch).

In Figure 13.8 we can see that the image space bounding box has dimensions of 5x5, so we will be adding 5 rows of 5 vertices. Therefore, if there are 5 vertices in each row, the pitch of our vertex array will be 5. When we visit the top left vertex, this will be vertex 0 in the array. Although the other three

vertices forming the quad have not yet been added (but will be added in future iterations of the loop) we do know the locations where each of these vertices will be in the vertex array and therefore we have the information with which to build the quad which uses the current vertex as the top left corner. We know for example that when processing a vertex at position *n*, the four vertex positions of all vertices forming the quad will eventually be in our vertex array at:

Top Left = n (Current Vertex)
Top Right = n+1
Bottom Left = n+pitch
Bottom Right = n+pitch+1

If we were currently processing the pixel at x=2 and y=10 in the rectangle, the vertices that would be added to the vertex buffer (assuming a pitch of 5 vertices per row) in the inner loop iteration would be:

Top Left = 2+10*pitch
Top Left = 52

In other words, the vertex we are currently processing will be added at location 52 in the vertex array. Furthermore, although they have not yet been added, the other three vertices comprising the quad will be added to the vertex array at positions:

Top Right = 2+1 + (10*pitch) = 53

Bottom Left = 2 + ((10+1)*pitch) = 67

Bottom Right = (5+1) + ((10+1)*pitch) = 68

As you can see, although we have only made it as far as processing vertex 52 (2nd vertex in the 10th row of our box), we can calculate the indices of the four vertices needed to comprise the quad. But this means that we must make sure we do not try to add any triangle data when processing the last vertex in each column and the last row of vertices. If you look at Figure 13.8 once again, you will see that the last column and the last row of vertices are highlighted yellow. When processing these vertices, we will not add any indices at all (only the vertices) because the quads that these vertices are a part of have already been added when processing the previous vertex in the column or row.

Let us now loop through each pixel in our bounding box and create the vertex and triangle data for it. First we calculate nPitch, which contains the number of vertices that will be in each row of the vertex array we will compile. We calculate this by adding 1 to the width of the image space bounding box.

```
    // Catch all exceptions
    try
    {
        // Store pitch value (to save us having to calculate each time
        nPitch = (nEndX - nStartX) + 1;
```

Notice how we add 1 to the result since this is the count of the number of vertices that will comprise each row of our vertex buffer, and we do not want it to be zero based. For example, if StartX=10 and

EndX=14 then this means there are actually 5 vertices on each row (the vertices at locations 10,11,12,13 and 14). If we were to just subtract the start dimension from the end dimensions we would get 14-10=4, which is not correct.

Now that we know the start and end positions of our bounding box along the X and Y axes of image space, we will loop through each row (outer loop) and each column (inner loop).

```
        // Build triangle data for each of the quads this falls into
        for ( nZ = nStartZ, nCounterZ = 0; nZ <= nEndZ; ++nZ, ++nCounterZ )
        {
            // For each column
            for ( nX = nStartX, nCounterX = 0; nX <= nEndX; ++nX, ++nCounterX )
            {
```

If we are not about to add the last vertex in a row or the last vertex in a column, we will allocate enough room in our triangle buffer to add two more CollTriangle structures. This is because we are about to create the quad for which the current vertex we are processing forms the top left corner. Notice how we allocate a temporary triangle structure that will be reused to add the data for each triangle of this quad to the triangle buffer.

```
                // Do not add triangle data for last column / row
                if ( nZ < nEndZ && nX < nEndX )
                {
                    CollTriangle Triangle;
                    ZeroMemory( &Triangle, sizeof(CollTriangle) );

                    // Grow the triangle buffer if required
                    if ( TriBuffer.capacity() < TriBuffer.size() + 2 )
                    {
                        // Reserve extra space
                        TriBuffer.reserve(TriBuffer.capacity()+m_nTriGrowCount );

                    } // End if should grow buffer
```

Each CollTriangle structure has a three element indices array, so we will add the indices for the first triangle. We will then add the triangle structure to the passed triangle buffer (STL vector).

```
                    // Build first triangle
                    Triangle.Indices[2] = nCounterX + nCounterZ * nPitch;
                    Triangle.Indices[1] = (nCounterX + 1) + nCounterZ * nPitch;
                    Triangle.Indices[0] = nCounterX + (nCounterZ + 1) * nPitch;

                    // Store first triangle
                    TriBuffer.push_back( Triangle );
```

Now we will reuse the CollTriangle structure to add the indices of the second triangle in the quad and add that to the triangle buffer also.

```
                    // Build second triangle
                    Triangle.Indices[2]= (nCounterX + 1) + nCounterZ * nPitch;
                    Triangle.Indices[1]= (nCounterX+1) + (nCounterZ + 1) * nPitch;
```

```
                    Triangle.Indices[0]=  nCounterX + (nCounterZ + 1) * nPitch;

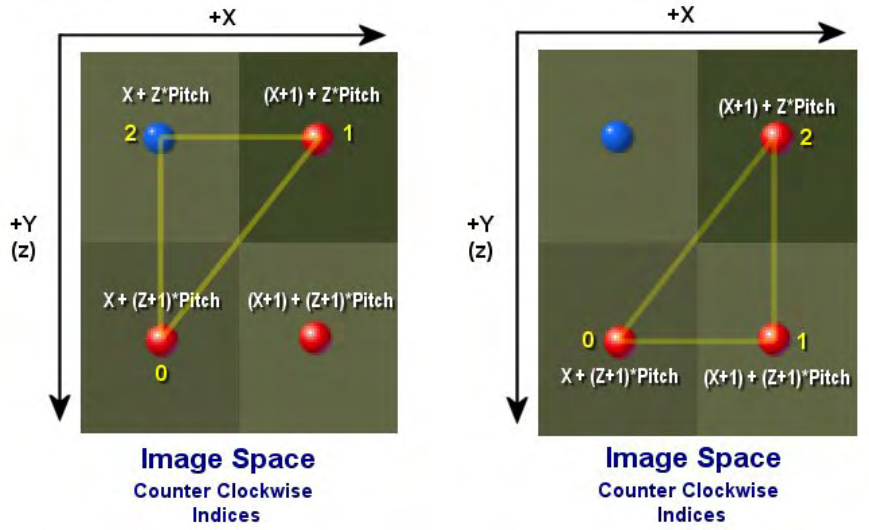
                    // Store second triangle
                    TriBuffer.push_back( Triangle );

                } // End if last column / row
```

At this point we have added the two triangles that form the quad. Remember, this quad is only created and added if the current vertex we are processing (nCounterX, nCounterY) is not the final vertex in a row or the final vertex in the column (Figure 13.8).

You might have noticed that we are defining the indices of each triangle in a counter clockwise winding order. Figure 13.9 should help you visualize both the first and second triangle we add in the above code.

Figure 13.9



Triangle 1 **Triangle 2**

The vertices have been clearly indexed by each triangle in a counter clockwise order in image space. However, we must remember that the image space Y axis is equivalent to our terrain space Z axis. Furthermore, while the image space Y axis increases as it goes down the screen, in terrain space, if we were looking down on the terrain mesh from above, the Z axis would decrease as it headed down the screen. Therefore, as discussed back in 3D Graphics Module I, when we first examined terrain building using height maps, when the image is mapped to terrain space (when the image space Y axis is used as the terrain space Z axis) there is an implied 'flip' of the terrain about the image space Y axis. If we change the direction of the image space Y axis so that it is facing the opposite direction (as is the case when we build a 3D mesh from this image) you will see that the triangles are now defined with a clockwise winding order. Therefore, we define them counter clockwise in image space so that when the image is flipped during the transformation to terrain space, the winding order changes and all is well. Figure 13.10 shows the two images flipped along the image space Y axis. This is what happens when the image space Y coordinates are mapped to the terrain space Z axis.

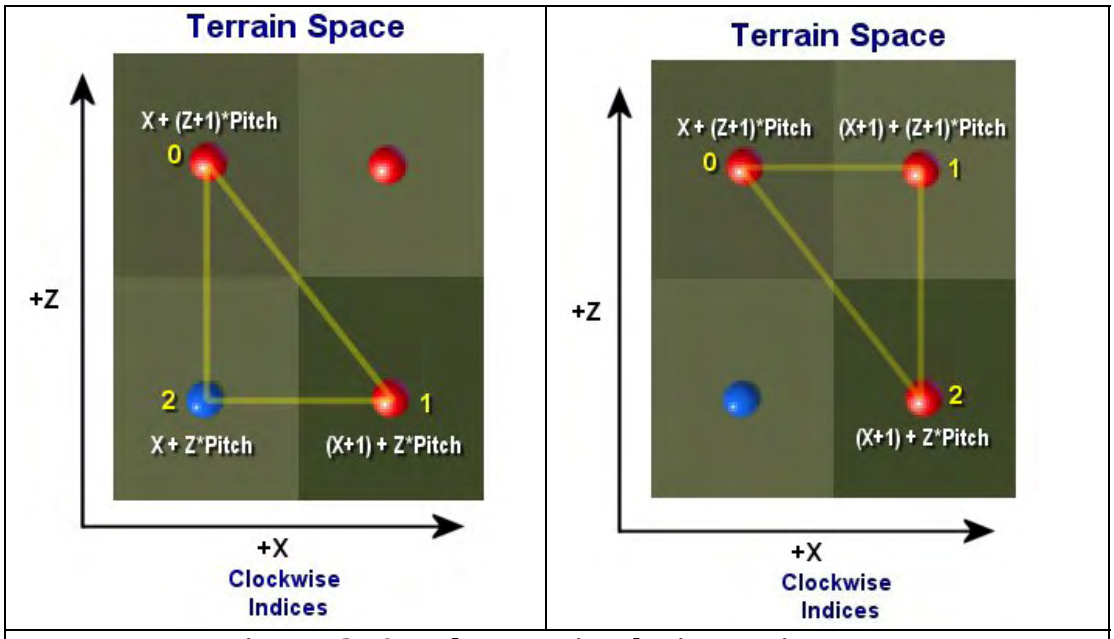


Figure 13.10 : The two triangles in terrain space

So we have added the quad (if applicable) whose top left corner is represented by the current pixel we are visiting. Now it is time to create and add the vertex itself. First we make sure there is enough room in the vertex array to add another vertex. If not, we resize the vector.

```
                // Grow the vertex buffer if required
                if ( VertBuffer.capacity() < VertBuffer.size() + 1 )
                {
                    // Reserve extra space
                    VertBuffer.reserve( VertBuffer.capacity()+m_nVertGrowCount );

                } // End if should grow buffer
```

The terrain space vertex position along the X and Z axes is simply the X and Y coordinate of the pixel scaled by the terrain object's scale vector. The Y coordinate of the vertex is the value of the pixel itself (stored in the pHeightMap array) scaled by the Y component of the terrain object's scale vector.

```
                // Calculate the vertex
                Vertex = D3DXVECTOR3( (float)nX * vecScale.x,
                                       pHeightMap[nX+nZ * Width] * vecScale.y,
                                      (float)nZ * vecScale.z  );
```

At this point, we have the terrain space vertex, but we need to return our triangle information in world space. So we multiply the vertex by the terrain object's world matrix before finally adding it to the vertex array.

```
                // Transform into world space
                D3DXVec3TransformCoord( &Vertex, &Vertex, &mtxWorld );
```

```
                // Add the vertex to the buffer
                VertBuffer.push_back( Vertex );

            } // Next Column

        } // Next Row
```

If we get to this point in the function we have successfully added a rectangular region of world space triangles to the passed vectors.

Our collision system also requires that each triangle have a normal which will be used as the slide plane normal in the case of impacts between the ellipsoid and the interior of triangle. Therefore, as a last step, we will loop through all the triangle structures we have just added to the triangle vector and generate a normal for each one. We do this using the same technique we have used many times before. That is, we use the vertices of the triangle to create two edge vectors that are tangent to the triangle surface and perform the cross product on them to generate a vector that is perpendicular to the surface. We then normalize the result.

```
        // Calculate resulting normals
        D3DXVECTOR3 v1, v2, v3, Edge1, Edge2;
        CollTriVector::iterator Iterator = TriBuffer.begin();
        for ( ; Iterator != TriBuffer.end(); ++Iterator )
        {
            // Get a REFERENCE to the underlying triangle
            CollTriangle & Triangle = *Iterator;

            // Retrieve vertices
            v1 = VertBuffer[ Triangle.Indices[0] ];
            v2 = VertBuffer[ Triangle.Indices[1] ];
            v3 = VertBuffer[ Triangle.Indices[2] ];

            // Calculate two edge vectors
            Edge1 = v2 - v1;
            Edge2 = v3 - v1;

            // Generate cross vector
            D3DXVec3Cross( &Triangle.Normal, &Edge1, &Edge2 );
            D3DXVec3Normalize( &Triangle.Normal, &Triangle.Normal );
        } // Next Triangle

    } // End Try Block

    catch ( ... )
    {
        // Return false. We failed.
        return false;

    } // End Catch

    // We added data successfully.
    return true;
}
```

At the end of the function you can see the catch block that simply returns false should an exception be thrown during execution.

Using the Collision System with Dynamic Objects

We have already discussed all the methods that allow our application to register dynamic object groups with the collision database. We discovered that when an object (or a hierarchy of objects) is registered with the collision system, an object set index is returned to the application. This index is the handle by which the application informs the collision system that it has altered the matrix (matrices) of an object (group of objects).

Some exterior entity (the application, a CObject, a D3DXFRAME, etc.) owns the matrix that contains the world space transformation for a dynamic object; the collision system simply maintains a pointer to it for access during dynamic object updates. The application can feel free to move the dynamic object about in the world by setting that matrix explicitly or by playing animations on the actor which owns the object.

CCollision::ObjectSetUpdated

Whenever the application updates the matrix of a dynamic object, it must inform the collision system by calling its ObjectSetUpdated method. The only parameter that need be passed is the object set index of the group that has had its matrix (matrices) updated. If the object set index represents a hierarchy of dynamic objects (an actor), then calling this function will cause the collision matrix of every effected dynamic object to be recalculated. Here is the code to the function.

```
void CCollision::ObjectSetUpdated( long Index )
{
    D3DXMATRIX mtxInv;

    // Update dynamic object matrices
    DynamicObjectVector::iterator ObjIterator = m_DynamicObjects.begin();
    for ( ; ObjIterator != m_DynamicObjects.end(); ++ObjIterator )
    {
        DynamicObject * pObject = *ObjIterator;

        // Skip if this doesn't belong to the requested set.
        if ( pObject->ObjectSetIndex != Index ) continue;

        // Generate the inverse of the previous frames matrix
        D3DXMatrixInverse( &mtxInv, NULL, &pObject->LastMatrix );

        // Subtract the last matrix from the current to give us the difference
        D3DXMatrixMultiply(   &pObject->VelocityMatrix,
                              &mtxInv, pObject->pCurrentMatrix );

        // Store the collision space matrix
        pObject->CollisionMatrix = pObject->LastMatrix;
```

```
        // Update last matrix
        pObject->LastMatrix = *pObject->pCurrentMatrix;

    } // Next Object
}
```

It loops though every dynamic object in the collision system's dynamic object array. For each one it finds with a matching object set index, it calculates the new velocity matrix. As discussed in the textbook, the velocity matrix describes the relative transformation from its previous position/orientation. We calculate this by inverting its previous world matrix and multiplying it with the new updated world matrix. This provides a relative movement matrix describing how the object has moved between this update and the previous one. We store this data in the velocity matrix member of the dynamic object. As we saw in the EllipsoidIntersectScene function, this matrix is used to extend the swept sphere so that intersection tests can be performed against the geometry of the dynamic object in its previous position. We then store the current previous world matrix in the collision matrix member. The collision matrix describes the previous world transform of the object and will be used alongside the velocity matrix by the intersection routines. We then copy the new current world matrix into the last matrix member so that the process can be repeated again and again every time the object group is updated. Remember, only the collision matrix and the velocity matrix are used by the intersection routines. The last matrix and current matrix members are used only to generate these two matrices.

CCollision::SceneUpdated

Rather than force the application to call the ObjectSetUpdated method for each updated object, a convenience function has been added that allows the application to tell the collision system that all dynamic objects should have their matrix states updated simultaneously with a single function call.

The SceneUpdate method of the CCollision class (shown below) is almost identical to the previous function. The difference is that it is not passed an object set index. It just updates the matrices for every dynamic object registered with the system.

```
void CCollision::SceneUpdated( )
{
    D3DXMATRIX mtxInv;

    // Update dynamic object matrices
    DynamicObjectVector::iterator ObjIterator = m_DynamicObjects.begin();
    for ( ; ObjIterator != m_DynamicObjects.end(); ++ObjIterator )
    {
        DynamicObject * pObject = *ObjIterator;

        // Generate the inverse of the previous frames matrix
        D3DXMatrixInverse( &mtxInv, NULL, &pObject->LastMatrix );

        // Subtract the last matrix from the current to give us the difference
        D3DXMatrixMultiply(   &pObject->VelocityMatrix,
                              &mtxInv,
                              pObject->pCurrentMatrix );
```

```
        // Store the collision space matrix
        pObject->CollisionMatrix = pObject->LastMatrix;

        // Update last matrix
        pObject->LastMatrix = *pObject->pCurrentMatrix;

    } // Next Object
}
```

Applications should ***never*** use this function with actors that have been registered as dynamic references. This is a simple convenience function that applied only in cases where actor references are not being used. Do you see why this must be the case?

To keep things simple, imagine a single mesh actor that has been initially registered with the collision system and then referenced 9 times (via AddActorReference). This means we will have 10 dynamic objects in the system. The first registered dynamic object allocates the geometry and its current matrix pointer would point at the object's absolute frame matrix in the hierarchy. The other 9 dynamic objects share the geometry buffers and have their matrix pointers pointing at the same frame matrix. Therefore, if you call this function, the matrix pointer of every dynamic object will point to the same matrix, the current position described by the frame. As discussed in the textbook, when actor references are used, we update the actor matrices first and then call the ObjectSetUpdated function so that the collision system can grab a snapshot of the current matrices. We then update the actor matrices for the second reference, call ObjectSetUpdated again, and so on. This is very important and has the potential to cause numerous problems if not remembered. There is no way the single actor can ever be in more than one pose at a time. If you were to call this function, all dynamic objects that were created from the same mesh in the same actor would all be assigned the same world matrix.

CCollision::Clear

There may be times when you wish to purge the collision system geometry database so that you can re-use the same collision object for a different task. The Clear method does just this. This method is also used by the CCollision destructor to release all memory before the system is deleted.

Clear resets the state of the CCollision object to its default state. It sets its internal transform matrix to an identity matrix and then loops through each dynamic object. For each dynamic object it finds that is not a reference, it will delete its geometry buffers. It does not do this for references as they do not own their own geometry. Whether a reference object or not, the dynamic object structure is then deleted from memory also. This is done for each dynamic object in the collision system's dynamic object vector.

```
void CCollision::Clear( )
{
    ULONG i;

    // Reset the internal transformation matrix
    D3DXMatrixIdentity( &m_mtxWorldTransform );
    // Release dynamic object pointers
    for ( i = 0; i < m_DynamicObjects.size(); ++i )
    {
```

```
        // Retrieve the object
        DynamicObject * pObject = m_DynamicObjects[i];

        // Delete if existing
        if ( pObject )
        {
            // We only delete our mesh data if were not a reference
            if ( !pObject->IsReference )
            {
                // Release the vectors
                if ( pObject->pCollVertices  ) delete pObject->pCollVertices;
                if ( pObject->pCollTriangles ) delete pObject->pCollTriangles;

            } // End if not reference

            // Delete the object
            delete pObject;
        }
    }
```

We then loop through each element in the collision system's terrain pointer vector. Before clearing this vector we must first call the Release method on each terrain pointer because our terrain object employs a COM style reference counting mechanism. You will recall how we incremented the reference count of a terrain object when its pointer was added in the AddTerrain method discussed earlier.

```
    // Release terrain objects
    for ( i = 0; i < m_TerrainObjects.size(); ++i )
    {
        // Retrieve the object
        CTerrain * pTerrain = m_TerrainObjects[i];

        // Release if existing
        if ( pTerrain ) pTerrain->Release();

    } // Next Terrain Object
```

Finally, we empty the static geometry vectors, the dynamic object vector, and the terrain vector, releasing all the memory they currently contain. We then reset the m_nLastObjectSet member variable back to its default state of -1 since there now no object sets registered with the collision system.

```
    // Empty our STL containers.
    m_CollTriangles.clear();
    m_CollVertices.clear();
    m_DynamicObjects.clear();
    m_TerrainObjects.clear();

    // Reset any variables
    m_nLastObjectSet = -1;
}
```

Registering Geometry with the Collision System

In this next section we will discuss the additions to the application's loading code that manage collision system registration. The CCollision object is actually a member of our CScene class. This is useful since this class manages loading geometry data, and the animation and rendering of that data in the main game loop. We will revisit functions such as CScene::ProcessMeshes, CScene::ProcessReferences, and CScene::ProcessEntities, which are no strangers to us. These are the functions we have used since the beginning of this training program to process the objects loaded from IWF files by the CFileIWF file object.

In this workbook we will focus on the additions to the IWF loading code in CScene. The CScene::LoadSceneFromX function will not be discussed since it has hardly changed from previous versions. It simply loads the single X file into a CActor object and then registers it with the collision system using the CCollision::AddActor function. Because adding actors to the collision system will be demonstrated in the IWF loading code, you should have no trouble noticing the necessary changes to this function.

Loading IWF Files – Recap

In virtually all of our previous projects we have used the CScene::LoadSceneFromIWF function to load in our geometry from IWF files. This function is called from the CGameApp::BuildObjects function which itself is called from CGameApp::InitInstance.

The LoadSceneFromIWF method uses the CFileIWF object contained in libIWF.lib. This library is part of the IWF SDK to automate the loading of IWF files. As we have discussed on previous occasions, the CFileIWF::Load function is used to load all the data objects contained in the IWF file into a number of vectors supplied by the library. For example, all entities contained in the IWF file are stored in the CFileIWF::m_vpEntityList vector and all internal meshes defined in the file are loaded into the CFileIWF::m_vpMeshList vector. Vectors also exist to store the materials and texture filenames. These vectors are automatically filled with data when CFileIWF::Load is called. This means all our scene object has to do on successful completion of this function is extract the data from these vectors and format it in the desired fashion. None of this is new to us as we developed this loading system way back in Module 1 and have been adding to it ever since.

The first updated function we will look at is the CScene::ProcessMeshes function. It is called from CScene::LoadSceneFromIWF to extract the data from the CFileIWF::m_vpMeshList vector. The function is passed a single parameter, the CFileIWF object that contains the meshes loaded from the file.

CScene::ProcessMeshes (Updated)

IWF files generally contain meshes in two different forms -- internal meshes and mesh references. If you have ever used GILES™ then you can think of the brushes that you place in the scene as the internal mesh type. The physical polygon data of such objects is saved out to the IWF file with a world matrix describing the position of the brush in the scene. In the case of GILES™, all brushes have their vertices

defined in world space, so the world matrix accompanying each mesh in the file will always be identity. The other type of mesh data that we have used is the reference entity. In GILES™, we can place a reference entity in the scene that contains the name of an X file. While GILES™ will physically render the geometry in the X file referenced by such an entity, this geometry is not saved out to the IWF file, only the filename of the X file is. The ProcessMeshes function is called to extract only internal geometry meshes whose geometry was stored in the IWF file. This geometry will have been loaded into the CFileIWF::m_vpMeshList array by the CFileIWF::Load function, so let us now parse this data.

We have discussed most of the code to this function before and as such we will simply step to the new code we have added.

In Lab Project 13.1, we decided only to add meshes to the collision database that are not flagged as detail objects (like a decoration), but you can easily change this behavior if you wish. After our mesh is constructed and the IWF copied, we call the collision system's AddIndexedPrimitive method and pass in the pointers to our new CTriMesh's vertex and index arrays. We use the member functions of CTriMesh to get all the information (vertex and face list pointers, the number of vertices and faces in those lists, and the stride of the vertex and indices). This single function call registers every single triangle of the CTriMesh with the collision system's static database. Notice that we do not bother setting the world transformation matrix because the internal meshes we load from GILES™ are already in world space.

```
        // Add this data to our collision database if it is not a detail object
        if ( !(pMesh->Style & MESH_DETAIL) )
        {
            // Add mesh data to collision database
            if ( !m_Collision.AddIndexedPrimitive(    pNewMesh->GetVertices(),
                                                      pNewMesh->GetFaces(),
                                                      pNewMesh->GetNumVertices(),
                                                      pNewMesh->GetNumFaces(),
                                                      pNewMesh->GetVertexStride(),
                                                      pNewMesh->GetIndexStride()))
            {
                // Clean up and fail, something bad happened
                delete pNewMesh;
                return false;

            } // End if failure to add data

        } // End if not detail object
```

CScene::ProcessReference

The CScene::LoadSceneFromIWF function calls the ProcessEntities function to process any entities that may have been loaded into the CFileIWF::m_vpEntities vector. External mesh references are stored as reference entities. The data area of a reference entity is arranged as a ReferenceEntity structure (CScene.h). This structure just contains the filename of the thing that it is referencing. When the ProcessEntities function determines it has found a reference entity, it calls the ProcessReference function. This function assumes that all reference entities are references to external X files and as such, the X files are loaded into actors along with any animation they may contain.

This function, while mostly unchanged, has a few new bits added. If the X file we are loading has already been loaded, then the actor is added to the collision system as an actor reference, otherwise it is added as a normal actor. We will move very quickly through this code, since most of it is familiar to us.

```
bool CScene::ProcessReference( const ReferenceEntity& Reference,
                               const D3DXMATRIX & mtxWorld )
{
    HRESULT                     hRet;
    CActor                    * pReferenceActor      = NULL;
    LPD3DXANIMATIONCONTROLLER   pReferenceController = NULL;
    LPD3DXANIMATIONCONTROLLER   pController          = NULL;
    long                        ObjectSetIndex       = -1;
    ULONG                       i;

    // Skip if this is anything other than an external reference.
    // Internal references are not supported in this demo.
    if (Reference.ReferenceType != 1) return true;
```

In the first section of code we test to see of the reference type member of the reference entity structure is set to 1 (external reference), if not we return as we do not currently support any other reference type. Notice how the ProcessEntities function will also pass in the world matrix of the reference which would also have been loaded from the file (as every entities is accompanied by a matrix in the IWF file).

Next we build the complete filename of the reference, and loop through each currently loaded actor. If we find an actor in the scene's CActor array that has the same name as the X file we are trying to load, then we know this X file has already been loaded into an actor and we break from the loop.

```
    // Build filename string
    TCHAR Buffer[MAX_PATH];
    _tcscpy( Buffer, m_strDataPath );
    _tcscat( Buffer, Reference.ReferenceName );

    // Search to see if this X file has already been loaded
    for ( i = 0; i < m_nActorCount; ++i )
    {
        if (!m_pActor[i]) continue;
        if ( _tcsicmp( Buffer, m_pActor[i]->GetActorName() ) == 0 ) break;

    } // Next Actor
```

We know at this point that if the loop variable *i* is not equal to the number of currently loaded actors, then the loop exited early because we found a matching actor. This means the X file geometry already exists in memory and we do not want to load it again. Instead, we will create an actor reference. We first get a pointer to the actor we are going to reference as shown below.

```
    // If we didn't reach then end, this Actor already exists
    if ( i != m_nActorCount )
    {
        // Store reference Actor.
        pReferenceActor = m_pActor[i];
```

We now see if any CObject exists in the scene's CObject array which is using the actor.

```
        // Find any previous object which owns this actor
        for ( i = 0; i < m_nObjectCount; ++i )
        {
            if (!m_pObject[i]) continue;
            if ( m_pObject[i]->m_pActor == pReferenceActor ) break;

        } // Next Object
```

If loop variable *i* is not equal to the number of objects in the CObject array, then we found an object that is using the actor we want to add to the collision system. Therefore, we will reference the object.

We first get a pointer to the CObject which contains the actor we wish to reference.

```
        // Add a REFERENCE dynamic object to the collision system.
        if ( i != m_nObjectCount )
        {
            CObject * pReferenceObject = m_pObject[i];
```

At this point we know that the CObject that already exists must have registered its actor with the collision system and as such, the CObject::m_nObjectSetIndex member will contain the object set index that was returned when this original actor was registered. We call the CCollision::AddActorReference function to register a new copy of this actor with the collision system at a different world space position. Notice how we pass in the object set index and the world matrix of the current reference we are processing. Provided the object set index we passed in exists, new dynamic objects will be created and added to the collision system as described by the matrix (the final parameter). These new dynamic objects (one for each mesh contained in the actor) will be added as a single new object set to the collision system and the index of that new set will be returned from the function.

```
            // Create a reference of this objects data in the collision system
            ObjectSetIndex = m_Collision.AddActorReference
                             ( pReferenceObject->m_nObjectSetIndex,
                               pReferenceObject->m_mtxWorld,
                               mtxWorld );
```

If the object we are referencing currently has no animation controller pointer, then it means no object references to this actor currently exist; it is only a single non-reference object. As soon as we add more than one CObject to the scene that uses the same actor, all CObjects that use that actor essentially become references and store their own animation controllers. We covered all of this logic before.

```
            // Is this the first reference?
            if ( !pReferenceObject->m_pAnimController )
            {
                // If this is the first time we've referenced this actor then
                // we need to detach its controller and store in the reference
                pReferenceObject->m_pAnimController =
                                        pReferenceActor->DetachController();

            } // End if first reference
```

```
            ULONG nMaxOutputs, nMaxTracks, nMaxSets, nMaxEvents;

            // Retrieve all the data we need for cloning.
            pController = pReferenceObject->m_pAnimController;
            nMaxOutputs = pController->GetMaxNumAnimationOutputs();
            nMaxTracks  = pController->GetMaxNumTracks();
            nMaxSets    = pController->GetMaxNumAnimationSets();
            nMaxEvents  = pController->GetMaxNumEvents();

            // Clone the animation controller into this new reference
            pController->CloneAnimationController( nMaxOutputs,
                                                   nMaxSets,
                                                   nMaxTracks,
                                                   nMaxEvents,
                                                   &pReferenceController );

        } // End if we found an original object reference.
```

The above section of code shows the conditional that happens when an object was found that uses the actor we wished to load. Outside that conditional code block, we test to make sure we have a valid object set index. If not, then it means that although the actor already exists (there is no need to create a new one, we can just reference it) it has ***not*** yet been assigned to a CObject or registered with the collision system. Therefore we cannot possibly register the actor with the collision system as a reference since it has not been added to the collision system in its non-referenced form. It is the first actor of this type we are registering.

When this is the case, we register the actor with the collision system as a normal actor. Notice that we register the actor with the collision system as a dynamic object group by passing false as the final parameter. Therefore, if this actor contains animation data, our application will be able to animate it and have the collision system respond to it in real time.

```
        // If the collision system could not match this object set index,
        // or we couldn't find an already existing object, add the full blown
        // actor.
        if ( ObjectSetIndex < 0  )
             ObjectSetIndex = m_Collision.AddActor( pReferenceActor,
                                                    mtxWorld,
                                                    false );

    } // End if Actor already exists
```

All the above code is executed if the file name of the external reference we are trying to load has already been loaded for a previous actor. In short, if it has, we decide we never want two copies of the same frame hierarchy in memory, so we reference it both in the scene and in the collision system.

The next section of code shows what happens when the actor has not already been loaded. When this is the case, we must create a new actor, load the X file and register its attribute callback function (CScene::CollectAttributeID). We then load the actor from the X file. The name of the X file we wish to load is the name of the external reference which is now stored in the Buffer array along with the data path.

```
    else

    {
        // Allocate a new Actor for this reference
        CActor * pNewActor = new CActor;
        if (!pNewActor) return false;

        // Load in the externally referenced X File
        pNewActor->RegisterCallback( CActor::CALLBACK_ATTRIBUTEID,
                                     CollectAttributeID, this );

       HRet = pNewActor->LoadActorFromX(  Buffer,
                                          D3DXMESH_MANAGED,
                                          m_pD3DDevice );

       if ( FAILED(hRet) ) { delete pNewActor; return false; }
```

With the actor now loaded, we make room at the end of the scene's CActor array for another actor pointer and store our current actor. Our code upgrade (in bold) now registers this new actor with the collision system. We also assign the local pRefereneActor pointer to point at this actor so that outside this conditional code block we can use the same pReferenceActor pointer whether a new actor was loaded, or whether it just points to an actor that was previously loaded.

```
        // Store this new Actor
        if ( AddActor( ) < 0 ) { delete pNewActor; return false; }

        m_pActor[ m_nActorCount - 1 ] = pNewActor;

        // Add the physical actor to the collision system
        ObjectSetIndex = m_Collision.AddActor( pNewActor, mtxWorld, false );

        // Store as object reference Actor
        pReferenceActor = pNewActor;

    } // End if Actor doesnt exist.
```

At this point, regardless of whether we created and loaded a new actor or are using one that was already loaded, pReferenceActor will point at it. Let us now create a new CObject to hold this actor. Notice again that we pass the actor pointer into the CObject constructor.

```
    // Now build an object for this Actor (standard identity)
    CObject * pNewObject = new CObject( pReferenceActor );
    if ( !pNewObject ) return false;
```

We also store the world matrix of the reference (passed into the function) and a pointer to the animation controller it will use. Along the way we will store a copy of the object set index that was assigned during actor registration with the collision system. Finally, we add this object to the end of the scene CObject array and return.

```
    // Copy over the specified matrix and store the colldet object set index
    pNewObject->m_mtxWorld        = mtxWorld;
```

```
    pNewObject->m_nObjectSetIndex = ObjectSetIndex;

    // Store the reference animation controller (if any)
    pNewObject->m_pAnimController = pReferenceController;

    // Store this object
    if ( AddObject() < 0 ) { delete pNewObject; return false; }
    m_pObject[ m_nObjectCount - 1 ] = pNewObject;

    // Success!!
    return true;
}
```

CScene::ProcessEntities

The process entities function has had one line added to it to register any loaded terrains with the collision database. We will not show the entire function but only a subsection of the code that deals with the terrain entity type. The complete loading code for the terrain entity was discussed in the previous lesson. We start at the switch statement used to determine which type of entity we are processing.

```
            switch ( pFileEntity->EntityTypeID )
            {
                  …
                  …
                  Code Snipped here for other entity types
                  …
                  …

                   case CUSTOM_ENTITY_TERRAIN:

                        …
                        … Code snipped here which copies entity info
                        … in to terrain entity structure Terrain

                        // Allocate a new terrain object
                        pNewTerrain = new CTerrain;
                        if ( !pNewTerrain ) break;

                        // Setup the terrain
                        pNewTerrain->SetD3DDevice( m_pD3DDevice, m_bHardwareTnL );
                        pNewTerrain->SetTextureFormat( m_TextureFormats );
                        pNewTerrain->SetRenderMode(GetGameApp()->GetSinglePass());
                        pNewTerrain->SetWorldMatrix
                                    ((D3DXMATRIX&)pFileEntity->ObjectMatrix );
                        pNewTerrain->SetDataPath( m_strDataPath );

                        // Store it
                        m_pTerrain[ m_nTerrainCount - 1 ] = pNewTerrain;

                        // Load the terrain
                        if ( !pNewTerrain->LoadTerrain( &Terrain ) ) return false;

                        // Add to the collision system
```

```
                        m_Collision.AddTerrain( pNewTerrain );

                    } // End if standard terrain

                    break;
```

In the source code shown above, we have also removed all the code that simply copies the terrain data of the terrain from the CFileIWF object into a terrain entity structure. It still exists in the source code but has been removed here for readability.

After doing all of our usual setup for managing the terrain, as a final step, we call the CCollision::AddTerrain method to add a pointer to this terrain object to the end of the collision object's terrain list. As we have seen, the collision system can handle collisions with such terrain objects in a memory efficient way because it does not need to store a complete copy of every terrain triangle.

Updating the Geometry Database at Runtime

You should be well aware by now that the heartbeat of our application is the CGameApp::FrameAdvance function. At a high level, our runtime processing comes down to repeatedly calling this function in a loop. This function controls what happens for every single frame of the game and controls the flow in which events are processed. For example, each time it is called, it instructs the application to process any input that may have been given by the user. It then instructs the scene to apply any animations to any of its objects that it wishes for the current frame update. It also instructs the camera to update its view matrix and finally, it instructs both the scene and the CPlayer objects to render themselves.

Below we see the main snippet of the CGameApp::FrameAdvance function. We have not shown the code that tests for and recovers lost devices or the code that presents the back buffer. Instead we see all of the function calls made to transform and render the scene and the order in which states are updated in a given iteration of the game loop.

```
    // Poll & Process input devices
    ProcessInput();

    // Animate the scene objects
    m_Scene.AnimateObjects( m_Timer );

    // Update the Player ( Used to be in ProcessInput )
    m_Player.Update( m_Timer.GetTimeElapsed() );

    // Update the device matrix
    m_pCamera->UpdateRenderView( m_pD3DDevice );

    // Clear the frame & depth buffer ready for drawing
    m_pD3DDevice->Clear(0,NULL, D3DCLEAR_TARGET | D3DCLEAR_ZBUFFER, 0x79D3FF,
                        1.0f, 0 );

    // Begin Scene Rendering
    m_pD3DDevice->BeginScene();
```

```
    // Render the scene
    m_Scene.Render( *m_pCamera );

    // End Scene Rendering
    m_pD3DDevice->EndScene();
```

Notice in the above code snippet from Lab Project 13.1 that we now have a CPlayer::Update call after the call to AnimateObjects. This function call used to update the position of the player was originally called directly from the ProcessInput function. We will discuss why we have moved it out of that function and into the FrameAdvance function shortly.

The above code clearly shows that the CScene::AnimateObjects function is called during every iteration of the game loop. This gives the scene a chance to update the matrices of any scene objects it wishes to animate. It also allows the scene object to advance animation controllers of any actors currently participating in the scene. We need to revisit this function so that we can add the code that will notify the collision system when the scene geometry has been animated.

CScene::AnimateObjects

In this lesson we will have to inform the collision system when any objects that have been registered as dynamic objects with the collision system have been animated.

The function first loops through every CObject in the scene's CObject array. In Lab Project 13.1, we only animate actors, so we are not interested in finding any objects in this function which contain only a single CTriMesh. You can see that at the start of the object loop, we skip the current object if it does not have a valid CActor pointer.

```
void CScene::AnimateObjects( CTimer & Timer )
{
    ULONG i;

    // Process each object for coll det
    for ( i = 0; i < m_nObjectCount; ++i )
    {
        CObject * pObject = m_pObject[i];
        if ( !pObject ) continue;

        // Get the actor pointer
        CActor * pActor = pObject->m_pActor;
        if ( !pActor ) continue;
```

We next test to see if the object we are about to animate has a valid animation controller pointer. If the pointer is NULL, then it means either the actor has no animation to play, or this is the only object that references the actor and therefore the animation controller is owned by the actor itself. If the object does have a valid animation controller pointer, then there are multiple objects that reference this object's actor. This means we must attach the animation controller of this reference object to the actor so that we can animate the hierarchy using the reference's animation data. Once we attach the controller to the

actor, we advance its timeline. This will cause the parent relative frame matrices of the actor's hierarchy to be rebuilt in the pose described by the reference's animation controller. The parent relative matrices of the hierarchy will now describe the actor exactly as it should look for this particular reference.

```
        if ( pObject->m_pAnimController )
            pActor->AttachController( pObject->m_pAnimController, false );

        // Advance time
        pActor->AdvanceTime( Timer.GetTimeElapsed(), false );
```

Next we get the object set index assigned by the collision system when it was registered during the CScene::ProcessReference function. We set the actor's world matrix and pass true to the CActor::SetWorldMatrix function which forces all the absolute matrices of the actor to be rebuilt in their correct world space positions. Remember, it is these absolute matrices that the dynamic objects in the collision system point to. We must remember to update the world space matrices *before* instructing the collision system to update the status of the object group.

```
        //If the object has a collision object set index,
        // update the collision system.
        if ( pObject->m_nObjectSetIndex > -1 )
        {
            // Set world matrix and update combined frame matrices.
            pActor->SetWorldMatrix( &pObject->m_mtxWorld, true );

            // Notify the collision system that this set of dynamic objects
            // positions, orientations or scale have been updated.
            m_Collision.ObjectSetUpdated( pObject->m_nObjectSetIndex );

        } // End if actor exists

    } // Next Object

}
```

Once the world matrices of the actor have been built, we call the CCollision::ObjectSetUpdated function, passing in the object set index for the reference. This will instruct the collision system to search for all dynamic objects that were spawned from this actor and recalculate their collision and velocity matrices based on the updated world space frame matrices.

Collision Geometry Management – Final Note

We have now covered everything we need to know about registering scene geometry of different types with our collision system. We have seen how to load and register static meshes, actor references, and terrain entities with the collision system. We have also talked about how we should correctly manage updates for scene geometry that is registered as dynamic.

What we have not yet discussed are the actual moving entities that will use our collision system to collide and slide in the environment. In Lab Project 13.1, we will use the CPlayer object as the moving

entity. It will support both a first and third person camera. The mesh of the player in first person mode will be our U.S. Army Ranger from the prior lessons on skinning.

By attaching the skinned mesh to the CPlayer object, we can move it about the scene and watch it collide and slide in the environment. However, our CPlayer object has always been a little rudimentary when it comes to its physics handling. Now we will need to pay a little more attention to these details because we want to implement player movement that is typical in a first/third person game. Therefore, in the next section, we will discuss the changes to our player class to see how some simple improvements to our physics model will provide better environment interaction in our collision system.

> **Note**: Our intent is not to design a proper physics engine in this course. That would be the subject of an entire course by itself. We are simply trying to provide a more realistic feel for our player as it navigates throughout the world. Although the system we use is based on some laws of Classical Mechanics, it is still going to be a very rudimentary system. Learning how to create an actual physics engine with support for rigid bodies, vehicles, and the like, falls into the domain of the Game Physics course offered here at Game Institute.

The Revised CPlayer Class

Our previous CPlayer class was pretty straightforward and much of the relationship between the CGameApp object and the CPlayer object will remain intact. However, the CPlayer::Update function, which was responsible for calculating the player velocity will be totally rewritten. For one thing, it will use more appropriate physics calculations. It will also issue an update request to the collision system via a CScene callback function.

Let us quickly recap the way things used to work so that we get a better idea for what has to change.

- The CGameApp::FrameAdvance function would call the CGameApp::ProcessInput function with each iteration of the game loop.

- The ProcessInput function would read the state of the keyboard to combine a number of CPlayer flags describing the user direction request. The mouse would also be read to determine if the user wished to rotate the view.

- If the player tried to move, the ProcessInput function would call the CPlayer::Move function passing in the direction(s) the player should move (using a combination of flags) and the distance to move. The CPlayer::Move function would build a vector pointing in the requested direction with the requested length and add it to the current velocity vector (maintained internally). This updated velocity vector would not yet be used to update the position of both the player object itself and its attached camera. That happened later. All we have done this point is added a force to the velocity vector.

- If the ProcessInput function determined that the user also wished to rotate the player object (via mouse input), it would call the CPlayer::Rotate function to perform a local rotation to the CPlayer's world matrix.

- At this point in the ProcessInput function, the player object has been potentially rotated and its velocity vector has been updated, but the position has not yet been altered based on that velocity. The ProcessInput function would finally call the CPlayer::Update function before returning to apply the movement described by the velocity vector that had just been updated.

- The CPlayer::Update function is the one that will require the most changes in this new version. Previously, it added a gravity vector to the player's velocity vector so that a constant downwards force was applied to the player each frame. This would make sure that if the player had no terrain underneath him (the only type of collidable geometry we supported), they would fall downwards. We would also downscale the velocity vector of the player each frame based on a friction constant. By shortening the length of the velocity vector based on friction each time this function is called, we allowed our player to slow to a halt when the user released the movement keys instead of carrying on forever, as would be the case in a frictionless environment. The larger the value we set for the player object's friction, the more suddenly it would stop when no movement was being applied by the user. This is because the velocity vector will be shortened the next time the update function is called as long as the user does not press another movement key.

- The CPlayer::Update function would update the actual position of the player using the velocity vector. This would physically move the player object in the world.

- Keep in mind that the player object may have updated its position with respect to another scene object. You will recall that the CPlayer object maintained an array of callback functions to help in this regard. In previous applications, the CTerrain class registered a callback function with the player. This callback was invoked from the CPlayer::Update function after the position of the player had been updated. The callback function had a chance to examine the new position of the player and modify it if it finds it improper. In our previous applications, the terrain callback function would test the position of the player against the terrain geometry. If it found that the position of the player had been moved below the height of the terrain at that location, it would modify the height of the player's position so that it sat on top of the terrain. This is what prevented our simple gravity model from pushing the player through the terrain. This callback function will now be replaced with a CScene callback function which will use our new collision system.

- As the CPlayer::Update function also updated the position of the camera, it also instructed the camera to call any callback functions which have been registered for it. This allowed the same collision detection function to be used to modify the position of the player and its attached camera before returning.

- The CGameApp::FrameAdvance function would also call the CPlayer::Render function each frame to instruct the player to render any attached mesh (such as the third person mesh).

Our CPlayer object will now have the following member variables. Not all of them are new to us since our player class has always maintained a velocity vector, a gravity vector, and a scalar used to store the amount of drag to apply to the camera position when tracking the player in third person mode. Some of the other members shown below will be new and their usefulness will be described in this section.

Except from CPlayer.h (Lab 13.1)

```
    // Force / Player Update Variables
    D3DXVECTOR3     m_vecVelocity;          // Movement velocity vector
    D3DXVECTOR3     m_vecAppliedForce;      // Our motor force
    D3DXVECTOR3     m_vecGravity;           // Gravity vector
    float           m_fCameraLag;           // Amount of camera lag in seconds
    float           m_fTraction;            // How much traction we can apply
    float           m_fAirResistance;       // Air resistance coefficient.
    float           m_fSurfaceFriction;     // Fake Surface friction scalar
    float           m_fMass;                // Mass of player
```

There are also some simple inline public member functions to set the above properties of the player.

```
void SetGravity  ( const D3DXVECTOR3& Gravity  ) { m_vecGravity = Gravity; }
void SetVelocity ( const D3DXVECTOR3& Velocity ) { m_vecVelocity = Velocity; }
void SetCamLag   ( float CamLag )                { m_fCameraLag = CamLag; }
void SetTraction ( float Traction              ) { m_fTraction = Traction; }
void SetSurfaceFriction ( float Friction       ) { m_fSurfaceFriction = Friction; }
void SetAirResistance   ( float Resistance     ) { m_fAirResistance = Resistance; }
void SetMass            ( float Mass           ) { m_fMass = Mass; }
```

Useful Concepts in Classical Dynamics

Before we start examining the implementation of our application's physics model, let us begin with a very high level overview of some of the physics concepts we would like to consider as we put together our new system. To be sure, this will be a very quick introduction to Classical Dynamics. For a much more complete discussion, it is highly recommended that you take the Game Physics course offered here at the Game Institute.

Newton's Laws of Motion

We will start with some very basic ideas: Newton's Three Laws of Motion.

First Law: *When the net force on an object is zero, the motion of an object will be unchanged. An object at rest will remain so, unless compelled to change because some amount of force is applied.*

The first law basically tells us that if an object is moving with some direction and magnitude (i.e., velocity), it will continue moving with that velocity unless some outside force acts on it causing some change.

Second Law: $\sum \boldsymbol{F} = m\boldsymbol{a}$

The second law talks about what happens to an object when forces are applied. As we can see, the law gives us a relationship between the net forces acting on the object, the object's acceleration, and the mass of that object. In other words, using this law, we can eventually figure out how fast an object will go based on how much mass it has and how much force is applied to it.

Note that in the above formula, force and acceleration are both vector quantities. Thus, they act along all three axes in the case of a three dimensional system.

It is also worth noting that the unit of measurement for force is called a newton (1 kg * m / s^2), often given by the letter N. The units of measurement might seem a little strange at first due to the s^2 concept in the denominator. But this makes more sense when you recall the relationship between position, velocity, and acceleration. We know that velocity represents a change in position with respect to time. This basically tells us how fast we are going (our speed).

$$\mathbf{v} = \Delta\mathbf{p} / \Delta t$$

Acceleration tells us how much our velocity is changing with respect to time.

$$\mathbf{a} = \Delta\mathbf{v} / \Delta t$$

This is where we see our unit for acceleration come into play. If we substitute in our equation for velocity, we get:

$$\mathbf{a} = (\Delta\mathbf{p} / \Delta t) / \Delta t$$

$$\mathbf{a} = (\Delta\mathbf{p} / \Delta t^2)$$

Since position is measured in meters and time is measures in seconds, we get our acceleration units of meters per second per second (or, given the rules of fractional division: m / s^2). When we factor in mass, which is measured in kilograms, we wind up with our newton as described above. Thus, one newton is the amount of force required to give an object with a mass of 1 kilogram an acceleration of 1 meter per second per second.

Third Law: *For every action, there exists an equal and opposite reaction.*

The third law gives us a relation between the forces that exist between two interacting bodies. What it basically states is that when an object A applies a force to another object B, object B is applying the same force to object A, just in the opposite direction. Mathematically, we can state this relationship as:

$$\mathbf{F}_B = -\mathbf{F}_A \quad \text{or} \quad \mathbf{F}_A + \mathbf{F}_B = 0$$

Thus when I am in contact with the ground, while gravity might force me downwards towards the center of the earth, the ground exerts an opposite upwards force that is equal and opposite and I remain in place on the surface. I do not get shoved through the surface, nor do I hover above the ground. I am in equilibrium when I am in contact with the surface.

Contact Forces

Now let us talk a little bit about the forces that come into play when objects are moving about in the environment.

On Earth, all solid bodies experience resistance to motion. Whether they are sliding on solid surfaces, rolling along on those surfaces, or moving through a liquid or gas, some amount of resistance will be given. For our purposes in this lesson, we will consider the general concept of resistance as falling within the domain of *friction*.

Friction forces depend on the types of surface that are in contact. Generally, the rougher the surface, the greater the friction. We can generally break down the concept of friction into two categories: *static friction* and *dynamic* (or *sliding*) *friction*. Static friction is essentially the amount of force that must be overcome before an object begins to slide. Once an object is in sliding, dynamic friction comes into play. Dynamic friction tells us how much force needs to be overcome in order to keep our object sliding along on that surface.

Consider the example of an automobile. There exists a certain amount of static friction between the rubber of the car's tire and the asphalt of the road at the point where the two come into contact. As long as the forces that are being applied to the tire (and thus the contact point) do not exceed this static friction threshold, the car tire is able to grip the road and propel the car forward. As the tire spins, it pushes down on the road, and because of static friction, the road pushes back on the tire (see Newton's Third Law) and the car continues it forward motion. But if the car were to suddenly hit a patch of ice, where the static friction between rubber and ice is significantly lower, the static friction hurdle would be much easier to overcome. If the forces were such that they exceeded the static friction threshold, the tire

would begin to slide. Although the tire is still spinning, it is not be able to get a good purchase on the surface and suddenly dynamic friction (sliding friction) comes into play.

Friction is ultimately proportional to the total amount of force pressing the objects together. In most cases, this will be the force due to gravity (a downwards acceleration) which we can describe as:

$$\mathbf{F}_G = m\mathbf{g}$$

Where m is the mass of the object and **g** is the gravitational acceleration (9.8 m/s^2). Note the use of Newton's Second Law as a means to describe gravity.

According to Newton's Third Law there must be a net equal and opposite force that counters this one. That is, if gravity forces a body downwards, assuming the body is in contact with a surface, there must be a force pressing back upwards on the bottom of the object. There is indeed such a force, and it is generally referred to as the *normal force* (**N**). The normal force is directed based on the orientation of the surface.

$$\mathbf{N} = -m\mathbf{g}$$

The proportionality between friction and the normal force can be expressed by a constant which can be introduced as a coefficient. This coefficient is represented by the Greek letter mu (μ). Thus:

$$\mathbf{F}_{(\text{sliding friction})} = \mu\mathbf{N}$$

We can substitute in our gravity values for the normal force and rewrite the equation as:

$$\mathbf{F} = -\mu\, m\mathbf{g}$$

In the case of static friction, we can describe this force using the formula:

$$\mathbf{F}_s \leq \mu_s\, m\mathbf{g}$$

μ_s is the coefficient of static friction that is associated with the two types of materials in contact. In other words, the static friction force remains below a certain threshold given by the normal force scaled by some constant.

Dynamic friction can be described by the very similar formula

$$\mathbf{F}_D = \mu_d\, m\mathbf{g}$$

Once again, we see the relationship with the normal force scaled by some constant. The following table provides some friction coefficient values that have been determined by experiment for various materials.

Material 1	Material 2	Static μ_s	Dynamic μ_d
Steel	Steel	0.74	0.57
Aluminum	Steel	0.61	0.47
Copper	Steel	0.53	0.36
Brass	Steel	0.51	0.44
Zinc	Cast Iron	0.85	0.21
Copper	Cast Iron	1.05	0.29
Glass	Glass	0.94	0.4
Rubber	Concrete (dry)	1	0.8
Rubber	Concrete (wet)	0.3	0.25

Not surprisingly, the coefficients of static friction turn out to be higher than those for dynamic friction. As you own experience tells you, it is generally easier to slide a heavy box along your kitchen floor after you have "broken it loose" from the grip of static friction.

> **Note:** The forces that exist when two bodies are touching are called *contact forces*. Thus friction and the normal force are both contact forces. The normal force is a perpendicular force that the surface exerts on the body it is in contact with. The friction force is a parallel force that exists in the direction of motion on the surface.

We used the example of an automobile earlier to introduce the concepts of static and dynamic friction. In practice, for objects that are rolling, a third type of frictional coefficient can be introduced called the *coefficient of rolling friction* (μ_r). This is sometime referred to as *tractive resistance*. The formula is pretty much the same as we see in all of our friction cases:

$$\mathbf{F} = \mu_r \mathbf{N}$$

For steel wheels on steel rails, μ_r generally equals 0.002. For rubber tires on concrete, μ_r equals ~0.2. Thus we see that the steel wheel/rail case experiences less resistance to movement than does the rubber/concrete case. This actually gives some indication as to why trains are typically more fuel efficient than automobiles.

> **Note:** We often hear the term *traction* used to describe this friction relationship as the amount of 'grip' that a wheel or tire has on the surface. The car tire on the asphalt surface has very good traction (a good grip), while the same tire on a sheet of ice has very poor traction (possibly no grip at all).

Fluid Resistance

We now understand that all bodies on Earth experience resistance to motion and we have seen friction at work with respect to movement on solid surfaces. But what about fluids (liquids and gases)? Certainly we all recognize from experience that moving through a pool of water is generally much more difficult than walking down the street. So there is obviously some manner of resistance happening there. Is this friction as well? Yes indeed.

Viscosity is a term used to describe the thickness of a fluid. Thicker fluids have higher viscosity and vice versa. Objects moving through high viscosity fluids will experience a greater amount of friction than similar movement through low viscosity fluids. However, as it turns out, when an object moves through a viscous fluid (including air), the resistance force also takes into account the speed of the object. To be fair, this will actually vary from one situation to the next and we are going to oversimplify things here a little bit, but in general, for slow moving objects we find that:

$$\mathbf{F}_R = -k\mathbf{v}$$

Where **v** is the velocity of the object and *k* is a constant (called the *coefficient of frictional drag*) that varies according to the size and shape of the body, as well as other factors having to do with the viscosity of the fluid.

For objects moving at higher rate of speed the formula becomes:

$$\mathbf{F}_R = -k\mathbf{v}^2$$

So as the speed of the object increases, so does the amount of resistance forces exerted on it by the fluid. This is the result of turbulence in the fluid due to the rapid movement of the object. The result is a higher level of friction between the moving object and the fluid.

If you were modeling slow moving vehicles in your game (cars, ships, etc.) then you would preferably use the first formula to model fluid resistance (often called *aerodynamic drag*, or just *drag*). If you were modeling high speed moving objects (racing cars, jet-skis, etc.) then the second formula would produce more accurate results.

Updating the CPlayer Class

At this point we have now covered all of the topics we will need to know about when we are updating our application's physics model. To be clear right upfront, we are *not* going to model precision physics that obey all of the formulas we have just discussed. Often it is not just practical or necessary to do so when working on a game. However, we will absolutely use the ideas that were presented as a basis for trying to simulate behavior that we find satisfying in our particular demo. We will attempt to maintain the spirit of a particular concept, but not necessarily follow the specific rules and equation. As we introduce concepts in our model, we will talk about how they relate to the theory just presented and, when we make some alterations of our own, explain why we did so.

While our new CPlayer object will work in a very similar manner to its prior incarnation, we will need to alter the CPlayer::Update function. But before we look at the code to the new CPlayer object, let us talk a little bit about the model on a high level and look at some of the member variables that were introduced to support that model. This should help set the stage for what is to come on the coding side.

Motor Force and Tractive Force (m_vecAppliedForce / m_fTraction)

Motor force is the amount of force that is applied to an object to make it move. If we think about the soles of a person's shoes in contact with the ground, when we apply motor force to the leg, that leg pushes on the ground with an applied force and in response, the ground pushes back in the opposite direction with its own force, essentially propelling the shoe (and thus the person) forward. We talked about some of these forces in the last section. For example, we know about the force pushing upwards from the ground (we called it the normal force) and we also know that some degree of resistance comes into play (friction). Our model will essentially take some liberties and combine these concepts together and we will call the resulting force the *tractive force*. That is, this tractive force will be the combination of the applied motor force(s) and the normal force (technically, the inverted gravitational force), with a dash of friction thrown in for good measure. We will discuss the friction model in more detail later. For now, the best way to understand our tractive force as it relates to friction is to think about the concept of traction introduced earlier. That is, we are going to say that there is a 'grip' factor that comes into play with respect to our surfaces as we attempt to apply accelerating forces. This will prove to be a very helpful concept when we model jumping a bit later on.

The amount of tractive force produced will depend on a traction coefficient for the surface (m_fTraction in our model). We can think of the traction coefficient as describing how good a grip the player's shoe will have with the surface and we will use a value in the range [0.0, 1.0]. The closer to 1.0 the traction coefficient is, the better the grip of the shoe on the surface. Since we will use this coefficient to scale the motor force, larger coefficient values mean the closer to the initially applied motor force the tractive force applied to the object will ultimately be. We can think of the motor force as being the force describing how much we wish to move, while the tractive force describes the amount we will actually move, once slippage between the surface and the object is taken into account. Again, gravity will play a role as well, but we will talk more about that shortly.

So our traction coefficient is actually going to act very much like a frictional coefficient in that it will scale the resulting force based on the properties of the contact surfaces. Consider an Olympic athlete's running shoes, which are specifically designed to get as near to perfect traction with the running track as possible. If we imagine the same athlete running on ice, the same amount of motor force would still be getting applied by the athlete, but because of the lack of grip between his/her shoes and the ice, the amount of tractive force actually pushing the athlete forward is going to be much less, and as such, slower running speeds are observed.

So a traction coefficient for an interacting surface/object pair of 0.5 would describe quite a slippery situation, since only half the applied motor force will be applied to the object in the forward direction.

Traction = 0.5

Let us also assume that we wish to apply a motor force of 20 to the object to move it along its velocity vector.

Applied Force = 20N

The amount of force that actually gets applied (the *tractive force*) is calculated as follows:

Tractive Force = Applied Force * Traction
= 20N * 0.5
= 10N

Again, for the moment, we are not including gravity in our model. We will address that a bit later.

In this example, you can see that although we applied a force of 20N to the object, the actual forwards force applied to the object was only half of that because of the lack of grip. As mentioned earlier, this is why traction is so important between the wheels of a racing car and the track on which it is racing. Racing cars often use tires that do not have treads in order to allow more rubber to come into contact with the surface of the track and provide a better grip for high speed racing.

Although the relationship between the player and the various surfaces in the level in real life would introduce a lot of different traction coefficients between surface types, we will simplify and assign our CPlayer object a single traction coefficient. This means, the traction between the player object and every surface in our level will be considered to be exactly the same. Obviously this could easily be extended so that a traction coefficient could be assigned at the per polygon level. That way, you could assign a polygon with an ice texture map a low traction of 0.2 but assign a much higher traction coefficient to a polygon with an asphalt texture mapped to it. In this demo, we will use a single traction coefficient for a given player object which will be set and stored in the CPlayer::m_fTraction variable shown above. The traction coefficient used by the player for its physics calculations can be set by the application using the CPlayer::SetTraction method.

Note that we will also be modeling dynamic friction, so you might wonder why we would need this traction concept if we intended to use proper friction anyway. As it turns out, in actual practice, our traction coefficient will almost always equal 1.0. The only time this changes (and drops to nearly zero) is when the player is no longer in contact with a surface (i.e., they are in the air). The idea was to give the player a little bit of ability to control the player while they are in mid-air. Since a person cannot actually walk on air, the traction concept gives them just a little bit control that they would not otherwise have using a standard model. This type of mid-air control is fairly common in games, so we decided to include it in our demonstration as well.

Applying motor force to our CPlayer object will be the primary means by which the application controls the speed of its movement. The CPlayer object will now have an ApplyForce method which allows the application to apply a motor force to the player. You will see later when we revisit the code to the CGameApp::ProcessInput function, that in response to keys being pressed by the user, we no longer call the CPlayer::Move function. Instead, we will call the CPlayer::ApplyForce method which adds motor force to the object. The more motor force we apply, the faster our object will move (assuming that our traction coefficient is not set to zero).

The CPlayer::ApplyForce function is shown below:

```
void CPlayer::ApplyForce( ULONG Direction, float Force )
{
    D3DXVECTOR3 vecShift = D3DXVECTOR3( 0, 0, 0 );

    // Which direction are we moving ?
```

```
    if ( Direction & DIR_FORWARD  ) vecShift += m_vecLook;
    if ( Direction & DIR_BACKWARD ) vecShift -= m_vecLook;
    if ( Direction & DIR_RIGHT    ) vecShift += m_vecRight;
    if ( Direction & DIR_LEFT     ) vecShift -= m_vecRight;
    if ( Direction & DIR_UP       ) vecShift += m_vecUp;
    if ( Direction & DIR_DOWN     ) vecShift -= m_vecUp;

    m_vecAppliedForce += vecShift * Force;
}
```

As you can see, ApplyForce accepts two parameters. The first is a 32-bit integer containing a combination of one or more flags describing the direction we wish to move the object. Remember, this function is called from the CGameApp::ProcessInput function, so the direction flags that are set correspond precisely to the direction keys being pressed by the user.

> **Note:** The movement flags such as DIR_FORWARD and DIR_UP are members of the Direction enumerated type that has been part of the CPlayer namespace since Chapter 4.

The function calculates a shift vector which describes the direction we wish to move the object. For example, if the forward key is pressed, then the player object's look vector is added to the shift vector. If both the up and forwards keys are pressed, then the shift vector will be a combination of the player object's up and look vectors, and so on. The result is a unit length shift vector describing the direction we wish to move the player. We then scale this vector by the passed motor force parameter before adding it to the m_vecAppliedForce member variable. Since forces are vector quantities that have both a direction and magnitude, you can see that in this particular case, we wind up with the proper result (just split over two logical code sections for ease of implementation, where the magnitude is passed in separately).

When we multiply the unit length direction vector by the motor force scalar in the above code, we generate a vector whose direction represents the direction we wish to move and whose length represents the amount of force we wish to apply to the object to move it in that direction (the motor force). Notice that we do not assign this value to the m_vecAppliedForce member variable but instead add it. Why?

The m_vecAppliedForce vector describes the direction and amount we wish to move. It contains the motor force that has been applied since the last frame. This is very important because you will see in a moment that this member is always set to a zero vector again after each CPlayer::Update call. Therefore, if it is always zero at the start of each iteration of our game loop, why are we not assigning (vecShift * Force) instead of adding it? The answer is that other places in the application may wish to apply forces to the player object in a given iteration of the game loop. As such, we will collect all forces that have been applied in this update. When we do eventually call the CPlayer::Update method to apply m_vecAppliedForce and generate the player's current velocity vector and calculate a new position, it will contain the combination of all forces applied since the last update.

We still have a ways to go yet, but now that we have seen the new ApplyForce method, let us quickly revisit the CGameApp::ProcessInput function. This is called at the start of the update process for each frame. It is called by the CGameApp::FrameAdvance function.

CGameApp::ProcessInput

Most of this function is unaltered so we will quickly skip past the bits we have already discussed in previous lessons.

```
void CGameApp::ProcessInput( )
{
    static UCHAR pKeyBuffer[ 256 ];
    ULONG        Direction = 0;
    POINT        CursorPos;
    float        X = 0.0f, Y = 0.0f;

    // Retrieve keyboard state
    if ( !GetKeyboardState( pKeyBuffer ) ) return;

    // Check the relevant keys
    if ( pKeyBuffer[ VK_UP    ] & 0xF0 ) Direction |= CPlayer::DIR_FORWARD;
    if ( pKeyBuffer[ VK_DOWN  ] & 0xF0 ) Direction |= CPlayer::DIR_BACKWARD;
    if ( pKeyBuffer[ VK_LEFT  ] & 0xF0 ) Direction |= CPlayer::DIR_LEFT;
    if ( pKeyBuffer[ VK_RIGHT ] & 0xF0 ) Direction |= CPlayer::DIR_RIGHT;
    if ( pKeyBuffer[ VK_PRIOR ] & 0xF0 ) Direction |= CPlayer::DIR_UP;
    if ( pKeyBuffer[ VK_NEXT  ] & 0xF0 ) Direction |= CPlayer::DIR_DOWN;
```

The first section of code (shown above) uses the GetKeyboardState function to read the state of each key into the local 256 byte buffer. The state of each key we are interested in (Up, Down, Left, Right, PageUp and PageDown) is checked to see if it is depressed. If so, the corresponding CPlayer::Direction flags are combined into the 32-bit variable Direction. At this point the Direction variable has a bit set for each direction key that we pressed.

Next we see if the mouse button is currently being held down, in which case our application window needs to be managing the capture of mouse input. If so, we get the current position of the mouse cursor and subtract from it the previous position of the mouse cursor for both the X and Y axes. Dividing these results by 3 (arrived at by trial and error) gives us our pitch and yaw rotation angles. We then reset the mouse cursor back to its previous position so that it always stays at the center of the screen. We must do this because if we allowed the cursor to physically move to the edges of the screen, the player would no longer be able to rotate in that direction when the operating system clamps the mouse movement to the screen edges.

```
    // Now process the mouse (if the button is pressed)
    if ( GetCapture() == m_hWnd )
    {
        // Hide the mouse pointer
        SetCursor( NULL );

        // Retrieve the cursor position
        GetCursorPos( &CursorPos );

        // Calculate mouse rotational values
        X = (float)(CursorPos.x - m_OldCursorPos.x) / 3.0f;
        Y = (float)(CursorPos.y - m_OldCursorPos.y) / 3.0f;
```

```
        // Reset our cursor position so we can keep going forever :)
        SetCursorPos( m_OldCursorPos.x, m_OldCursorPos.y );

    } // End if Captured
```

The next section of code is only executed if either the player needs to be moved or rotated. If the X and Y variables are not equal to zero then they describe the amount of pitch and yaw rotation that should be applied to the player. First we will deal with the rotation.

If the right mouse button is being held down then the left and right mouse movement should apply rotations around the player object's local Z axis (roll). Otherwise, the left and right movement should apply rotations around the player object's Y axis (yaw). In both cases, the backwards and forwards movement of the mouse will apply rotation about the player's X axis (pitch).

```
    // Update if we have moved
    if ( Direction > 0 || X != 0.0f || Y != 0.0f )
    {
        // Rotate our camera
        if ( X || Y )
        {
            // Are they holding the right mouse button ?
            if ( pKeyBuffer[ VK_RBUTTON ] & 0xF0 )
                m_Player.Rotate( Y, 0.0f, -X );
            else
                m_Player.Rotate( Y, X, 0.0f );

        } // End if any rotation
```

At this point we will have rotated the player. Now let us handle the movement. If any movement flags are set in the Direction variable then we need to apply some motor force to the player. We apply a motor force magnitude of 600 in this application but you can change this as you see fit. If the shift key is depressed, we set the applied motor force magnitude to 1000, which allows the shift key to enable a run mode for the player that moves it more quickly. We then call the CPlayer::ApplyForce function to add this motor force to the player.

```
        // Any Movement ?
        if ( Direction )
        {
            // Apply a force to the player.
            float fForce = 600.0f;
            if ( pKeyBuffer[ VK_SHIFT ] & 0xF0 ) fForce = 1000.0f;
            m_Player.ApplyForce( Direction, fForce );

        } // End if any movement

    } // End if camera moved
```

Remember that at this point the player has not had its position updated; we have simply added the force we have just calculated to its m_vecAppliedForce vector. The actual position change of the player happens in the CPlayer::Update method, which used to be called at the end of this function. This will

actually no longer be the case, since we have moved the CPlayer::Update call out of this function and into CGameApp::FrameAdvance just after the call to the CScene::AnimateObjects function.

We did this because, now that our scene geometry may be moving and the CPlayer::Update function is responsible for invoking the collision system and calculating the new position of the player, this must be called after the scene objects are updated. This will ensure that we are colliding with the position of these scene objects in their current state (instead of the previous frame state). In short, we should move the scene objects first and then try to move our CPlayer, and not the other way around. We will look at the CPlayer::Update method shortly.

The next section of code is new to the ProcessInput function and handles the reaction to the depression of the control key by the user. In this lab project, the control key will allow the player to jump up in the air. This is easily accomplished by getting the current velocity vector of the player and simply adding a value of 300 to its Y component. The code is shown below and uses two new functions exposed by CPlayer in this lab project.

```
    // Jump pressed?
    if ( m_Player.GetOnFloor() && pKeyBuffer[ VK_CONTROL ] & 0xF0 )
    {
        D3DXVECTOR3 Velocity = m_Player.GetVelocity();
        Velocity.y += 300.0f;
        m_Player.SetVelocity( Velocity );
        m_Player.SetOnFloor( false );

    } // End if Jumping Key
```

While our player is now allowed to jump, it must only be allowed to do so if its feet are on the ground. The control key should be ignored if the player is not in contact with the ground since there is no surface for their feet to push off from and thus no possible way to apply an upwards motor force. Later we will see how our traction coefficient allows for a little extra control when the player has jumped into the air.

In the above code you will notice that CPlayer now exposes a function called GetOnFloor that will return true if the player's feet are considered to be in contact with the ground. Do not worry about how this function works for the time being, as it is closely coupled with the collision detection update. For now, just know that if it returns true, our player is on the ground and should be allowed to jump. Notice that after we adjust the velocity of the player to launch our player into the air, we use the CPlayer::SetOnFloor function to inform the player object that its feet are no longer on the ground. This function will be discussed in a little while as well.

> **Note:** While you might assume that we would have modeled jumping as an upwards motor force, it turns out that it really is not worth the effort to go to so much trouble. Adjusting the velocity vector directly works just fine for our purposes and is certainly the simplest way to accomplish our objective.

Finally, if the 0 key on the num pad is pressed we adjust the player's camera offset vector to show the front view of the mesh (3rd person mode only).

```
    // Switch third person camera to front view if available.
    if ( m_pCamera && m_pCamera->GetCameraMode() == CCamera::MODE_THIRDPERSON )
    {
```

```
        if ( pKeyBuffer[VK_NUMPAD0] & 0xF0 )
            m_Player.SetCamOffset( D3DXVECTOR3( 0.0f, 26.0f, 55.0f ) );
        else
            m_Player.SetCamOffset( D3DXVECTOR3( 0.0f, 26.0f, -35.0f ) );

    } // End if
}
```

And there we have our new ProcessInput function. We have shown how it applies motor forces to the player object in response to user input. Again, note that at the end of this function, motor force has been applied to the player but no position update has been applied yet.

Introducing Resistance

We have now discussed what motor force is and how it is applied in the new CPlayer system. We have also mentioned that the amount of force we actually apply to the object to propel it forward is equal to the tractive force. The tractive force is the motor force scaled by the traction coefficient between the object and the surface (plus the addition of gravity as we will look at shortly).

But these are not the only forces we will have to apply to our object in order to calculate its new position in the CPlayer::Update function. If we were to simply add a constant tractive force to our player in each update call, our object would eventually accelerate to infinite speeds. Just think about it; if the velocity vector of the object is not diminished based on some concept like friction or drag, every time we applied a force, the velocity vector would get longer and longer. Since the (length of the) velocity vector is commonly referred to as the speed of the object, we know that our speed would increase with each update, forever. This makes perfect sense of course since we know from Newton's Second Law of Motion that

$$\mathbf{F} = m\mathbf{a}$$

If we rearrange this equation to look at the acceleration, we see that:

$$\mathbf{F}/m = \mathbf{a}$$

What this tells us is that our acceleration is always going to equal the total force applied to the object scaled by the inverse of the object's mass. Since the mass is a constant, you can see that if we assumed that mass equals 1 (for simplicity) our acceleration will equal our total applied forces. If we keep increasing our force, our acceleration will continue to increase. Since acceleration is simply the change in velocity with respect to time:

$$\mathbf{a} = \Delta\mathbf{v} / \Delta t$$

we know that over time, our velocity will simply get larger and larger (i.e., the speed increases because the object continues to accelerate).

Clearly this is not the case in real life. Just as we have tractive force propelling the object forward, we also experience forces between the surface and the moving object which counteracts the tractive force we are trying to apply to varying degrees. As we discussed earlier, these forces fall under the category of resistance forces (or contact forces for object in contact). We learned that on Earth, all solid bodies experience resistance to motion. Whether they are sliding on solid surfaces, rolling along, or moving through a liquid or gas, some amount of resistance is to be expected. We looked at multiple types of friction and also talked about viscous drag. Now let us look at how these ideas will apply in our player physics model.

Surface Friction – m_fSurfaceFriction

As mentioned earlier, friction forces depend on the types of surface that are in contact and we can generally break down the concept of friction into two categories: static friction and dynamic (or sliding) friction. In our demonstration, rather than deal with multiple friction models and how they influence forces, we are simply going to focus on two high level ideas – forces that speed us up (positive forces) and those that slow us down (negative forces). The motor forces and gravitational force fall into the category of positive forces because they will act to speed us up. Friction and drag are going to fall into the category of negative forces because they will serve to slow us down.

It is worth noting that we are not going to bother modeling static friction in our demonstration. Our goal is to slide our player on command based on user input and we decided not to worry about overcoming a friction threshold before we can begin movement. After all, while we may be sliding a sphere around the environment in our code, we are assuming our player is walking, not sliding around in the world. So we need to take some liberties with the theoretical models and focus on what works for us in this application. In a sense we are trying to model what is a nearly frictionless environment so that we can get smooth rapid movement, but be sure to include just enough dynamic friction to be able to slow us down (and maybe even do so differently depending on the surface material properties when desired).

To be fair, there is a downside to not modeling static friction which comes into play on sloped surfaces - due to the force of gravity, a motionless player on an inclined plane will slide downwards. This is not a terribly difficult problem to solve and there are a number of ways to tackle it should you decide you want static friction in your game. Keep in mind that should you decide to model actual static friction, calculating the normal force can be a little tricky. While you do get back the normals of the colliding triangles from the collision system, do not forget that you may have cases where you are intersecting more than one surface simultaneously. Averaging surface normals might be one way to tackle this, but in truth, the results are not very dependable. Rather than model pure static friction, you could simulate it far more cheaply by simply zeroing out your velocity vector (when you are not moving of course) when the surface normal is less than some particular inclination.

In this application we will stick to modeling dynamic friction only, since our primary movement model is based on sliding anyway. Our equation for dynamic friction was as follows:

$$\mathbf{F} = -\mu\, m\mathbf{g}$$

If we wanted to, we could plug in proper friction coefficients or even attempt to calculate our own based on the above formula. But for the most part, it fairly common to arrive at some fixed constant value(s) that produces a good feeling result in the game. Again, for simplicity in this lab project, rather than have every surface in our game store friction coefficients, we will store a single coefficient in our CPlayer class and apply it universally to all surfaces. Feel free to alter this behavior should you deem it necessary for your particular needs.

Our formula for calculating dynamic friction will be very straightforward. Friction will act in the opposite direction of our current movement vector, and our goal is to essentially have a force that will act to reduce the speed of the player over time. We can model idea this using the following calculation:

Friction = -m_fFriction * Velocity

> **Note:** Depending on how you decide to represent and store your friction coefficients, you could either calculate the constant as (1 – m_fFriction) or just m_fFriction.

In this case, Velocity is the current velocity vector of our player and m_fFriction is the friction coefficient. Again, we are using a single surface friction coefficient in our lab project but this could be extended and stored at the per polygon level.

Note that the friction calculation we are using is pretty much identical to the formula we learned for viscous drag for slow moving objects:

$$\mathbf{F}_R = -k\mathbf{v}$$

The resulting friction vector in the above calculation can later be added to our velocity vector. Since the sign of the friction coefficient is negative, this generates a vector pointing in the opposite direction of the velocity vector with the length scaled by the friction coefficient. Adding this vector to the velocity vector would essentially subtract some amount of length (i.e., reduce speed) from the velocity vector each frame, eventually whittling it down to zero magnitude over a number of frames (assuming no further motor forces were applied).

We can set the friction coefficient of our CPlayer object using the CPlayer::SetFriction function. This same friction coefficient is used for every surface, so there will be constant friction force working against our velocity vector in each update.

Air Resistance / Drag – m_fAirResistance

Another negative force we will consider is that of air resistance / drag. The amount of air resistance we will apply is going to be calculated using a drag coefficient just as we discussed earlier. This coefficient will ultimately describe how aerodynamic the object is. The less aerodynamic the shape of an object, the more air resistance will be experienced. Drag is an extremely important force to consider when modeling the movement of high speed objects, such as a car in a racing game.

The drag vector can be calculated with the following calculation where m_fAirResistance is a scalar value assigned to the object describing how aerodynamic it is (drag coefficient). Other factors could also

be considered when calculating this drag coefficient such as the type and density of the fluid being navigated, or even wind strength and direction (although this could be modeled as a separate motor force). In our demonstration we will actually use the higher speed version of our drag formula, but you can obviously experiment with this as you see fit. Recall that our formula was:

$$\mathbf{F}_R = -k\mathbf{v}^2$$

In code then, we will simply calculate the drag force as:

vecDragForce = -m_fAirResistance * m_vecVelocity * |m_vecVelocity|

Once again, we can see that this vector represents force acting in the exact opposite direction of the velocity vector. The length of this vector is equal to the squared length of the velocity vector scaled by our drag coefficient.

Gravity – m_vecGravity

As mentioned earlier, gravity is another force that we will include in our model. Keep in mind that gravity has been part of our CPlayer object since its first incarnation. We will represent gravity using a vector which will be directed down the -Y axis in world space. While it is not a system necessity that the gravity vector point down, this is obviously going to be preferable in most real world simulations. The magnitude of the gravity vector describes the strength of the gravitation pull of the planet on which our player is moving. To calculate the gravitational force applied to the object, we will turn to Newton's Second Law of Motion and multiply the gravity (acceleration) vector by the mass of the object.

vecGravForce = vecGravityVector*m_fMass

Updating our Velocity Vector

As discussed, we will apply motor force to our player object using the CGameApp::ApplyForce function (called from the CGameApp::ProcessInput). Regardless of how many times this function is called prior to the CPlayer::Update function, the forces will be combined in the m_vecAppliedForce vector.

After CGameApp::FrameAdvance has called the CGameApp::ProcessInput function to apply any forces, and has called the CScene::AnimateObjects function to update the scene and collision database, it next calls the CPlayer::Update function. Prior to going into this function we know that the m_vecAppliedForce member will contain a combination of all the motor forces applied in this iteration of the game loop.

As m_vecAppliedForce contains all motor forces we have applied to the object, we will first scale this vector by the traction coefficient to generate part of our final tractive force. This force vector will describe the actual force applied in the requested direction of motion. As mentioned, we will also include gravity in our tractive force. We will treat this a little differently from the motor force case and it

will not be scaled by our traction coefficient. Therefore, to generate the final tractive force we will scale the gravity vector by the mass of our player object and add the result to the applied force(s) vector.

m_vecAppliedForce = m_vecAppliedForce * m_fTraction
m_vecTractiveForce = m_vecAppliedForce + (m_vecGravity * m_fMass)

At this point, m_vecTractiveForce contains a vector describing the direction and force that should be applied to the object. Note that by giving ourselves a little bit of traction while we the player is airborne (we can set the value fairly low, but not quite 0), we are given a minor degree of control during jumps without having to write a lot of extra code. You can think of it as giving the player a bit of 'grip' on the air even though there is no actual surface to push off from.

Going back to our earlier discussion of what we are attempting to model at the high level, this vector represents our positive forces (i.e., those that will attempt to accelerate the player). Next we need to focus on generating our negative forces (i.e., the resistance forces acting against the force vector we have just created).

We start with the dynamic friction force. As discussed, this will be calculated as the negated result of the friction coefficient multiplied by the object's current velocity:

m_vecFrictionForce = - m_fSurfaceFriction * m_vecVelocity

While this approach would work fine, we decided to tweak the model a bit and take into account our traction idea as well. This could be described as a bit of a hack, but it makes it much easier to adjust the starting and stopping properties of the object given that we are using a constant friction in our demonstration. While the surface friction coefficient will be an arbitrary value, the traction coefficient will always be in the 0.0 to 1.0 range. By scaling the surface friction coefficient by the traction coefficient, we essentially make the assumption that if the friction of the surface is low (such as ice), it will take our player a while to ramp up to full speed. It would also take the player longer to stop given the difficulty getting a good grip on the surface. This friction force is going to be subtracted from the velocity vector of the player each time:

m_vecFrictionForce = - (m_fTraction * m_fSurfaceFriction) * m_vecVelocity

Next we calculate our final resistance force -- drag. Since we are decided to use the drag calculation for high speed movement, this force will be calculated by scaling the drag coefficient by a vector that is equal in direction to our velocity but with a squared length and then negating the result.

m_vecDragForce = - m_fAirResistance * (m_vecVelocity * | m_vecVelocity |)

We can now calculate the total force working on the body by summing the tractive force vector, the friction force vector, and the drag vector:

m_vecTotalForce = m_vecTractiveForce + m_vecFrictionForce + m_vecDragForce

Now that we know the total amount of force acting on the object, we use Newton's Second Law to do the rest. We divide out total force by the mass of the object to calculate the actual acceleration (or deceleration) of the object:

m_vecAcceleration = m_vecTotalForce / m_fMass

Now we must scale the acceleration by the elapsed time between frames so that we can determine the amount of acceleration to apply for this frame update. Recall that our definition of acceleration was a change in velocity with respect to time:

$$\mathbf{a} = \Delta\mathbf{v} / \Delta t$$

How can we use this knowledge to figure out what our new velocity needs to be? Well, for starters, let us consider what the change in velocity represents. If we had a previous velocity (v0) and we wanted to determine our new velocity (v1) based on our acceleration, we could say the following:

$$\Delta\mathbf{v} = \mathbf{v}1 - \mathbf{v}0$$

$$\mathbf{a} = (\mathbf{v}1 - \mathbf{v}0) / \Delta t$$

$$\mathbf{a}\Delta t = \mathbf{v}1 - \mathbf{v}0$$

$$\mathbf{v}0 + \mathbf{a}\Delta t = \mathbf{v}1$$

So we can see that all we need to do is scale our acceleration by the elapsed time, add it to our old velocity, and we will have our new velocity:

m_vecVelocity += m_vecAcceleration * TimeScale

Remember that the total force we calculated above may be acting primarily against the current velocity vector if the resistant forces are stronger than the sum of applied forces. This is what allows our player's velocity to decrease (i.e., deceleration) when the user lets go of the movement keys.

Our final important step will be resetting the applied forces vector to zero for the next frame since we have now used up all the force it contained updating the velocity vector.

We will grant that has been a very simplified introduction to physics, but it has given us all we need to implement fairly good handling in our CPlayer::Update function. You are strongly encouraged to take your knowledge further by trying out the Game Physics course, where you will get much more detail about the concepts discussed here and explore many other interesting topics in the world of physics.

We will now discuss the functions from the CPlayer class that have been updated.

CPlayer::CPlayer()

The constructor has had very few changes made to it. The friction, traction, drag coefficient, and the mass of the player object are set inside the constructor of CPlayer to default values. We use these default values in our application but you can change these values using the CPlayer methods as needed.

```
CPlayer::CPlayer()
{
    // Clear any required variables
    m_pCamera            = NULL;
    m_p3rdPersonObject   = NULL;
    m_CameraMode         = 0;
    m_nUpdatePlayerCount = 0;
    m_nUpdateCameraCount = 0;

    // Players position & orientation (independent of camera)
    m_vecPos             = D3DXVECTOR3( 0.0f, 0.0f, 0.0f );
    m_vecRight           = D3DXVECTOR3( 1.0f, 0.0f, 0.0f );
    m_vecUp              = D3DXVECTOR3( 0.0f, 1.0f, 0.0f );
    m_vecLook            = D3DXVECTOR3( 0.0f, 0.0f, 1.0f );

    // Camera offset values (from the players origin)
    m_vecCamOffset       = D3DXVECTOR3( 0.0f, 0.0f, 0.0f );
    m_fCameraLag         = 0.0f;

    // The following force related values are used in conjunction with Update
    m_vecVelocity        = D3DXVECTOR3( 0.0f, 0.0f, 0.0f );
    m_vecGravity         = D3DXVECTOR3( 0.0f, 0.0f, 0.0f );
    m_vecAppliedForce    = D3DXVECTOR3( 0.0f, 0.0f, 0.0f );
    m_fTraction          = 1.0f;
    m_fAirResistance     = 0.001f;
    m_fSurfaceFriction   = 15.0f;
    m_fMass              = 3.0f;

    // Default volume information
    m_Volume.Min         = D3DXVECTOR3( 0.0f, 0.0f, 0.0f );
    m_Volume.Max         = D3DXVECTOR3( 0.0f, 0.0f, 0.0f );

    // Used for determining if we are on the floor or not
    m_fOffFloorTime      = 1.0f;

    // Collision detection on by default
    m_bCollision         = true;
}
```

Notice that there is a new member variable called m_fOffFloorTime. This is used to track how long the player has not been making contact with the ground. It works as follows…

Every time the collision query is run on the player (shown in a moment) we will get back the bounding box describing the extents of the intersections that occurred between the player object and the environment. We can use this box to determine whether intersections have happened between the underside of the ellipsoid and a scene polygon. If so, we can assume that the player is in contact with the ground and the CPlayer::SetOnFloor method is called with a parameter of true.

```
void CPlayer::SetOnFloor( bool OnFloor )
{
    // Set whether or not were on the floor.
    if ( OnFloor )
        m_fOffFloorTime = 0.0f;
    else
        m_fOffFloorTime = 1.0f;
}
```

As you can see, this sets the value of the m_fOffFloorTime variable to zero. This happens every frame when the underside of our ellipsoid is found to be making contact with a surface.

Going further, in every subsequent frame (in the CPlayer::Update function), this variable is incremented by the elapsed time. Thus, if the ellipsoid is always making contact with the ground, it will be getting incremented by some small value and then ultimately reset to zero each frame by the collision test. However, if the collision query finds that the ellipsoid is not in contact with the ground, the SetOnFloor function is not called, but the value is still incremented so the off floor timer continues to increase.

We know that if the player is not making contact with the floor, they should not be allowed to jump. We also saw in the CGameApp::ProcessInput function that it used the CPlayer::GetOnFloor function to determine whether the player is considered to be making contact with the floor or not. It was only when this function returned true that a control key press was processed and the player's Y velocity adjusted to launch the player up into the air. The CPlayer::SetOnFloor function was then called to inform the player that it is currently in the air.

The CPlayer::GetOnFloor function is shown below.

```
bool CPlayer::GetOnFloor() const
{
    // Only return true if we've been off the floor for < 200ms
    return (m_fOffFloorTime < 0.200);
}
```

As you can see, it only returns true if the off floor timer has not been incremented past 200 milliseconds. Now, we know that in reality, as soon as this timer is not equal to zero, the player is off the ground and the function should return false for floor contact. The problem with doing it in that way is that it makes our system a little too sensitive. There may be times when our player is minimally bouncing along a surface and may be just a bit off the surface for a very small amount of time. In such cases we do not want to disable the jump ability since the player is not really supposed to be considered to be in the air; it may just be bumping over rough terrain for example. Therefore, only if the player has been off the ground for 200 milliseconds or more will we consider the character to be truly off of the ground and return false.

When we look at the constructor we are also reminded that our CPlayer object has two vectors describing its bounding box. The half length of this box will be used as the radius vector of the ellipsoid used by the collision system. That is, the bounding box describes a volume that completely and tightly encases the ellipsoid.

CGameApp::SetupGameState

The CGameApp::SetupGameState function of our framework is called to allow the application to initialize any objects before the game loop is started. This is where the player object has many of its properties set to their starting values. Some of the values shown here may vary from the actual source code in Lab Project 13.1 due to some last moment tweaking.

```
 void CGameApp::SetupGameState()
{
    // Generate an identity matrix
    D3DXMatrixIdentity( &m_mtxIdentity );

    // App is active
    m_bActive = true;

    m_Player.SetCameraMode( CCamera::MODE_FPS );
    m_pCamera = m_Player.GetCamera();
```

First we set the player object (a member of CGameApp) into first person mode. We then grab a pointer to the player's camera.

Next we set the acceleration due to gravity which will be applied to the player object during updates. Again, our gravity vector magnitude was basically determined by trial and error. Feel free to modify any of these values to better suit your own needs. We also set the offset vector describing the position of the player's camera relative to its position and set the camera lag initial to zero seconds.

```
    // Setup our players default details
    m_Player.SetGravity( D3DXVECTOR3( 0, -800.0f, 0 ) );
    m_Player.SetCamOffset( D3DXVECTOR3( -3.5f, 18.9f, 2.5f ) );
    m_Player.SetCamLag( 0.0f );
```

We then set up a suitable bounding box that encases the mesh of our CPlayer object. We use the CPlayer::SetVolumeInfo to set the player's bounding volume.

```
    // Set up the players collision volume info
    VOLUME_INFO Volume;
    Volume.Min = D3DXVECTOR3( -11,  -20, -11 );
    Volume.Max = D3DXVECTOR3(  11,   20,  11 );
    m_Player.SetVolumeInfo( Volume );
```

Next we set the camera's viewport properties and its bounding volume:

```
    // Setup our cameras view details
    m_pCamera->SetFOV( 80.0f );
    m_pCamera->SetViewport(   m_nViewX,
                              m_nViewY,
                              m_nViewWidth,
                              m_nViewHeight,
                              m_fNearPlane,
                              m_fFarPlane );
```

```
    // Set the camera volume info (matches player volume)
    m_pCamera->SetVolumeInfo( Volume );
```

Then we set the initial position of the player in the world.

```
    // Lets give a small initial rotation and set initial position
    m_Player.SetPosition( D3DXVECTOR3( 50.0f, 50.0f, 20.0f ) );

    // Collision detection on by default
    m_bNoClip = false;
}
```

CPlayer::Update

Before we look at the code to the CPlayer::Update function, you should be aware of a new line of code that has been added to the CScene::LoadSceneFromIWF function. This new line of code registers a CScene callback function with the player that will be called from the update function. We will see this in a moment.

Excerpt from CScene::LoadSceneFromIWF

```
GetGameApp()->GetPlayer()->AddPlayerCallback( CScene::UpdatePlayer, this );
```

With this knowledge in hand, we can look at the modified Update method which is now called from CGameApp::FrameAdvance just after the input has been processed and the scene objects have been animated. In this function, we will use the physics model we discussed earlier. CPlayer::Update is passed one parameter, the amount of time (in seconds) that has elapsed since the previous Update call.

The first thing we do is scale the applied motor forces by the traction coefficient to get the first part of our tractive force. We then add our gravitational force calculated by multiplying the gravity acceleration vector by the mass of the object:

```
void CPlayer::Update( float TimeScale )
{
    D3DXVECTOR3 vecTractive, vecDrag, vecFriction, vecForce, vecAccel;
    bool        bUpdated = false;
    float       fSpeed;
    ULONG       i;

    // Scale our traction force by the amount we have available.
    m_vecAppliedForce *= m_fTraction;

    // First calculate the tractive force of the body
    vecTractive = m_vecAppliedForce + (m_vecGravity * m_fMass);
```

At this point we have our total tractive force. Now it is time to calculate the resistance forces that act against this tractive force vector.

First we will calculate drag based on our model discussed earlier (for high speed objects):

```
    // Now calculate the speed the body is currently moving
    fSpeed = D3DXVec3Length( &m_vecVelocity );

    // Calculate drag / air resistance (relative to the speed squared).
    vecDrag = -m_fAirResistance * (m_vecVelocity * fSpeed);
```

Next we calculate the dynamic friction vector, once again using the model introduced earlier (similar to viscous drag for slow moving objects). We can then add the friction vector, drag vector, and the tractive force vector together and divide the resulting vector to get our total force. Dividing by the mass of the object gives us the current acceleration of the object.

```
    // Calculate the friction force
    vecFriction = -(m_fTraction * m_fSurfaceFriction) * m_vecVelocity;

    // Calculate our final force vector
    vecForce = vecTractive + vecDrag + vecFriction;

    // Now calculate acceleration
    vecAccel = vecForce / m_fMass;
```

Now we can scale our acceleration by the elapsed time to get an acceleration value for this frame update. The result is then added to our previous velocity vector and we have our final velocity for this frame. The applied forces vector is then reset to zero since we have used up all applied forces at this point.

```
    // Finally apply the acceleration for this frame
    m_vecVelocity += vecAccel * TimeScale;

    // Reset our motor force.
    m_vecAppliedForce = D3DXVECTOR3( 0.0f, 0.0f, 0.0f );
```

We have now successfully calculated our new velocity vector.

In the next step we will loop through any callback functions that have been registered for the player. In our application there will be just one -- a pointer to the CScene::UpdatePlayer function which is responsible for running the collision query. We will see this in a moment when we discuss the source code.

```
    // Only allow sources to fix position if collision detection is enabled
    if ( m_bCollision && m_nUpdatePlayerCount > 0 )
    {
        // Allow all our registered callbacks to update the player position
        for ( i = 0; i < m_nUpdatePlayerCount; i++ )
        {
            UPDATEPLAYER UpdatePlayer =(UPDATEPLAYER)m_pUpdatePlayer[i].pFunction;

            if ( UpdatePlayer( m_pUpdatePlayer[i].pContext, this, TimeScale ) )
                bUpdated = true;
        }
    } // End if collision enabled
```

At this point the callback function would have been called to run a collision query on the position and velocity of the player. It would have now set the player in its new non-colliding position. We will look at the callback function next since it is the final piece in our puzzle.

In the next section of code we call some legacy code if the collision system is not being invoked or if no callback functions have been registered to update the position of the player. When this is the case the pUpdated member will not have been set to true (see above code), so we scale the new velocity vector we just calculated by the time scale and pass this movement vector into the CPlayer::Move function to physically alter the position of the player. This next section of code will not be executed by our application in Lab Project 13.1 since we are using the collision system.

```
    if ( !bUpdated )
    {
        // Just move
        Move( m_vecVelocity * TimeScale );

    } // End if collision disabled
```

Next we call the Update method of the player's camera object so that it can also alter its position. This is important when the camera is a third person mode since it will cache the new position of the player and start to track it (with the desired amount of lag). This function is a no-op for other camera modes since they do not implement this virtual function.

```
    // Let our camera update if required
    m_pCamera->Update( TimeScale, m_fCameraLag );
```

If this is a no-op for other camera modes, you may be wondering how the position of those cameras are updated. The answer will become clear when we look at the callback function momentarily.

Next we also loop through any callback functions which may have been registered for the player's camera and call those functions as well. This allows us to register functions which will handle the collision of the camera with the scene if we wish. If this callback function calling code looks unfamiliar to you, refer back to Chapter 4 where we first implemented and discussed this callback system.

```
    // Only allow sources to fix position if collision detection is enabled
    if ( m_bCollision && m_nUpdateCameraCount > 0 )
    {
        // Allow all our registered callbacks to update the camera position
        for ( i =0; i < m_nUpdateCameraCount; i++ )
        {
            UPDATECAMERA UpdateCamera =(UPDATECAMERA)m_pUpdateCamera[i].pFunction;

            UpdateCamera( m_pUpdateCamera[i].pContext, m_pCamera, TimeScale );

        } // Next Camera Callback

    } // End if collision enabled.
```

Next we use the GetOnFloor function to adjust the traction and surface friction coefficients. If the player is not currently in contact with the floor, we will assume that there is no surface friction acting against its velocity. It would seem strange if the velocity of our player was being diminished by surface friction if the player is currently falling through the air.

As mentioned earlier, in reality the player should not have any traction in the air since there is nothing for the player's feet to push against. In this case we will set the surface friction coefficient to zero but set the traction coefficient to a very low value. Although it would be more correct to set the traction to zero too, we set it to a very low value so that the player still has limited directional control even when in mid air. This is consistent with gameplay mechanics in many first and third person titles. If the player is in contact with the floor, we set its traction and friction values to 1.0 and 10.0 respectively. Feel free to experiment with these values to change the feel of the player as it navigates the scene to something that suits your tastes.

```
    if ( !GetOnFloor() )
    {
        SetTraction( 0.1f );
        SetSurfaceFriction( 0.0f );

    } // End if not on floor
    else
    {
        SetTraction( 1.0f );
        SetSurfaceFriction( 10.0f );

    } // End if on floor
```

Finally, we increment the m_fOffFloorTimer value by the elapsed time as we must do each frame. We will see in a moment how this value is set to zero when the collision test determines that the player is in contact with the ground. Only when this variable has been incremented past 200 (milliseconds) do we consider the player to truly be off the ground for a significant enough amount of time for us to consider the player to be in the air. Thus it is only when this variable is greater than or equal to 200 does the GetOnFloor function returns false.

```
    // Increment timer
    m_fOffFloorTime += TimeScale;

    // Allow player to update its action.
    CPlayer->ActionUpdate( TimeScale );
}
```

As the final line of the function you can see us call the CPlayer::ActionUpdate function, which was added in the previous lesson. This function adjusts the current animation action of the third person object attached to the player. It sets the object's world matrix and also sets the actor action based on whether the character is idle or shooting, for example. Any other animations you wish to be played based on input or game events should be placed in this function.

We have now seen how the Update function of the player has been enhanced to include a more realistic physics model. We have not yet seen where the velocity vector we calculate in the above code is

actually used to update the position of the player object. As discussed, this is done in the CScene callback function that is registered with the player and called from the function previously discussed. Let us look at this callback function now to conclude our discussion.

CScene::UpdatePlayer

This callback function is the glue that holds this whole application together. It is called from the previous function and is passed a pointer to the player we wish to move. It is also passed the elapsed time between frames (in seconds) so that it knows how to scale that movement. As the code to the previous function demonstrated, when this function is called, the current velocity vector has been calculated using our player physics model so that at this point, the player object contains a velocity vector describing the direction and speed it would *like* to move. This function will call the collision system to see if the player can be moved along the velocity vector without obstruction, and if not, the collision system will return a new position for the player that is free from intersection. This function will then update the position of the player as dictated by the collision system. The collision system also returns a new velocity vector describing the direction and speed the player should be traveling after intersections have been factored in. We will see in a moment that we will not simply set the velocity of the player to the one returned from the collision system since this will cause some problems in our physics model. Instead, we will make a few adjustments so that our player's velocity will not diminish too significantly when trying to ascend shallow slopes.

We decided against placing the call to CCollision::CollideEllipsoid directly inside the CPlayer update function because then the CPlayer object would be reliant on the CCollision class and the design of CPlayer would be less modular. It makes sense that the callback function used for this purpose should be part of the CScene namespace since it is the scene object that contains both the scene geometry and the collision database (CCollision). The scene object also has the functions that load the scene and register it with the collision database. So it seemed a sensible design that this object should also be the one responsible for running queries on the collision database in our application.

Let us look at this function a little bit at a time. The function (like all player callback functions) accepts three parameters. The first is a void context pointer that was registered with the callback function. This data pointer can be used to point at anything, but we use it when we register the callback function to store a pointer to the CScene object. This is important because in order for the CScene::UpdatePlayer function to be a callback function, it must be static and therefore have no automatic access to the non-static members of the CScene class. In our code, this first parameter will point to the instance of the CScene object that contains the collision geometry. For the second parameter, a pointer to the calling CPlayer is passed. The third parameter will be the elapsed time since the last update.

```
bool CScene::UpdatePlayer( LPVOID pContext, CPlayer * pPlayer, float TimeScale )
{
    // Validate Parameters
    if ( !pContext || !pPlayer ) return false;

    // Retrieve values
    CScene     *pScene   = (CScene*)pContext;
    VOLUME_INFO Volume   = pPlayer->GetVolumeInfo();
    D3DXVECTOR3 Position = pPlayer->GetPosition();
```

```
    D3DXVECTOR3 Velocity = pPlayer->GetVelocity();
    D3DXVECTOR3 AddedMomentum;

    D3DXVECTOR3 CollExtentsMin, CollExtentsMax, NewPos, NewVelocity;
    D3DXVECTOR3 Radius = (Volume.Max - Volume.Min) * 0.5f;
```

In the first section of code we cast the context pointer to an object of type CScene so we can access the scene's methods and member variables. We also extract the position, velocity and bounding box information from the player into local variables. The ellipsoid that will be used to approximate the player in the collision system has its radius vector generated by using half the length of the bounding box. Remembering that the radius vector describes the distance of the ellipsoid surface from the center of the ellipsoid, we can see that this describes an ellipsoid that fits relatively tightly in the player's bounding box. We also allocate two 3D vectors called CollExtentsMax and CollExtentsMin which will be used to transport information about the extents of the collisions that occur with the ellipsoid during the detection process.

We now have all the information we need to run the collision test.

```
    // Test for collision against the scene
    if ( pScene->m_Collision.CollideEllipsoid(  Position,
                                                Radius,
                                                Velocity * TimeScale,
                                                NewPos,
                                                NewVelocity,
                                                CollExtentsMin,
                                                CollExtentsMax ) )
    {
```

When the CollideEllipsoid function returns, the local variables NewPos and NewVelocity will contain the new position and velocity of the object calculated by the collision system. The CollExtentsMax and CollExtentsMin vectors will describe the maximum and minimum points of intersection along the X, Y and Z axes that occurred in this movement update.

The first thing we do is test the minimum Y coordinate of the intersections bounding box returned by the collision system. If the minimum point of intersection along the Y axis is smaller than the Y radius of the ellipsoid, minus a quarter of the Y radius of the ellipsoid, then it means we have an intersection that occurred with the ellipsoid in its bottom quarter (roughly) as shown in Figure 13.11.

Figure 13.11

When this is the case, we consider the ellipsoid to be in contact with the floor and we call the CPlayer::SetOnFloor function to reset the player's m_fOffFloorTimer to zero. It will take at least another 200 milliseconds of non-contact between the ellipsoid and the floor for the player to be considered in the air.

```
        // If the lowest intersection point was somewhere in the
        // bottom quarter (+tolerance) of the ellipsoid
        if ( CollExtentsMin.y < -(Radius.y - (Radius.y / 4.25f)) )
        {
            // Notify to the player that were in contact with a "floor"
            pPlayer->SetOnFloor( );

        } // End if hit "feet"
```

The reasons for the existence of the next section of code will require some explanation as it is responsible for generating the new velocity vector of the player. Is it not true that the collision function returned us the new integration velocity? Well, yes and no.

It is true that the collision system does correctly calculate our new velocity, and in a perfect world we could simply set this new velocity as the player's velocity. If collisions occurred, the velocity vector will now be pointing in the slide direction, which is what allows our collision system to slide our player over bumps and steps. If we were passing in a really large initial velocity vector each time, we would cruise over most slopes and bumps with little trouble. However, now that we have integrated more complex physics into our model, our velocity also has resistant forces working against which diminish it each frame. Therefore, the amount of motor force we would usually apply to allow the ellipsoid to slide around a section of flat floor will not be enough to slide the same ellipsoid up a steep slope.

If we think about this in real terms, imagine applying enough force to a ball so that it slides at a fairly slow constant speed across your carpet. Now imagine that the ball hits a step. If you applied the same force to the ball, it would be nowhere near enough to allow you to push the ball up and over the step. The same is true here. What we consider a nice motor force for the player when moving along flat ground will not be enough to slide up most ramps with gravity and drag working against us.

We know that our collision system will project the input velocity vector onto the sliding plane so that the direction of the player changes to slide along corners and up steps. However, we also know that if our ellipsoid was to hit a step of significant size, the velocity vector would have its direction diverted so that it pointed up into the air, for the most part. The velocity vector returned will have most of its movement diverted from horizontal movement along the X and Y axes to vertical movement along the Y axis. Even if the player had enough force so that the projected velocity vector was enough to push the ellipsoid up higher than the step, we will have lost most our forward (X,Y) momentum contained in the original velocity vector. Essentially, we might have enough projected velocity to clear the step vertically, but then we would not have enough to actually move forward and onto the step.

To solve this particular problem we could use only the Y component of the velocity vector returned from the collision system and use the X and Z components of the original velocity vector. This way, the collision system can correctly inform us about how we need to move up and down when a step is hit, but the original X, Z velocity is still maintained (not diminished) so we have enough horizontal force to move not only up the step, but up and over. It is vitally important that we always obey the Y component of the velocity vector returned from the collision system since this is what prevents us from falling through floors. Remember, we might pass in a velocity vector with a massive downwards force (e.g., a very strong gravitational force has acted) of say (0, 300, 0). The collision system would detect that we cannot fall downwards as described by the velocity vector because there is geometry underneath us and

the returned velocity vector would have a Y component of zero. So, the Y component of our player's velocity must be set to the exact Y velocity returned from the collision system.

Ignoring the returned X and Z velocity components and simply using the original (pre-collision) X and Z velocity components along with the Y velocity returned from the collision system would certainly solve our problem in one respect. It would mean that the collision system can tell us the new up/down velocity that should be applied to our position to clear obstacles and steep slopes, while the original horizontal velocity would keep us moving in the XZ direction with the original forces applied. This would allow us to glide over steps and slopes with ease since our horizontal momentum would not be diminished at all by the obstacles we encounter. Indeed we would be able to slide up very steep slopes; just about any slope that was not perfectly vertical. Of course, that in itself is problematic since we do not want our player to be able to slide up near perfect vertical slopes.

To be sure, ignoring the X and Z components is certainly what we want to do to help us get over small obstacles. That is, we want to obey their direction but not necessarily the length. We need a way of knowing that if the object is fairly small, like a shallow slope or a small step, then we should use the original (pre-collision) X and Z velocity components so that we slide up **and over** the obstacle with ease. However, when we are dealing with larger obstacles or much steeper slopes, we do not want to ignore the X and Z velocity components returned from the collision system. In this case, they describe the way our horizontal momentum should be diminished, preventing us from climbing very steep slopes or large steps. Doing otherwise would seem unnatural unless you were making a Spiderman® style game and it is your intention to allow the player to traverse vertical walls.

So it seems that the degree to which we ignore the diminished X and Z components of the velocity vector returned by the collision system depends on how tall/steep the object we have collided with is. Fortunately, this is no problem; we can determine how high the object we collided with was because we have the collision extents bounding box. We will use the maximum height of the intersection to scale the amount that the horizontal velocity was diminished by the collision system.

Let us get started and see how this will work.

First, the velocity vector returned from the collision system is a per-frame velocity, but when performing our physics calculations we work with per-second values. By dividing the returned velocity vector by the elapsed time we get the new velocity vector specified as a per-second velocity. This is the velocity vector returned from the collision system describing the new direction and speed we should be traveling. We then copy the Y component of the velocity vector returned by the collision system into the velocity vector of our player object. We must retain the Y component of the collision velocity vector because it keeps us from falling through the floor.

```
        // Scale new frame based velocity into per-second
        NewVelocity /= TimeScale;

        // Store our new vertical velocity. Its important to ignore
        // the x / z velocity changes to allow us to bump over objects
        Velocity.y = NewVelocity.y;
```

We have now modified the Y velocity in accordance with the collision system. Next we will determine the maximum height of intersection and use that to scale the difference between our original undiminished horizontal velocity and the horizontal velocity returned from the collision system. It should be noted that this works well with slopes and not just steps, as shown in Figures 13.12 and 13.13

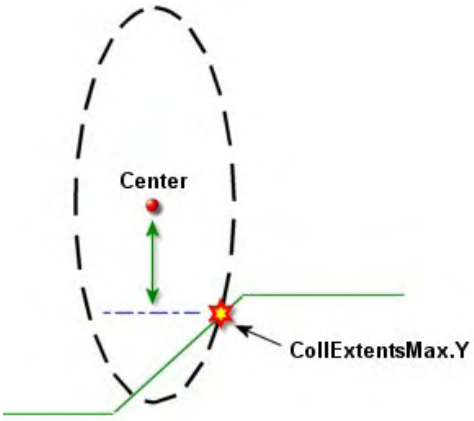

Figure 13.12

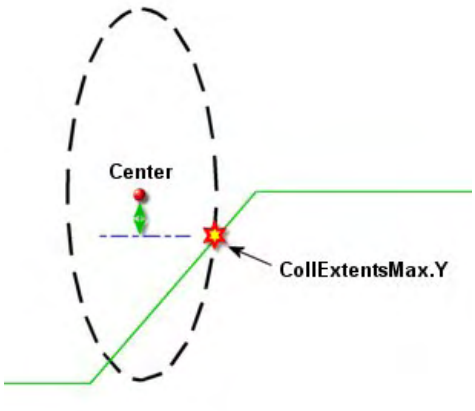

Figure 13.13

In Figure 13.12 we see an ellipsoid colliding with a fairly shallow slope and we can see that the point of intersection is further down the ellipsoid than the intersection shown in Figure 13.13 (where a taller, steeper slope is collided with). It is easy to see that the steeper the slope, the closer to being vertically aligned with the center point of the ellipsoid the intersection point will be. Therefore, we can scale the amount we want to diminish the horizontal movement of the player (as described by the collision system) based on how near to the center of the ellipsoid (vertically) the closest intersection point is. We can imagine for example, that if the ellipsoid collided with a brick wall, the intersection point would be perfectly aligned with the center of the ellipsoid and we should fully obey the collision system when it tells us we need to stop our horizontal movement immediately. On the other hand, if we find that the intersection point is closer to the bottom or top of the ellipsoid, we can ignore the new X and Z diminished velocity vector components returned by the collision system and use the original XZ velocity. This will allow us to slide up and over small obstacles or shallow slopes with ease. This works the same for collisions with both the top and bottom of the ellipsoid. We are interested in finding the intersection point that is closest to the center of the ellipsoid vertically since it is this ratio that will be used to scale the amount by which we factor in the diminished XZ velocity returned by the collision system. The next section of code will show how the new X and Z velocity components of the player's velocity vector are calculated.

First we will subtract about one quarter of the radius height from the radius. We are essentially going to say that if the closest intersection point to the vertical center of the ellipsoid is contained in the bottom quarter or top quarter of the ellipsoid's radius, this is a small obstruction. In that case we remove it completely and do not diminish our original horizontal momentum at all.

```
        // Truncate the impact extents so the interpolation below begins
        // and ends at the above the players "feet"
        Radius.y -= (Radius.y / 4.25f);
```

Having shaved a little over a quarter of the radius length (both sides of the center point), we will now find the Y coordinate of intersection that is closest to the center point. We will first take the maximum of the –Radius.y (the bottom of the new shaved ellipsoid) and the maximum Y intersection point. We will then take the minimum of the positive radius (top of the ellipsoid) and the maximum we just calculated.

```
        CollExtentsMax.y = max( -Radius.y, CollExtentsMax.y );
        CollExtentsMax.y = min( Radius.y, CollExtentsMax.y );
```

What we have now is the Y component of the intersection point that is closest to the center of the ellipsoid, or a value that is equal to the Y radius of the ellipsoid. We do this just to make sure that we get an intersection point along the diameter of the ellipsoid (-Radius to +Radius). This is important because if our player is falling though the air, it will not be colliding with anything and we need the value to be in the [–Radius, +Radius] range to perform the next section of code. Furthermore, because we shaved ¼ of the Y radius of the ellipsoid, if the maximum intersection point is in the bottom or top quadrant of the ellipsoid, it would initially be smaller than the shaved radius. That is why we clamp the values in the range of the shaved vertical diameter of the ellipsoid.

Now we will create a weighting value called fScale which will be calculated by dividing the absolute value of our closest Y point (closest to the ellipsoid center), by the radius of the ellipsoid and subtracting the result from 1.

```
        float fScale = 1 - (fabsf(CollExtentsMax.y) / Radius.y);
```

fScale is a parametric value in the range [0, 1] describing the Y difference between the ellipsoid center and our closest intersection point. If the intersection point is equal to the center of the ellipsoid (vertically), a value of 1.0 will be generated. If the closest intersection point is right at the top or bottom of the ellipsoid (or anywhere in the top or bottom zones), a value of 0.0 will be generated. We will now use this value to scale the difference between our original horizontal velocity (pre-collision) and the diminished horizontal velocity returned from the collision system.

```
        Velocity.x = Velocity.x + (((NewVelocity.x ) - Velocity.x) * fScale);
        Velocity.z = Velocity.z + (((NewVelocity.z ) - Velocity.z) * fScale);
```

As you can see, we subtract the original components from the new diminished horizontal velocity components:

(NewVelocity – Velocity)

Since NewVelocity is always smaller in the case of an intersection, this generates a vector acting in the opposite direction to that of the original velocity vector. Therefore, adding it to the original velocity vector actually subtracts the correct amount from its length such that it is equal to the diminished velocity vector. For example, if our original velocity vector was <10, 10> but the collision system returned a diminished velocity vector of <2, 2>, subtracting and adding to the original velocity vector would give:

OriginalVelocity += NewVelocity – OriginalVelocity
= <2, 2> <-10, -10>
= <-8, -8>

Therefore:

<10,10> += <-8,-8>
= <2 , 2>

That seemed like a lot of manipulation to do just to scale the original velocity so that it is equal to the velocity returned from the collision system. Why not just use the velocity returned from the collision system as the new velocity in the first place? Well, if that is all we intended to do then we would, but notice that the negative vector created from (NewVelocity – Velocity) is actually scaled by fScale. Therefore, the amount we diminish our velocity vector as dictated by the collision system, ends up being dependant on how close to the center of the ellipsoid a collision happened. As such, we have achieved our goal! For little bumps or shallow slopes, fScale will be close to zero, allowing us to continue our horizontal movement unhindered. When the slope is steep or the obstacle is tall, fScale will be closer to 1.0 and the full diminishment of horizontal momentum is applied to the player's velocity as directed by the collision system.

With our velocity vector now correctly calculated and the new position of the ellipsoid returned from the collision system, we can set them as the CPlayer's current position and velocity before returning from the function.

```
        // Update our position and velocity to the new one
        pPlayer->SetPosition( NewPos );
        pPlayer->SetVelocity( Velocity );

        // Hit has been registered
        return true;

    } // End if collision

    // No hit registered
    return false;
}
```

We have now covered the function in its entirety and have no further code to discuss. Do not expect to understand all of the code we have added in this lab project right away. Expect to have to study it again before you feel comfortable implementing such a system yourself from the ground up. The main areas of focus in this lesson have been the CCollision class and the updated CPlayer code.

Conclusion

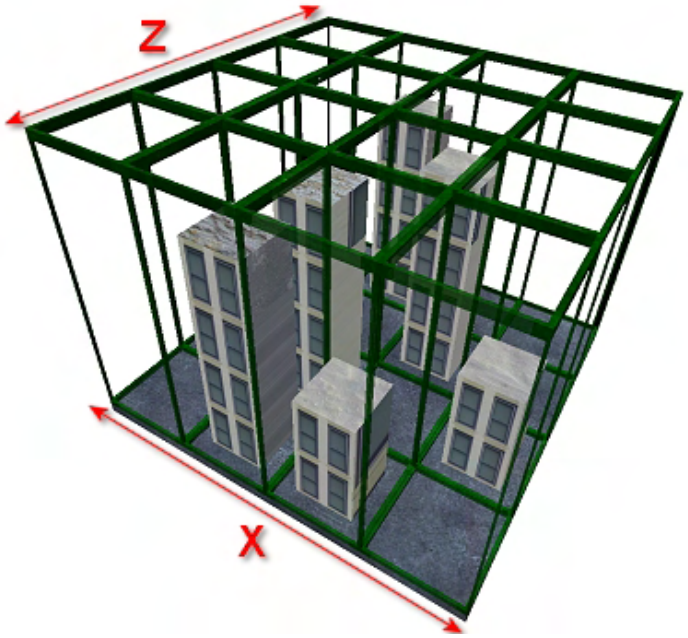
In many ways, this lesson has been a very exciting one. We now have a reusable collision system that can be plugged into our future applications to provide collide and slide behavior with arbitrary scene geometry. We have implemented it in such a way that our existing classes such as CActor can also be registered with the collision system's geometry database. We have even employed a system that allows us to support animating collision geometry when the situation calls for it.

We also upgraded our CPlayer object with a nicer (but still admittedly simplistic) physics model which allows us much greater control over how the player interacts with the collision environment. The CCollision class will be used in all lab projects from this point onwards.

In the next lab project we will implement hierarchical spatial partitioning to improve our collision system's performance (among other things). We will add a spatial partitioning system to our CCollision class so that a fast broad phase can be introduced to quickly identify potential colliders, even when dealing with huge data sets. The broad phase component will significantly speed up our collision system by performing efficient bulk rejection of polygons that are not contained within the same region of the scene as the ellipsoid that is currently being queried. This is going to be very important since our collision system currently has to perform the full range of intersection tests on every triangle that has been registered. This will simply not be good enough as we progress with our studies and start to develop larger and more complex scenes. Before moving on, please be sure that you are comfortable with the material covered in the textbook and workbook as we will see a lot of it again in the next chapter.

Chapter Fourteen

Hierarchical Spatial Partitioning



Introduction

In this lesson we will study various hierarchical spatial partitioning techniques and use them to implement a broad phase for the collision detection and response system developed in the previous chapter. The techniques we learn in this lesson and the next will also be used to speed up the rejection of non-visible polygon data from the rendering pipeline.

The concepts you learn in this chapter are some of the most important you will ever learn as a game developer, or even as a general programmer. Indeed you will find yourself using them at many points throughout your programming career to optimize a particular task your application has to perform. Although we will apply the tree traversal techniques discussed in this lesson to the area of 3D graphics programming, the usefulness of the ideas we will introduce reach far beyond game creation. For example, such techniques are used by image processing routines to optimize the mapping of true color images to a limited palette of colors. Hierarchical tree structures are also used to perform quick word searches in databases and efficiently sort values into an ascending or descending order. This lesson will be the first of four studying spatial partitioning. It will eventually lead to the implementation of a broad phase for our collision system and an efficient hardware friendly PVS rendering system.

Fortunately, many of the concepts we discuss will not require us to cover a lot of new ground since we already have a fair understanding of the two areas that hierarchical spatial partitioning essentially borrow from: parent/child relationships and bounding volumes. Combined, they allow us to spatially divide our scene into a hierarchically ordered set of bounding volumes that contain all of the scene geometry. These spatial trees can be quickly traversed and entire branches of the tree (along with child bounding volumes and the polygon/mesh data they contain) can be rejected from consideration with only a few simple bounding volume intersection tests.

Over the next few chapters we will be implementing spatial hierarchies in a variety of different flavors. We will implement a base tree class that can be used by the application to interface with all our spatial tree types. We will discuss and implement quad-trees, oct-trees, kD-trees and the famous (or infamous) BSP tree. These four tree types all provide a different way for the scene to be spatially subdivided and each has its uses in certain situations. The BSP tree (Chapters 16 and 17) will be vitally important as it will be used to aid us in the calculation of a Potential Visibility Set (PVS); this is a process that involves pre-computing what polygons can be seen from any point within the level at development time. The calculation of a PVS will allow our application to render scenes of an almost unlimited size (memory permitting) while keeping our frame rates fast and interactive. But before we get ahead of ourselves, let us focus on the basics, since there is a lot to cover.

This chapter will be focused on examining some of the common tree types that are used in games and the theory behind how they partition space and how they can be used. Later in this lesson and in our lab project, we will implement a broad phase for our collision system that will significantly speed up polygon queries on the collision system's geometry database. We will also discuss the usefulness of such systems for rendering, although this will not be implemented or demonstrated until the following lesson where a hardware friendly system will be introduced. Furthermore, in this chapter we will discuss the various utility techniques which typically accompany spatial partitioning algorithms: polygon clipping and T-junction repair, for example. So why don't we get started?

14.1 Introducing Spatial Partitioning

It is difficult to overstate the importance of spatial partitioning in today's computer games. Every game you currently play will undoubtedly use spatial partitioning as the core of its collision system and rendering logic. We learned in Chapter 4 of Module I how the frustum culling of a mesh's bounding volume could be used to prevent its polygon data from being passed through the transformation pipeline unnecessarily. Although the DirectX pipeline does perform a form of frustum rejection on our behalf, it does so at the per-polygon level, and worse still, only after the vertices of that polygon have undergone the calculations needed to transform them into the homogenous clip space.

We discovered that by surrounding a mesh with an axis aligned bounding box, we could test this box against the frustum to introduce a broad phase rejection pass in our mesh rendering logic. If we determined that the mesh's bounding box was outside the frustum, then we knew we did not have to bother passing its polygon data through the transformation pipeline. If that mesh was comprised of 20,000 polygons, we just avoided needlessly transforming them at the cost of a simple AABB/Frustum test. Of course, the same logic can be applied when performing any query on the scene that is required at the per-polygon level, such as we find with collision detection. We know that if our swept sphere does not intersect the bounding volume of a mesh then we do not have to test any of its individual triangles. We might perceive this to be a very simple broad phase implementation when added to our collision system. However, we do not always have our scenes comprised of multiple meshes, such as the internal geometry loaded from an IWF file for example. In such cases the entire scene is represented as a single mesh, so surrounding this with a single AABB would not help at all. That is, it would not allow us to reject portions of that mesh during frustum tests or collision queries. Spatial partitioning is the next level in bounding volume rejection and it works just as well for polygon soups as it does for scenes comprised of individual meshes.

In the first section of this lesson we will bias the demonstrations of spatial partitioning towards performing pure collision queries from the perspective of game physics, such as those discussed in the last chapter. But later we will discuss and implement a rendering system that will also benefit from spatial partitioning while remaining hardware friendly. We will also slant our early discussions toward the spatial partitioning of a polygon soup, although later we will discuss how spatial trees can also be built that partition complete meshes. In fact, the spatial trees we implement will be capable of managing both. That is, we can divide space into bounding volumes that contain both a list of polygons and a list of mesh objects that exist in that area of space. This allows our system to handle cases where the core geometry might be comprised of a huge list of static polygons but the dynamic objects are individual meshes or actors. We want both types to be supported by our tree so that we can quickly reject not only the core scene geometry that lay outside the frustum for example, but any dynamic objects (such as skinned characters) which are also not visible.

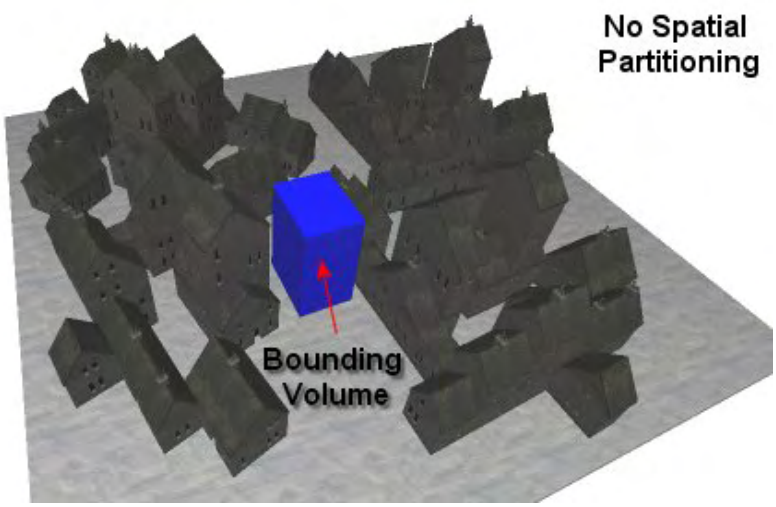


Figure 14.1

Let us begin our journey by imagining a simple town scene (Figure 14.1) consisting of 100,000 polygons. Assume that the blue bounding box in the figure represents an AABB that has been compiled around the source and destination positions that our swept sphere will move between in the current update. We used a similar technique when collecting the terrain polygons for our collision system in the previous chapter. You will recall that rather than trying to test the awkward shape of the swept sphere against the terrain to get a list of potential colliders, we simply built an AABB around the swept sphere and collected any terrain geometry that fell inside it. We will assume that the same logic is being applied here. After all, we are only interested in quickly finding which polygons will possibly intersect our swept sphere so that they can be passed on to the narrow phase. Only polygons that are contained partially or completely inside the bounding volume will need to be tested in the computationally expensive narrow phase of our collision system.

A naïve approach to a broad phase implementation might be to test every polygon in the scene against the AABB surrounding the swept sphere and reject all polygons that do not intersect it. This would certainly work and at the end of the process we would have compiled a list of polygons which intersect the AABB and thus have the potential to be a collider with the swept sphere. This list of potential colliders would then be passed to the narrow phase where the swept sphere intersection tests are performed on each polygon. Remembering that this scene is assumed to be comprised of 100,000 polygons, the pseudo-code to such a broad phase implementation would be as shown below.

> **Note:** We will assume for now that we have a function called 'AABBIntersectPolygon' which determines whether a polygon intersects an axis aligned bounding box. The function in this example is passed the minimum and maximum extents of the axis aligned bounding box and a pointer to the polygon that is to be tested.

```
for (i = 0; i < 100000; i++)                              // Loop through every poly
{
    CPolygon *Poly = CScenePolygonList[i];                // Get current poly to test

    if (AABBIntersectPolygon( BoxMin , BoxMax , CPoly ))  // Does it intersect AABB
    {
         PotentialColliderList.Add ( CPoly );               // Add to List that will
    }                                                       // be passed to narrow
}                                                           // phase

NarrowPhase ( PotentialColliderList );
```

In this example CPolygon is assumed to be the structure used to contain an individual polygon and CScenePolygonList is assumed to be an array that contains the list of polygons comprising the scene. BoxMin and BoxMax are the minimum and maximum extents of an AABB that encompasses the swept sphere's movement in this update. PotentialColliderList is some type of container class that manages a list of polygons and exposes methods allowing us to add polygons to its internal list. Whenever a polygon is found to be intersecting or totally inside the bounding box, it is added to this list. At the end of the loop the broad phase is complete and we have compiled a list of potential colliders. This list is then passed to the narrow phase where each polygon would have to be inspected against the swept sphere as described in the previous chapter.

This is a broad phase implementation to some degree, however any broad phase that requires 100,000 bounding volume tests just to find the potential colliders is obviously not very efficient. When we consider the incredible geometric detail in today's games, testing every individual polygon (even against a simple AABB) every time we wish to perform a query on the scene data is not going to suffice when it comes to performance. The idea of the broad phase is to quickly reject large blocks of polygon data from consideration very quickly. The number of tests needed to find the potential colliders in the broad phase should not come anywhere close the polygon count of the scene as is the case in the above example implementation. We need to be able to say, "My bounding volume is not located within this entire area, so all polygons in this area should be dismissed right away".

So let us start with a naïve approach to spatial partitioning, but one that will serve to solidify certain concepts in less obfuscated way before moving on to the subject of more common spatial hierarchies.

Let us imagine the same scene again, only this time, when the level was first loaded, we built an axis aligned bounding box around the entire level. Let us also imagine that with this information in hand, we divided the area of the scene's bounding box into a 7x7 grid (an example) of bounding boxes as shown in Figure 14.2.

Generating these 49 bounding boxes would be trivial. Once we had the bounding volume of the scene we could just divide its width and depth by 7 giving us a value of N and M for the width and depth deltas, respectively. We would then set up a loop to step through along the width of the scene's bounding box in steps of N and along the depth of the scene's bounding box in steps of M. In the inner loop (M), the coordinate (N*Column, M*Row) describes the minimum extent of the current bounding box being calculated and vector (N*Column + N, M*Row + M) describes its maximum extent.

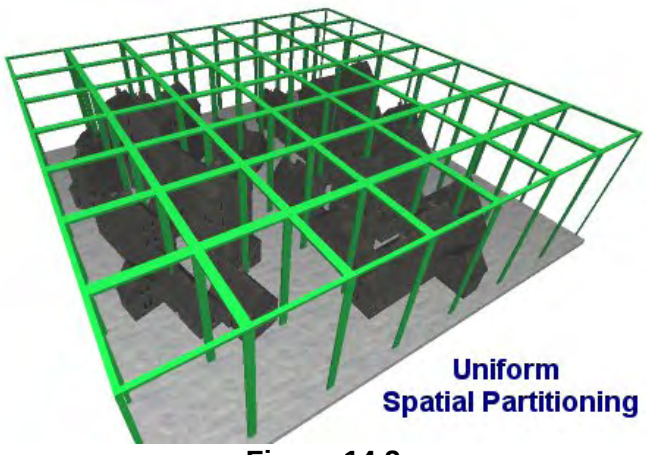

Figure 14.2

We might imagine that in this simple example, we could employ a scene class that contains an array of CBoxNode structures.

Note: The code we discuss in this first section is purely for teaching purposes and will not be used by any of our applications. It is used to solidify concepts. Later in the lesson we will develop the actual code that our applications will use.

```
class CScene
{
    public:
    CScene ( CPolygon **ppPolygons , long PolygonCount);
    CBoxNode  BoxNode [49] ;
};
```

In this very simple example, the scene has a constructor that accepts an array of CPolygon pointers and the number of pointers in this array. This is where we would pass in the array of 100,000 polygons we have loaded from our town file. This function would be responsible for calculating the bounding box of the entire scene and then generating the 7x7 (49) CBoxNode structures.

The CScene class has an array of CBoxNode structures, one for each bounding box we will create to represent the level. This structure might be defined like so:

```
class CBoxNode
{
   public:
   D3DXVECTOR3       m_vecBoxMin;
   D3DXVECTOR3       m_vecBoxMax;
   CPolygonContainer m_PolyContainer;
};
```

This simple class stores the minimum and maximum extents of the bounding box this node will represent, and a polygon container. We might imagine this to be a simple class that wraps an array of polygon pointers and exposes member functions for adding and retrieving polygon pointers to/from that array. We provided many classes that did similar things in Module I and of course, STL vectors could be used for the same task. This container will initially be empty for each box node. We will discuss why we will need this container stored in the box node class in a moment.

The job of the scene's constructor would be to compile a bounding box for the entire scene. This is done by simply testing the vertices of every polygon passed in and recording the maximum and minimum x, y, and z components found. The first section of such a function is shown below.

```
CScene::CScene ( CPolygon **ppPolygons, long PolygonCount )
{
   // Set master scene bounding box to dummy values
   D3DXVECTOR3 vecBoundsMin(  FLT_MAX,  FLT_MAX,  FLT_MAX );
   D3DXVECTOR3 vecBoundsMax( -FLT_MAX, -FLT_MAX, -FLT_MAX );
   int i , k , j;

   // Loop through each polygon in list and calculate bounding box of entire scene
   for ( i = 0;  i < PolygonCount; i++ )
   {
     // Get pointer
     CPolygon * pPoly =  ppPolygons[ i ];
```

```
    // Calculate total scene bounding box.
    for ( k = 0; k < pPoly->m_nVertexCount; k++ )
    {
      // Store info
      CVertex * pVertex = &pPoly->m_pVertex[k];

      // Test if this vertex pierces the current maximum or minimum
      // extents if adjusting extents if necessary
      if ( pVertex->x < vecBoundsMin.x )  vecBoundsMin.x = pVertex->x;
      if ( pVertex->y < vecBoundsMin.y )  vecBoundsMin.y = pVertex->y;
      if ( pVertex->z < vecBoundsMin.z )  vecBoundsMin.z = pVertex->z;
      if ( pVertex->x > vecBoundsMax.x )  vecBoundsMax.x = pVertex->x;
      if ( pVertex->y > vecBoundsMax.y )  vecBoundsMax.y = pVertex->y;
      if ( pVertex->z > vecBoundsMax.z )  vecBoundsMax.z = pVertex->z;

    } // Next Vertex

  } // Next Polygon
```

At this point we have the bounding box for the entire scene. We will now carve this box into 49 boxes (7 rows of 7 columns) and assign the resulting bounding boxes to the 49 CBoxNode objects of the scene class. This code first divides the width and depth of the scene's bounding box (calculated above) by 7 along the X and Z extents to carve the bounding box into 49 sub-boxes in total.

> **Note:** In this example we are subdividing the scene along the X and Z extents, which can be seen if you look at the previous diagram and imagine that we are looking down on the scene from a bird's eye view.

The two loops shown below are used to loop through each row (i) and each column (k) and calculate the index of the current CBoxNode object that we are processing. We use the formula (i * 4) + k. If *i* is the number of rows of boxes that we want (7) and *k* is the number of columns we want on each row (7) then we can see that when *i*=2 and *k*=1 we are calculating the bounding box for the ((2*7)+1) = 15th CBoxNode object in the scene's array. Remembering that arrays use zero-based indexing, we can see how this CBoxNode object would represent the 2nd box (*k*) in the 3rd row (*i*) of our scene.

```
float StepX  = ( vecBoundsMax.x - vecBoundsMin.x)  / 7.0f ; // Seven Columns
float StepZ  = ( vecBoundsMax.z – vecBoundsMax.z)  / 7.0f ; // Seven Rows

for ( i = 0; i < 7; i++ )
{
  for ( k = 0 ; k < 7 ; k++ )
  {
    // Get the index of the Box Node we are currently calculating
    int nBi = ( i * 7 ) + k ;

    BoxNode[ nBi ].m_vecBoxMin.x  =  ( k * StepX );
    BoxNode[ nBi ].m_vecBoxMax.x  =  BoxNode[nBi].m_vecBoxMin.x + StepX;
    BoxNode[ nBi ].m_vecBoxMin.z  =  ( i * StepZ );
    BoxNode[ nBi ].m_vecBoxMax.z  =  BoxNode[nBi].m_vecBoxMin.z + StepZ;
    BoxNode[ nBi ].m_vecBoxMin.y  =  vecBoundsMin.y;
    BoxNode[ nBi ].m_vecBoxMax.y  =  vecBoundsMax.y;
  }
}
```

At this point in the scene's constructor we have uniformly subdivided the bounding volume of the entire scene into 49 separate bounding volumes that together represent the space that was described by the scene's original bounding box. These bounding volumes are now stored in the scene's CBoxNode array.

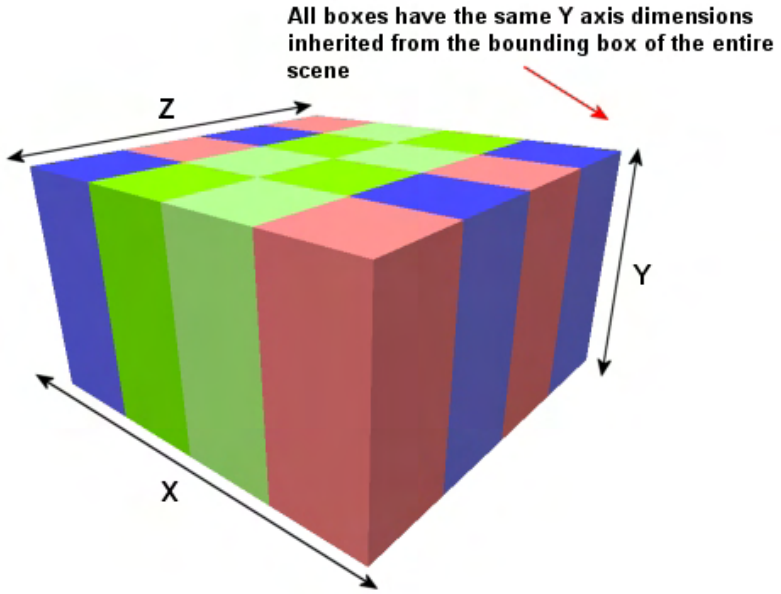

Figure 14.3

Because we are only dividing the scene along the X and Z axes in this example, we assign the minimum and maximum Y axis extents of the bounding box recorded for the entire scene to each of the CBoxNode objects. This means that all 49 sub-boxes generated will all have identical heights along the Y axis. Those Y axis extents are inherited from what we can refer to as the parent bounding box (i.e., the bounding box calculated for the entire scene at the top of the function). Figure 14.3 illustrates the spatial partitioning that has been applied to the scene's original bounding box (albeit for a 4x4 example in this case).

Having 49 empty bounding boxes is fairly useless until the next aspect of our scene preparation is performed. We must now loop through each bounding box and, for each box, loop through each polygon in the scene and test which ones intersect it. For a given bounding box, any polygons that intersect it or are contained completely inside it have their pointers added to the CBoxNode's polygon container. At the end of the following code, our constructor will be complete and when the scene is initialized, we will not only have 49 bounding boxes, in each box node structure we will have a list of polygons that are contained (or partially) contained within that region of space.

```
for ( k = 0 ; k < 49 ; k++ )  // 49 box nodes in this example
{
  // loop through each box
  CBoxNode * pNode = &BoxNode[ k ];

  // Loop through each polygon and test for intersection with box
  for ( j = 0;  j <  PolygonCount; j++ )
  {
    // Get pointer
    CPolygon pPoly =  ppPolygons[ j ];

    // If polygon intersects add its pointer to the box node's container
    if ( AABBIntersectPolygon(   pNode->m_vecBoxMin ,
                                 pNode->m_vecBoxMax
                                 pPoly ))
    {
       pNode->m_PolyContainer.AddPolygonPointer( &pPoly );

   }  // End if Intersect
```

```
    } // End Each Polygon
  } // End Each box
} // End function 'CScene::Constructor'
```

> **Note:** Again you are reminded that this code is not used by any of our applications. It is being used to demonstrate a concept and nothing more. We are using classes with methods here that we have never written, nor do we intend to. Please view these listings as being semi-pseudo code for the time being.

As you can see by examining the final piece of the function code, it involves nothing more than testing each bounding box node to see whether or not any of the scene polygons intersect with it. If so, then a pointer to that polygon is added to the polygon list in the box node. This code assumes that the polygons are stored in each box in a container class that has a member function called AddPolygonPointer, which simply adds the passed pointer to the end of polygon pointer array maintained by the container.

In this particular example, if a polygon is found to be contained in multiple boxes, we store a copy of its pointer in each. This causes no real harm, although when performing subdivision in this way we often wish to make sure that we do not test the same polygon more than once. For example, if we performed a collision query and found that three boxes were intersected by the bounding volume of our swept sphere, we might collect all the polygons from all those boxes and add them to a potential colliders list that is then passed onto the narrow phase. However, it is possible that a large polygon may have intersected all three of those box nodes and as such would be added to the potential colliders list three times. We can certainly work around this in the intersection testing case by testing to see if the given polygon has already been tested for collision so that we do not test it again. However, we must bear in mind that if we have to employ complex loop logic to determine such things, this could possibly outweigh a lot of the savings that the broad phase has introduced.

A common technique when using such a scheme is to allow the polygon structure to store a 'current time' member. When the narrow phase steps through the list, it will process a polygon and set its time member to the current time of the application. If it encounters a polygon in the list with the same time as the current application time, then this must be a pointer to a polygon it has already processed and will skip it. However, this still adds a per-polygon conditional test in the case where the bounding volumes contain polygon data. Under certain circumstances, this can harm performance as well. However, this might be a good strategy for dynamic objects that are assigned to nodes and can have this test performed on the per object level where the conditional tests would introduce negligible overhead. Things are also less simple when spatial partitioning for your rendering pipeline. We desire the vertices of the renderable versions of the geometry to be stored in vertex buffers (static buffers, preferably) rather than CPolygon structures. As such, we have no good way of setting a variable on a per-polygon basis like this and neither would want to. In this case, we may be forced to render the same polygon multiple times.

You will see later that one way to get around this problem is by clipping our scene polygons during the compilation of the spatial tree. In this scenario, a bounding volume will contain only polygons that fit fully inside its volume. If, during the compilation of the bounding volumes, a polygon is found to be inside two boxes at the same time, the polygon will be split into two pieces at the box boundary and the separate fragments will be stored in the respective bounding box. We will also implement an elegant solution for the case when you do not wish clip the polygon data and increase the polygon count of the scene, which will be explained later. For the sake of this current discussion, we will just assume that we

have assigned any polygon spanning multiple nodes to all nodes in which it is contained and will just live with the cost of having it exist multiple times in the potential colliders list.

The kind of spatial subdivision we have shown above would be performed once when the scene is first loaded. Alternatively, the compilation could be done at development time and the scene saved out to file in its subdivided format. Compiling the scene organization at development time is often necessary when we start subdividing scenes with hundreds of thousands or more polygons into thousands of bounding boxes. In these instances, the subdivision of the scene can take quite a long time. Remember, if we are testing hundreds of thousands of polygons against thousands of AABBs, even on today's microprocessors, compilation time will not be instant. If performed at run time when the level is first loaded into the computer's memory, this might subject the user of our application to an unacceptable delay. Therefore, it is often common for a file containing scene data to also contain the information in a subdivided format. Using our simple 49 box subdivided scene, we might store the data in the file such that the file contains 49 bounding box data structures and a list of polygons with accompanying bounding box index values describing which bounding boxes each polygon belongs in. The loading code could simply pull the bounding box data out of the file and use it to create the box nodes. The polygon data could then be extracted and its box index list for each polygon examined and used to assign the polygon to its pre-determined bounding box(es).

14.1.1 Efficient Polygon Queries

Let us now return to the problem of trying to determine which polygons in our level should be considered for the narrow phase during a collision test. Recall that we had assumed the compilation of an AABB around our swept sphere and now wish to calculate the polygons that intersect that bounding box and thus should be added to a potential colliders list. Figure 14.4 reminds us of the current location of our bounding volume within the scene.

We have assumed a level size of 100,000 polygons which each originally had to be tested against the AABB. Now our scene had been divided into 49 bounding boxes and as such, the broad phase requires nothing more than performing an AABB/AABB intersection test between our swept sphere's bounding volume and the 49 bounding volumes of the level. AABB\AABB tests are very cheap to perform and we can narrow down the number of polygons that need to be passed to the narrow phase to just the relative handful of polygons that have been assigned to the bounding boxes that our swept sphere's bounding box intersects.

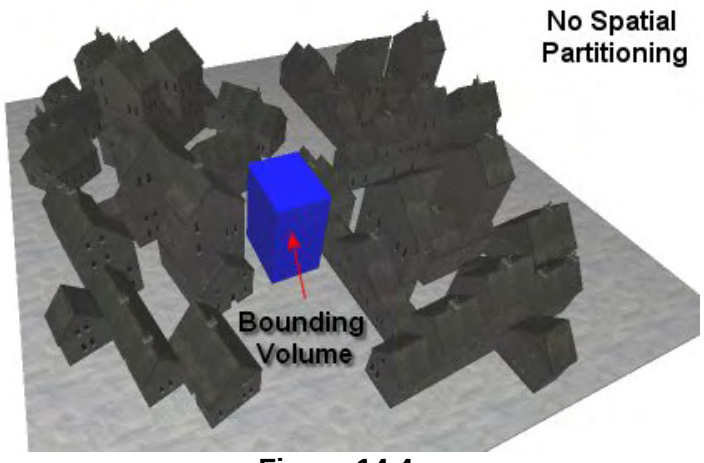

Figure 14.4

As Figure 14.5 demonstrates, after performing only 49 AABB\AABB tests, we find that only two of the scene's bounding volumes intersect our swept sphere's AABB. We can then quickly fetch the polygons assigned to each of these two box nodes and add them to the potential colliders list.

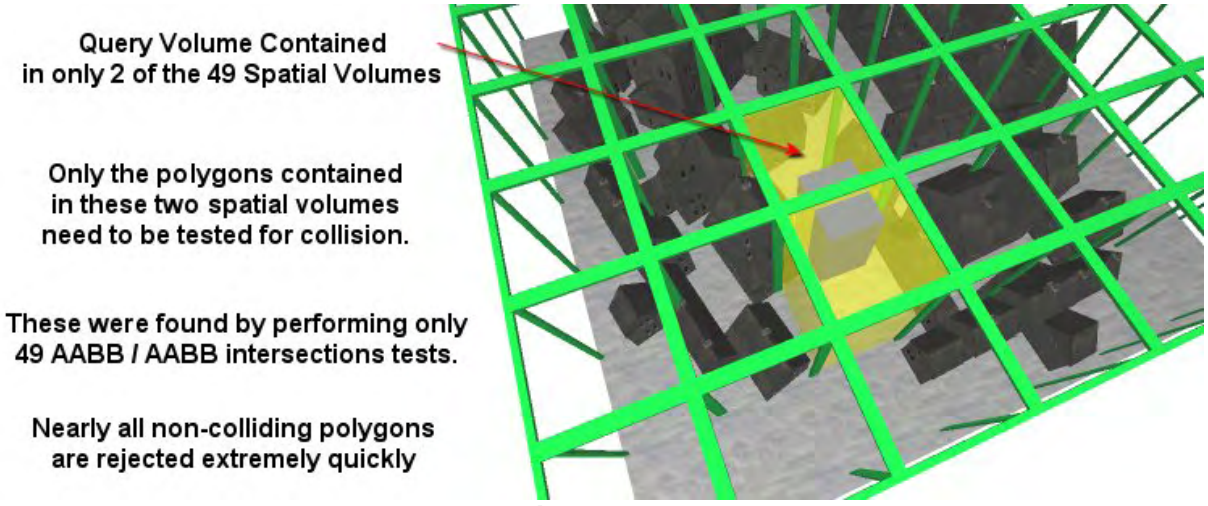

Figure 14.5

If we assumed for the sake of demonstration that the polygons were evenly distributed throughout the level, each box would contain 100,000 / 49 = 2040 polygons.

Figure 14.6

Thus with only 49 very efficient AABB/AABB tests, we have just rejected 47 of these boxes and the 2040*46 = 95,880 polygons contained within. Not bad! Only 2*2040 = 4080 polygons would need to be passed to the narrow phase for closer inspection by the collision routines.

As far as the narrow phase is concerned, the world is only as large as those two boxes since these are the only polygons it will need to test. Through the 'eyes' of our narrow phase, the world would look what is shown in Figure 14.6.

Below we see the code to a function that would implement a broad phase in this manner called GetPotentialColliders.

This function could be called by the collision system as its broad phase when the sphere has moved. It would be passed a pointer to the scene and the minimum and maximum extents of the AABB that is bounding the swept sphere. As its final parameter it takes a pointer to an object of type CPolygonContainer. We will assume for now that this is a simple class that encapsulates a polygon array and allows polygon pointers to be added to its array via its member functions. The container is assumed to be empty when this function is called and will be used to store the potential colliders it collects. When the function returns, the collision system will be able to pass this container to the narrow phase.

The function has been deliberately hardcoded for our 49 box example for the purpose of demonstration (again, we will not be using any of this code in practice). It also uses a function called AABBIntersectAABB which is an intersection testing function which we will discuss shortly. The AABBIntersectAABB function takes the extents of the two bounding boxes that are to be tested as its parameters and returns true if the two are intersecting.

```
void GetPotentialColliders( CScene *pScene,
                            D3DXVECTOR3 BoxMin,
                            D3DXVECTOR3 BoxMax,
                            CPolygonContainer *pContainer)
{
     for ( ulong i = 0; i < 49 i++ )
     {
          CBoxNode *pNode = &pScene->BoxNode[i];
          if ( AABBIntersectAABB( BoxMin, BoxMax,
                                  pNode->m_vecBoxMin,
                                  pNode->m_vecBoxMax )
          {
              for ( ulong k = 0; k < pNode->m_PolyContainer.GetSize(); k++ )
              {
                  pPoly = pNode->m_PolyContainer.GetPolygonPointer(k);
                  pContainer->AddPolygonPointer( pPoly );
              }
          }
     }
}
```

As you can see, this function simply tests the bounding volume passed in against the bounding volumes for the scene. If any scene bounding volume is intersecting, the polygons are fetched from the box node's container and added to the potential collider container. When the function returns, the passed container will contain all the polygons that should be more closely examined in the narrow phase.

The application of spatial partitioning is obvious when discussed in the context of running polygon queries such as those often required to be performed by a collision detection system. But does spatially partitioning the scene provide us with any other benefits? Does it possess the ability to speed up rendering as well? It certainly does.

14.1.2 Efficient Frustum Culling

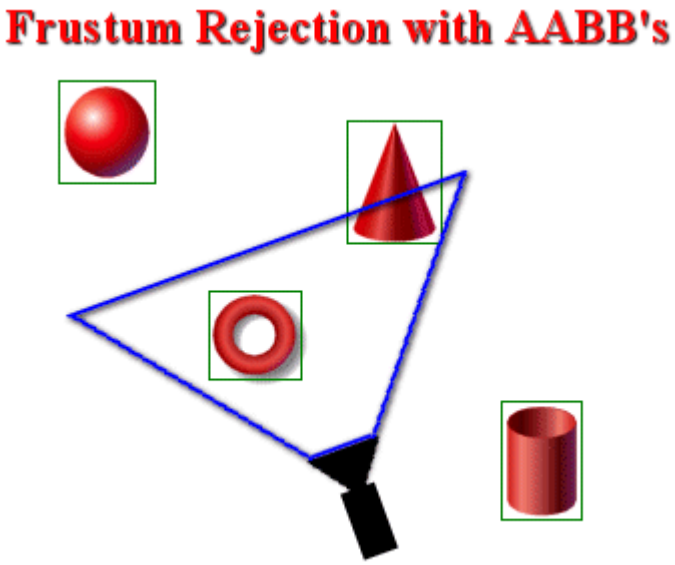

Figure 14.7

In Module I we learned how to perform AABB/frustum culling and used it to reject non-visible meshes prior to being passed through the rendering pipeline. Rather than passing a mesh containing thousands of polygons to the DirectX pipeline and allowing DirectX to determine which polygons are visible and which are not, we decided to help the process along by performing mass polygon culling using bounding boxes.

While the Direct X pipeline is good at what it does and has some very efficient code to reject polygons from the pipeline as soon as they are found to lay outside the view frustum, this culling still has to be performed on a per-polygon basis. If your scene consists of 100,000 polygons, the pipeline will need to perform 100,000 polygon/frustum tests each time the scene is rendered. Even worse is the fact that these polygons all need to be transformed into homogeneous clip space before the culling can commence. While hardware is very fast, this can become a bottleneck with scenes comprised of a large number of polygons.

In Module I we also learned that we could greatly increase our rendering performance if we assign each mesh an AABB and test it against the world space frustum planes prior to rendering that mesh. If we can detect that a mesh's AABB is completely outside the view frustum, we do not have to bother rendering it. Figure 14.7 shows four meshes and a camera along with its frustum. In this example we can see that only two of the four meshes need to be rendered, as the cylinder and the sphere are positioned well outside the camera's frustum.

Let us now return to our little town scene consisting of 100,000 polygons. We are assuming for the time being that this data is loaded as one big polygon soup. It should now be obvious that since we have subdivided our scene into AABBs, the same frustum culling strategy can be employed for our scene's bounding boxes, allowing us to frustum cull geometry in (theoretically) even bigger chunks than the mesh based approach covered in Chapter 4. Any one of our scene's bounding boxes may contain many polygons or perhaps many separate meshes, all of which could be frustum culled from the rendering pipeline with a single AABB / Frustum test.

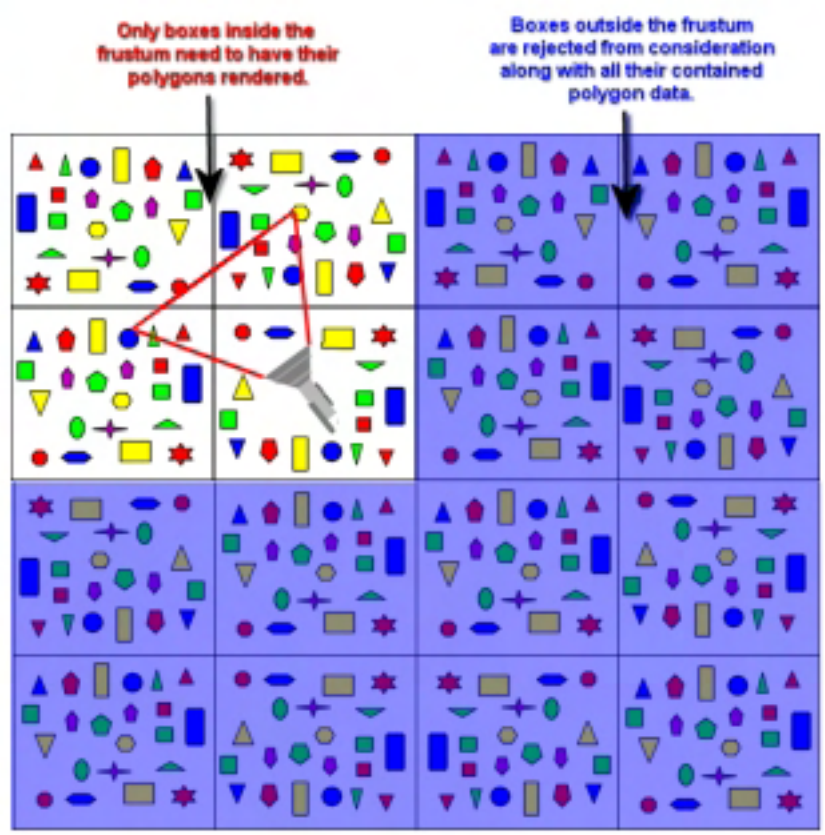

Figure 14.8

Using a 16 box scene example, this time we can see that in Figure 14.8 the camera is positioned and oriented such that only the polygons in 4 of the 16 boxes could possibly be visible. The frustum is shown as the red lines extending out from the camera and we can see that only the four top left boxes intersect the frustum in some way.

Using exactly the same frustum/ AABB code we covered in Chapter 4 of Module I, we have the ability to mass reject quite a bit of scene geometry. If the depicted scene consisted of 100,000 polygons equidistantly spaced such that each of the 16 boxes contained 6250 polygons, we can see that before we render the scene, we would test the 16 AABBs (box nodes) of our scene against the camera's frustum and find 12 of the boxes to be completely outside of it. With just 12 efficient tests, we have rejected 12 * 6250 = 75,000 polygons. Since only four of the boxes intersect the frustum we would only need to transform and render 4 * 6250 = 25,000 polygons (1/4th of the scene).

The following function shows a strategy that might be used to render the 16 box scene shown above. Assuming the scene has already been compiled into its 16 box format and that we are using an AABB / Frustum function which is a member of the camera class called IsAABBInFrustum (the code of which was covered in Module I), the rendering strategy might look something like this:

```
void CScene::Render( CCamera *pCamera )
{
      // Loop through each box
      for ( int i = 0 ; i < 16 ; i++ )
      {
         // Is this box inside the frustum or partially inside the frustum
         if ( pCamera->IsAABBInFrustum( &BoxNode[i].m_vecBoxMin ,
                                        &BoxNode[I].m_vecBoxMin ) )
         {
            // It's a visible box so render all the polygons stored here
            for ( k = 0 ; k < BoxNode[i].m_PolyContainer.GetPolygonCount(); k++ )
            {
                  // Get a point to the current polygon we wish to test
                  CPolygon * pPoly = BoxNode[i].m_PolyContainer.GetPolygon( k );

                  // Render Polygon
```

```
                    RenderPolygon ( pPoly );
                }
            }
        }
}
```

Of course, the above code is for example only and you certainly would not want to render all the polygons assigned to a given box one at a time as that would negate any performance gained from batch rendering. Later we will implement a system that will provide our code the benefits of spatial rejection during rendering but do so in a way that makes it hardware efficient (in fact, this will be the main focus of the next lesson). Hopefully though, even this simple code demonstrates the benefits of spatial partitioning, not only for performing per-polygon queries on the scene's data set such as intersection testing, but also for efficiently rendering that dataset when much of the scene lay outside the frustum.

Indeed it may have occurred to you as you were considering this concept that frustum culling is simply another form of intersection testing. That is, we are colliding one volume (our frustum) with some other volume (the boxes) to collect a set of potentially *visible* polygons. Those polygons are then passed on to a narrow phase (the DirectX pipeline) where the actual visible polygons will be rendered and the others fully or partially clipped away.

Finally, it should be noted that this same system can be used whether your scene is represented as a single mesh or comprised of multiple meshes or both. For example, a box node could contain a list of mesh pointers instead of a list of polygons. Assigning a mesh to bounding boxes could be done by simply figuring out which scene bounding boxes it intersects during the compile process. Later on, we will provide support for both of these systems. That is, the static geometry we load from an IWF file will be spatially partitioned and stored in bounding volumes at the per-polygon level, while dynamic objects such as actors will be assigned to bounding volumes at the object level. In our case, the nodes of our spatial tree will have an understanding of what polygons are contained inside them and our dynamic/detail objects will have knowledge of which spatial nodes they are contained within (more on this later).

Although we have seen how vital spatial partitioning is and how it can improve polygons querying efficiency, the system described so far is really quite inadequate. We have been using very simple numbers to demonstrate the point, but in reality, game scenes tend to be quite large and we ultimately wish to send as few polygons to the narrow/rendering phases as possible. This means that we generally wish to have far fewer polygons stored in each box node. Logically this also means subdividing the scene into many more box nodes. It is more probable that we would want to divide the average scene into thousands of boxes so that each box only contains a handful of polygons. This would mean for example, that if our swept sphere's AABB was found to be intersecting two box nodes, we would only be sending a handful of polygons to the narrow phase, instead of 4000 as in our previous example.

> **Note:** To be fair, given the performance of today's rendering hardware, larger node sizes are not necessarily going to be a bad thing. However, for CPU oriented tasks like collision detection, smaller batch sizes are definitely preferable.

Now that we basically understand what spatial portioning is and how bounding volumes can have scene polygon/mesh data assigned to them, we can take this conversation to the next level and discuss hierarchical spatial partitioning.

14.2 Hierarchical Spatial Partitioning

While the strategy discussed in the last section was great for demonstrating the basic process, it left much to be desired. In our previous example we simply used the value 49 as the number of boxes to divide our scene into, but in reality you would probably want to divide your scene into many more regions than this. If a level contained 100,000 polygons for example, each box would contain 2040 polygons. Even if the query volume only intersected a single box, that is still far too many polygons to send to the narrow phase of our collision system. Remember, given all that must be accomplished in any given game frame, our polygon queries will need to be executed within mere microseconds if frame rates are to remain acceptable.

It would seem that in order to make this strategy more efficient, we would want to divide a typical scene into many more boxes than this. For example, we might decide that we do not want any more than 100 polygons to be contained within a single box node. This would require the scene to be divided into 1000 boxes in our previous example. While this obviously means the initial scene would take much longer to compile (as we would now have to test each polygon against 1000 AABBs instead of just 49) this is not a problem since this can be done as a pre-process at development time and the information saved out to file as discussed earlier. The real problem now is that the broad phase has now been made much more expensive because it would have to test 1000 AABBs instead of just 49 to collect potential colliders for the narrow phase. This is obviously going to be quite a good bit slower. Also, it means that the rejection of a single box now only rejects 100 polygons instead of 2040 polygons, so each AABB/AABB test has less bulk rejection impact. On the bright side, after we have performed all the AABB/AABB tests in the broad phase, we would be left with a considerably smaller polygon list that needs to be passed to the narrow phase.

So while the dividing of the scene into many more smaller boxes has reduced the number of potential colliders that are collected and passed to the narrow phase of our collision system (or rendered in the case of frustum culling), much of CPU savings is lost to the larger number of AABB/AABB tests we have to perform. To be sure, this would still be much faster than just passing every polygon to the narrow phase, but unfortunately it is still nowhere near fast enough.

So how can we divide the scene into many more boxes with small clusters of polygons stored in each box while still maintaining the ability to reject the individual boxes from queries extremely quickly? We use a spatial hierarchy.

We discussed hierarchies in Chapter 9 when we learned how to load in hierarchical X files. The hierarchies in that chapter established spatial relationships between meshes in an X file. The hierarchy could be thought of as a tree structure where each node of the tree was a D3DXFRAME which had pointers (or branches) to other sibling and child frames in the tree. Some of the frames actually contained meshes (via mesh containers) and using the tree analogy, we can think of these nodes as being the leaves of the tree. When we examined the D3DXFrame hierarchy, the parent-child relationship between the frames in the tree established how meshes in the scene were related. If rotation was applied to a node in the tree, the children of that node also inherited the rotational change. This allowed us to store a car model as separate meshes, where the wheel meshes could be rotated independently from the car body stored in a parent node (frame). Any movement or rotation applied to the car body node was

also inherited by the wheel nodes so that when the car body was moved, the wheels always moved with the car body and maintained their correct spatial relationship.

Hierarchies are used so often in game development and in so many different areas that it is hard to imagine creating a 3D application without them. Spatial partitioning data can also be represented as a hierarchy which makes finding the regions of the scene that need to be queried or rendered extremely efficient. If we think back to our D3DXFrame hierarchy from Chapter 9, we can easily imagine that we could assign each frame in the hierarchy a bounding box which was large enough to contain all the meshes below it in the hierarchy (i.e., meshes belonging to direct and indirect child frames). If we were to do this, then the frame hierarchy could be traversed from the root node down during a frustum culling pass and as soon as a frame was found that had a bounding box that was situated outside of the frustum, we could stop traversing down that section of the hierarchy and reject the frame along with all of its descendants from rendering consideration. This rejected frame may have had many child frames which each had many child frames of their own with meshes attached. By simply rejecting the parent frame of the hierarchy, we reject all of the children and grandchildren, etc. with one simple test at the parent node. Of course, this strategy assumes that the parent node's bounding volume has been calculated such that it encompasses the bounding volumes of all its child nodes, and so on right down the hierarchy (i.e., bounding volumes are propagated *up* through the tree, getting larger as more children join in).

It might have occurred to you that this same hierarchical technique could be employed with spatial partitioning. Rather than simply divide the scene into 49 bounding boxes and store all 49 boxes in the scene class, we could instead recursively divide the level, creating a tree or hierarchy of bounding volumes. In this example, the bounding volume being used is an AABB, but we could use other bounding volumes also (spheres are another popular choice).

The following images demonstrate the division of our same example scene hierarchically. The end result in this example is actually a scene that will be divided into 64 bounding boxes (at the leaves of the tree). Because these bounding volumes are connected in a tree like structure, queries can be done extremely quickly.

Forgetting about how we might represent this subdivision technique in code for the moment, let us just analyze the properties of the images. The scene is as before, a large rectangular region of polygon data. The bounding box of this entire region would be considered the bounding box of the entire scene.

When the scene constructor is called we might imagine calculating this bounding box node and storing it in the scene class. This will be the root node of the tree and the only node pointer the scene will store. This concept is not new to us. Recall that our CActor class stores only the root frame of the hierarchy. The rest of the frames in the hierarchy can be reached by traversing the tree from the root. We are now imagining a similar relationship between our spatial nodes. To accommodate this arrangement we can upgrade BoxNode to store pointers to child BoxNode structures.

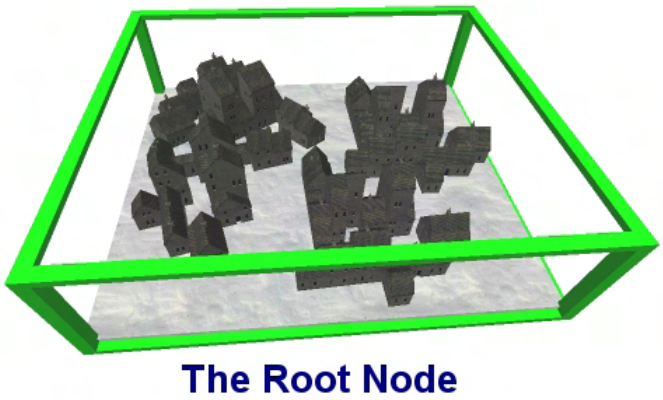

Figure 14.9

```
class CBoxNode
{
   public:
   D3DXVECTOR3       m_vecBoxMin;
   D3DXVECTOR3       m_vecBoxMax;
   CPolygonContainer m_PolyContainer;
   CBoxNode *        m_Children[4];
};
```

Notice that we have now added an array of four CBoxNode pointers to the CBoxNode class. This means each node will have four child nodes.

> **Note:** A spatial tree that divides the parent node space into four at each node is called a *quad-tree*. Thus, what we are looking at above is a Quad-tree node. You will discover later how the only real difference between an oct-tree, quad-tree, and kD-tree is simply how many children each node in the tree has. For the sake of explaining hierarchical spatial partitioning in this section, we will use a Quad-tree in our examples.

As Figure 14.9 shows, the first step in compiling our spatial tree is to compute the bounding box of the entire scene. The bounds calculated will be stored in a CBoxNode structure whose pointer is stored in the scene class. This will be the root node of our tree.

In our example we will be using a quad-tree to partition space which essentially means each node in our tree has four direct child nodes and therefore, at any given node in the tree, its immediate children partition its bounding volume into four equal sub-volumes (called *quadrants*).

With the root node created, we enter a recursive process to build the rest of the tree. At each recursive step (starting at the root) we are passed a list of polygons contained in that node's volume and have to decide whether or not we wish to partition this space any further. If we do decide that the bounding volume of the current node is sufficiently small or that the number of polygons that have made it into this volume are so low in number that further spatial subdivision of this region would be unnecessary, we can simply add the polygons in the list to the node's polygon container and return. We do not bother creating any children for this node. It is essentially a node at the end of a branch and is therefore referred to as a *leaf node*. Leaf nodes are the nodes at the ends of branches which contain polygon/mesh data. The branch nodes are sometimes called *normal nodes* or *internal nodes* or *inner nodes* or simply just nodes (versus leaves).

However, if we do wish to further partition the space represented by the node's bounding box, we divide the node's bounding box into four sub-boxes. We then create four child nodes and assign them the bounding boxes we have just calculated. We then classify all the polygons in the list of polygons that made it to this node against the four bounding boxes of the child nodes. This allows us to create four sub-polygon lists (one per child). We then recur into each of the four child nodes, sending it its polygon list so that this same process can occur all the way down the tree. Notice that when a node has children, it stores no polygon data (at least in this vanilla implementation) and is considered to be a normal node (as opposed to a leaf node at the end of a branch of the tree).

In Figure 14.9 we generated the root node and its bounding volume. Let us step through the process of building the quad-tree with images to solidify our understanding. Please note that in these examples we are still only carving up the scene into 49 boxes at lowest level of the tree since this makes the images much easier to decipher. You can imagine however that this same process can be performed to divide the scene into 1000s of boxes which are hierarchically arranged.

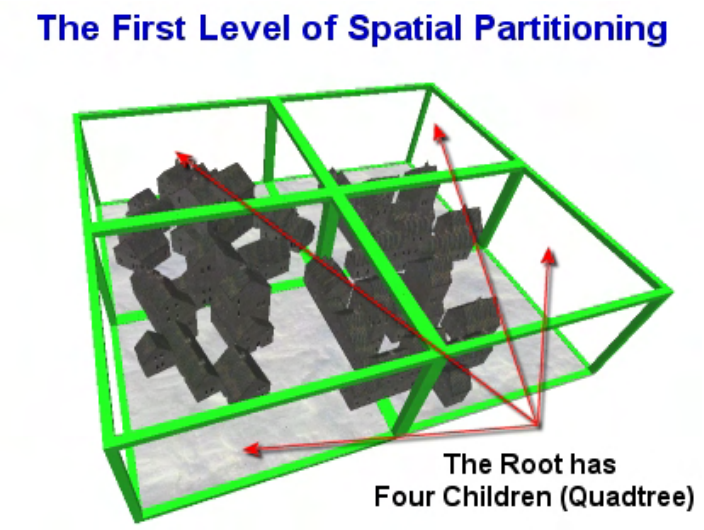

Figure 14.10

We would first process the root node, being passed the list of polygons for the entire scene. We would determine that the node's bounding box is very large and therefore its space should be further partitioned. The polygon list would contain a large number of polygons and we will not be creating a leaf at this node. Remember, we generally want to store only a handful of polygons in the leaf nodes so that we minimize the number of polygons that are collected and sent to the narrow phase when a leaf node's volume is intersected.

Thus, we create four child nodes and attach them to the root node. We would then divide the bounding box of the root node uniformly into four sub-boxes, each of which describes a quadrant of the parent volume (Figure 14.10). Each child node would be assigned one of these child bounding volumes. The list of polygons would then be tested against the four bounding volumes and a list compiled of the polygons contained in each box (four lists). It is at this stage that any polygons found to be spanning a box boundary could be clipped so that the polygon list compiled for each child will contain only the exact polygons that are contained inside its volume. If clipping is being used, a child node will never be sent a polygon list that contains polygons that span the boundary of its bounding box. We would then recur into each child passing in the polygon list that was compiled for it by the parent.

Remembering that this is a recursive process, Figure 14.11 shows what our tree would look like after we have stepped into each child of the root and subdivide their space into four, with polygon lists created for each child node. In reality, the repeated subdivision of each child branch will typically be performed at one time, but we took a bit of artistic license here to demonstrate the subdivision.

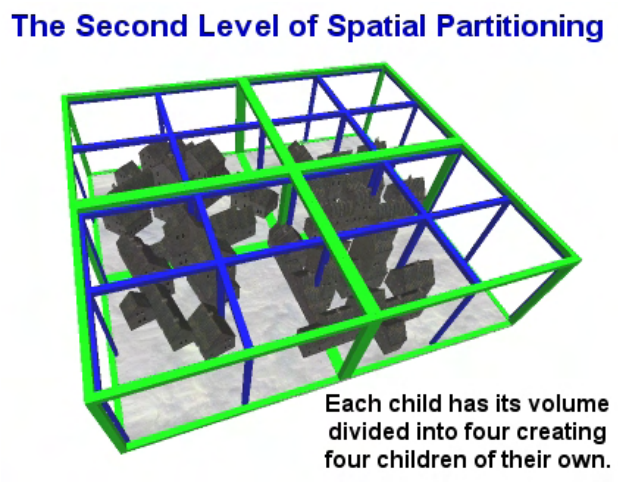

Figure 14.11

If the children of the root node's children are where our recursive process was to end, Figure 14.11 would show the total level of subdivision. As we can see, the root node's bounding box have been divided into four quadrants representing the volume of its four immediate children. Then, each child node of the root, has four children of its own which further partition its volume into four more sub volumes. The blue bounding boxes in Figure 14.11 show the bounding volumes for nodes positioned at the 3rd level in the hierarchy. If we decided to stop partitioning here, then each blue box would be a leaf node and would store a list of polygons that are contained within its volume; the nodes at the first and second level would not. They would just store a bounding volume and pointer to the child nodes. However, in this example we will not stop partitioning at the 3rd level, but will stop at the 4th level instead.

This means that each blue box node in Figure 14.11 would also have four children of its own as shown by the red boxes in Figure 14.12. In our example we are going to stop subdividing here at the 4th level in the hierarchy (3rd level of partitioning). This means, the 4th level of our hierarchy will contain the leaf nodes where the polygon data will be stored.

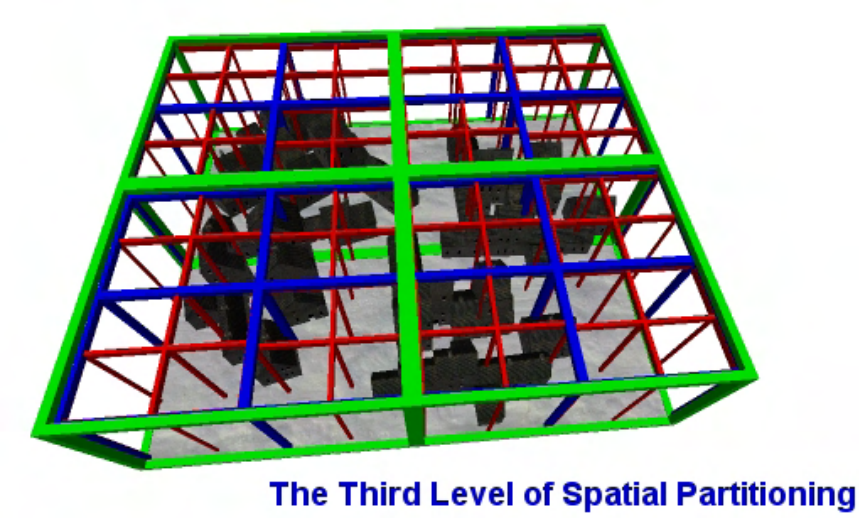

Figure 14.12

Of course, in reality we would subdivide this level to a much greater degree than just 64 bounding boxes, but this subdivision is easy to illustrate in diagrams and subsequently discuss. An actual level that contained 100,000+ polygons would need to be partitioned into hundreds of bounding boxes in order to get optimal collision query performance.

It is also worth noting that in our example we are uniformly partitioning space to get certain sized bounding volumes at the leaf nodes. When this is the case, the quad-tree built will be balanced and every child node at a certain level of the tree will have the same number of children. This is because the scene would be uniformly divided into equal sized leaf nodes. However, often we will not want to subdivide space further if, at any level in the hierarchy, a node contains no polygon data. When this is the case we will generally just make the node an empty leaf (i.e., a node with no children or polygon data). An example of this is shown in Figure 14.13

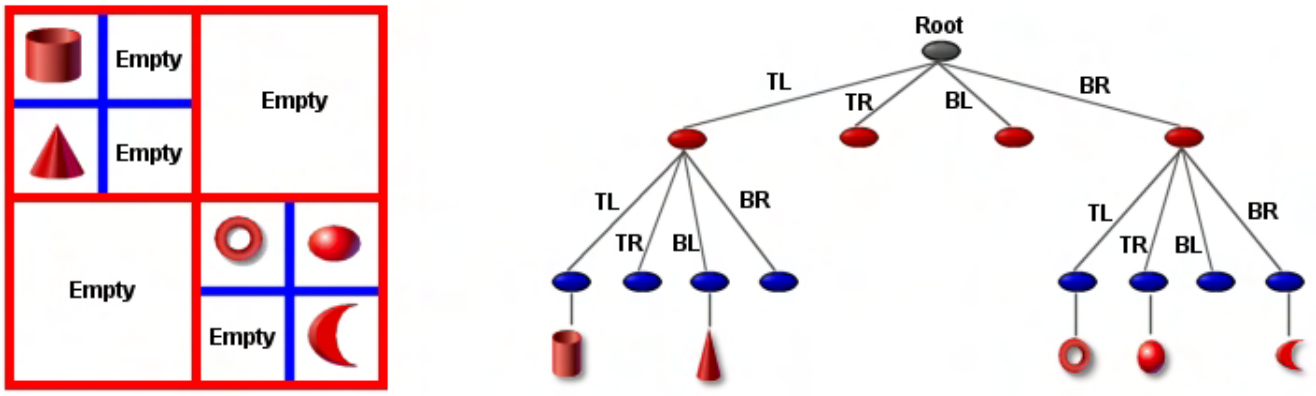

Figure 14.13

On the left side of the image we see the top down view of some shapes being compiled into a quad-tree. At the root node we store the entire bounding box which is then divided into four child nodes representing the four quadrants of the original bounding box. We can see that when building the second level of the hierarchy, the top left and bottom right child of the root contain polygon data and therefore, they are further subdivided (we step into the child nodes and continue our recursion). However, the top right and bottom left children of the root node have no polygon data contained in them so we will not do anything here and return. The fact that we have not created any children for these nodes makes them leaf nodes. Since they have no polygon data, they are empty leaf nodes. On the right of the image we show the shape of the quad-tree. The root has four children and two of those have four children of their own. At the third level, subdivision stops and some of the nodes at this level are empty leaf nodes and some are actual leaf nodes containing polygon data. Notice that we also have empty leaf nodes in the second level too (TR and BL). It would be wasteful in most circumstances to subdivide empty space as these empty volumes will have to be traversed and tested when collision queries are made even though we know that no polygon data will ever be found. The spatial tree shown in Figure 14.13 is not perfectly balanced as the leaf nodes are not all contained at the same level in the hierarchy. Does this matter?

Ideally it would be nice if our tree could be completely balanced so the situation does not arise where some queries may take substantially longer to perform than others merely because the queries are being performed in a section of the tree where the leaf nodes go very deep and more nodes must be traversed before the queried data is located. In a perfectly balanced tree where all leaf nodes existed in the same level of the tree, scene queries would take almost identical times to execute, giving us a consistent query time. We would also use a consistent amount of stack space during the traversal. However, while a balanced tree is a nice thing to achieve, that does not mean we should needlessly subdivide sparse regions of the scene simply to push the sparsely populated or empty leaf nodes down to a uniform level (i.e., alongside leaves from densely populated regions of the scene). After all, making the tree deeper than it need be in many places would essentially be forcing all tree queries to operate under the worst case performance scenario. Tree balance is a more important factor to consider when dealing with kD-trees or BSP trees, as we will discuss in time, but is still something you should bear in mind with all tree implementations. If you find that your scene is taking much longer to query in some area versus others, it may be a balance issue, and in some cases the tree can be made shallower in the troubled areas by not subdividing to such a large degree. It is generally preferable to have you frame rate run consistently at

50 frames per second rather than being at 100 frames per second in some regions and 10 frames per second in others. So consistent query times are certainly desirable where possible.

Using the example quad-tree generated in Figure 14.12, let us see how we might efficiently query the tree for collision information. Once again, at the moment our focus is very much on the implementation of a broad phase for our collision system. We will discuss using spatial trees to speed up rendering later in this lesson and flesh this theory out in the next lesson with a hardware friendly rendering solution.

14.2.1 Hierarchical Queries using Spatial Trees

For this demonstration we will once again assume that we are testing an AABB (surrounding the swept sphere) against the tree starting at the root node. We are interested in finding any polygons in the level that have the potential to collide with the swept sphere. Ideally, we wish to reject all non-potential colliders from consideration as quickly as possible.

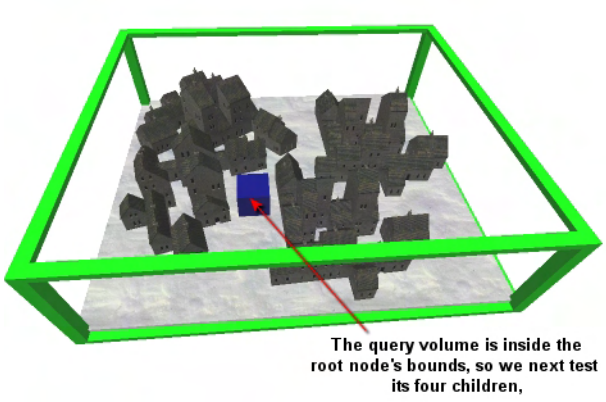

Figure 14.14

The query function would be a simple recursive function which steps through the tree performing intersection tests between the query volume and the bounding boxes of the child nodes of the current node being tested. When an intersection occurs with a child node, the function recursively calls itself to step into that child and continues down the tree. So whenever we find a child node that does not intersect the query volume, we can immediately reject it and all its child nodes (and all the data they contain) instantly.

If at any point we visit a node that has polygon data, we add the data contained in that leaf node to the container being used to collect the polygons for the narrow phase. In Figure 14.14 we show our query volume positioned somewhere within the root node's bounding volume. The first thing we would do is test this bounding volume against the bounding volumes of the root node's four children.

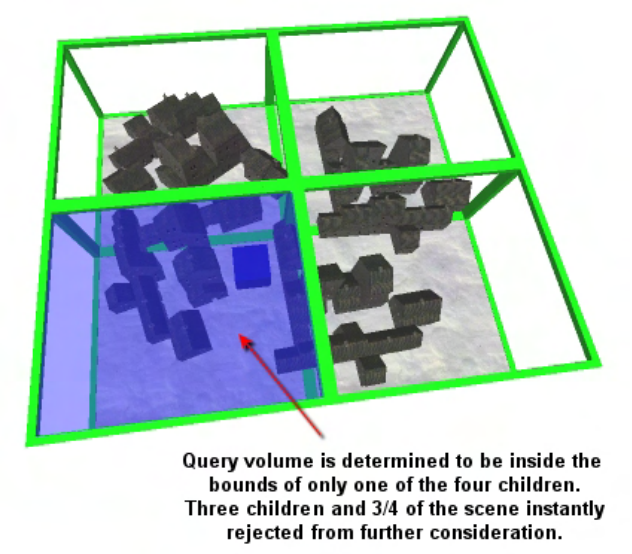

Figure 14.15

As Figure 14.15 illustrates, the query volume would be found to be inside only one of the bounding volumes of the root's children. In this example we can see that it is contained in only the bottom left child node. At this point, we can ignore the other child nodes completely and they do not have to be further traversed. So with four AABB/AABB tests we have just rejected ¾ of the entire scene (assuming even polygon distribution). We know that nothing in the other three child nodes can possibly intersect our query volume, so we ignore those child nodes and their children, and their children, and so on, right down that branch of the tree. If we assume that our level contains 100,000 evenly distributed polygons, we have just rejected 75,000 of them with four simple AABB/AABB tests. Bear in mind that we are only performing very light spatial subdivision here (four levels), but in reality, that step would have probably rejected 100's if not 1000's of leaf nodes and all the polygon data contained within them.

In this instance of the recursive query routine we discovered that the bottom left child of the root was intersected, so the function will now traverse into that node. In the next step we do the same thing all over again. That is, we test the query volume against the four child nodes of the bottom left child of the root. The children of the bottom left child of the root are shown as the blue boxes in Figure 14.16. As you can see, we discover an intersection with only one of the children and the other three child nodes can be ignored. In the first step we whittled away ¾ of the scene, in this second step, we have whittled it down to just a ¼ of that again. With just eight AABB tests, we have rejected 15/16^{ths} of the entire scene. Not bad at all.

Figure 14.16

At this point we are located at the bottom left child of the root and have determined that only its top right child is intersected by our query volume. Therefore, the function would call itself recursively again stepping into this child (the highlighted blue box in Figure 14.16)

Next we would step into the top right blue child (Figure 14.16) and would see that it too has four children of its own. Once again, we would test the query volume against its four children (the four red boxes highlighted blue in Figure 14.17) and determine that the query volume is contained in only two of them. When we traverse down into both of these child nodes we find that they have no children and we have reached the leaf nodes of the tree. We then collect the polygon/mesh data stored in those two leaves and add them to the potential colliders container. We can now return from the function, unwinding the call stack back up to the initial function call made to the root by the application. We would have a container filled with only the potential colliders which can then be passed into the narrow phase. We achieved our goal with only 12 AABB tests. Imagine the savings when the geometry has been divided many levels deep and has created 100's of leaf nodes instead of just 64. For example, if the scene was compiled had 1000 leaf nodes, the first four AABB tests at the root would have instantly rejected 750 of those leaves. This is exactly why hierarchical spatial subdivision is so powerful.

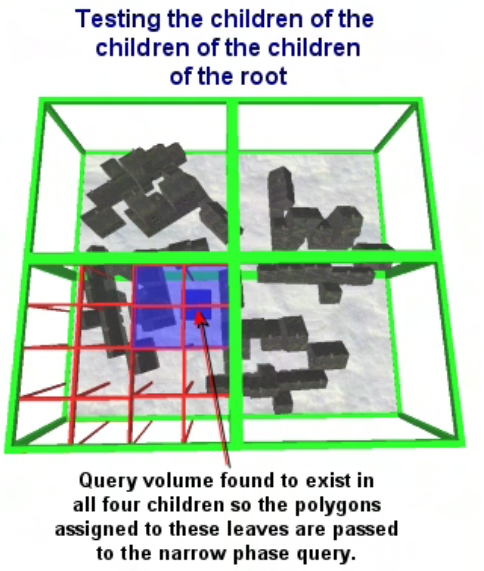

Figure 14.17

14.2.2 Hierarchical Frustum Culling

Let us quickly discuss scene rendering as another example of the benefits of hierarchies. This will only be lightly discussed in this lesson since implementing a hardware friendly rendering system for our spatial trees will be the core subject of the next lesson.

Figure 14.18 shows the first phase of the rendering of this spatial hierarchy. Starting at the root node and traversing down the tree, we can see that at the root node we test its four child nodes (the four quadrants of the entire scene) against the view frustum using AABB / Frustum tests. After these four simple tests we can see that only one of the child nodes of the root intersects the frustum, so the other three child nodes are ignored along with all their children. We have just rejected ¾ of our scene's polygon data from being rendered with these four tests.

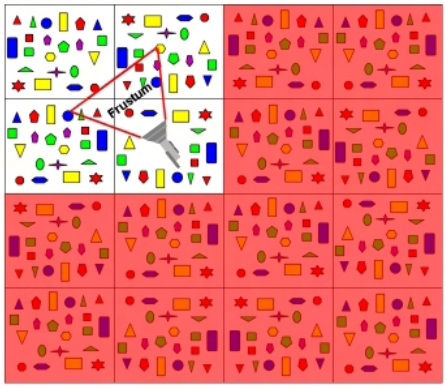

Figure 14.18

The top left child of the root does contain the frustum however, so we will need step down into this node and narrow the set further by testing its four child nodes against the view frustum.

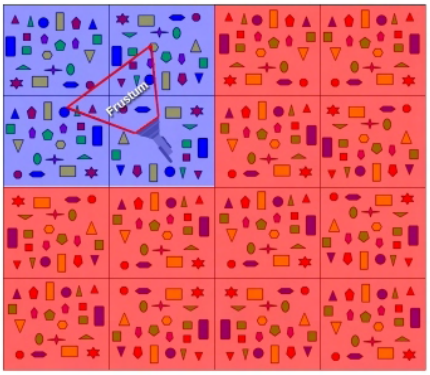

Figure 14.19

When we visit the top left child of the root we must then test to see whether any of that node's child nodes are within the frustum. Once again, we test the frustum against the four bounding boxes of the child nodes, which are shown in Figure 14.19 as the four blue boxes.

One thing that should be obvious looking at Figure 14.19 is that at this level in the tree, all four of the blue child nodes are partially inside the frustum, so we are unable to reject any child nodes at this point. All four child nodes of the top left child of the root will need to be visited to further refine the polygon set that needs to be rendered.

For each of the four blue nodes, we step down and visit their four child nodes. One at a time we determine which of its child nodes have bounding boxes that intersect the frustum. In our simple example scene (Figure 14.20), the children of the blue nodes are also the leaf nodes at the bottom of the tree. These leaf nodes contain the polygon data, so once we find that a leaf node is inside the frustum, we can render the polygons contained there. Alternatively, if you are doing a deferred rendering pass (such as storing the polygons in a queue for sorting purposes) then these are the polygons that should be collected and added to your rendering list.

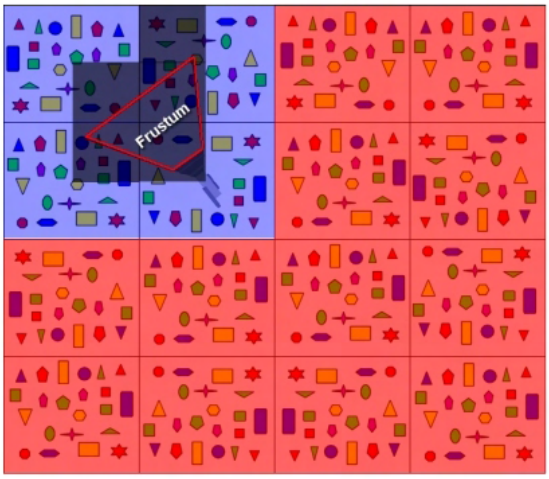

Figure 14.20

As we visit each blue node we determine which of its children are inside the frustum and need to be rendered. We can see in Figure 14.20 that if we start by visiting the top left blue node, only its bottom right child intersects the frustum and it is the only one of its four leaf nodes that needs to be rendered. Then we visit the top right blue node and determine that its top left and bottom left child nodes partially intersect the frustum and need to be rendered. When we visit the bottom left blue node, we see that only one of its four child leaf nodes intersect the frustum (its top right child node). Finally, when we visit the final blue child node on the bottom right, we see that the only child leaf node that is visible is its top left leaf node.

Thus, with the camera positioned as shown in this diagram, only five leaf nodes from a scene comprised of sixty four leaf nodes need to be rendered. By stepping through the hierarchy and performing 24 AABB / Frustum intersection tests, we have rejected 92% of our scene polygons from having to be rendered.

Unfortunately, coming up with a hardware friendly rendering solution is not as trivial as it may appear to be. Even with such large scale rejection of polygon data at our disposal, the strategy of collecting the visible polygons and rendering them must be well thought out so that CPU burden is kept to a minimum. On modern graphics cards, the GPU is very, very fast and you may easily find cases where brute force rendering beats a naïve implementation of hierarchical spatial partitioning. A system that burdens the

CPU will suffer greatly when compared to its brute force counterpart when the entire scene is contained inside the frustum and nothing can be culled. If the entire scene is contained inside the frustum, then everything will need to be rendered anyway. In that case, brute force will always be faster due to the fact that it does not need to perform any tree traversals. So what are our options?

One implementation you might come across in your research steps through the tree and collects the polygon data from the visible leaves into a dynamic vertex and index buffer for rendering. Unfortunately, for large polygon datasets this technique is fairly useless. The memory copying of the vertex and index data into this dynamic buffer set will kill performance. An improvement to this method maintains a static vertex buffer and collects only indices during the traversal. This is a much better design, but still not quite optimal since memory copying is a costly operation no matter what, even if you are only dealing with 16-bit indices. We will examine an alternative approach in the next lesson that does not require a dynamic buffer (although they will be handy for specific tasks as we will discover later on).

Other strategies can also be employed to speed up the frustum rejection pass of the tree by reducing the number of plane/box tests that must be performed.

One of the most popular is called *frame coherence* (or sometimes *temporal coherence*). It works by having each node remember the first frustum plane that caused the node to be rejected so that in the next frame update, we can test the failed plane first and hopefully benefit from the fact that the node is still outside the frustum. This takes advantage of the fact that between any two given frames (a small time step), a node that was invisible last time is likely to be invisible again as a result of the same plane failure. The basic idea is that the node says, “The last time I was tested, I failed against frustum plane N, so let me check plane N first this time because it is likely that in the short amount of time that has elapsed, I will fail again against this plane and get rejected straight away”. This reduces the number of plane/box tests down from 6 to 1 when all goes well.

Just as we can reject large swaths of the tree when a node is outside the frustum, another important optimization can be implemented when a node’s bounding volume is found to be contained completely *inside* the frustum. If a node is totally inside the frustum then we know for certain that all of its child nodes must also be contained inside the frustum also. Thus, once we find a node fully contained in the frustum, we no longer have to test the bounding volumes of its children -- we can traverse immediately to its leaf nodes and render them. If we do not allow for node spanning polygons (i.e., they were clipped to the nodes during compilation), hardware clipping can also be disabled since we know that none of the polygons contained within the frustum will require clipping. This is not really a major savings these days since hardware clipping is quite fast, but it is worth noting nonetheless. If you ever need to implement a software renderer, this would be something to factor in.

Finally, another common optimization to reduce plane testing involves the child nodes benefiting from information that was learned during the parent node’s frustum tests. This works for cases where there was partial intersection. We know for example that if a node is found to be inside a frustum plane, then all of its children must also be inside that frustum plane. Therefore, there is no need to test that frustum plane against any of the child nodes. We can always assume that the child currently being tested against the frustum is inside that plane without performing any test.

All of the above techniques and optimizations will be fully explained and implemented in the next lesson when we discuss rendering our spatial trees in more detail. They have been introduced only briefly here to make you aware of the complexities of such a system and the various optimizations that can be performed.

14.2.3 Hierarchical Ray Intersection

One of the most common intersection routines used in games and related applications is the intersection test of a ray with a polygon. Such techniques are used to calculate light maps, form the narrow phase of our collision detection system, and determine whether line of sight exists between two objects in the game world. For example, we often wish to determine whether a ray cast from one location in the scene to another is free from obstruction (line of sight). The only way to know that without performing spatial partitioning is to intersection test the ray with every polygon in the scene. Only when we reach the end of the polygon list with no intersections found do we know that the ray is free from obstruction and a clear line of sight exists. Unfortunately, if our scene is comprised of many thousands of polygons, that query is going to be unsuitable for real-time applications. Furthermore, we may often want to perform such tests many times in a single frame update. Spatial partitioning speeds up such ray/scene intersection tests by reducing the per-polygon component. The only polygons that need to be individually tested against the ray are the ones inside the leaf nodes whose bounding boxes are intersected by the ray. To demonstrate this, in this next example we will assume that a scene has been spatially divided into a tree, resulting in 16 leaf nodes.

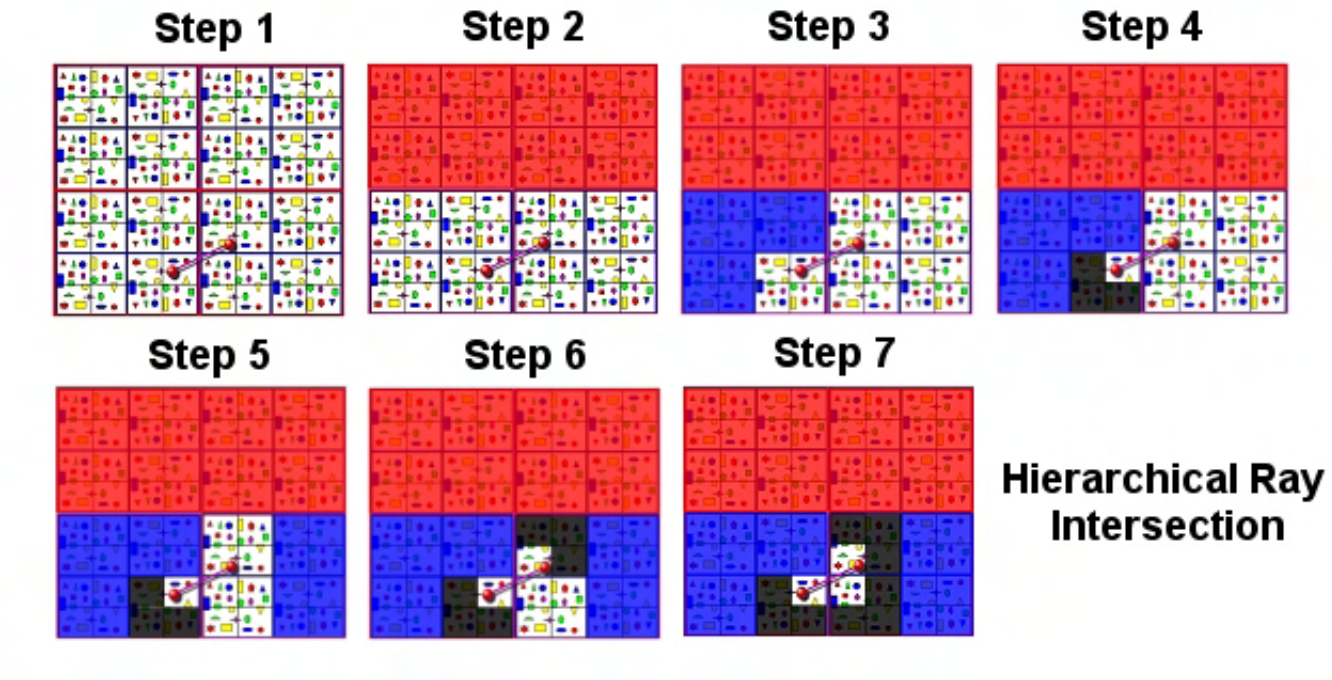

Figure 14.21

In Step 1 we see the ray end points (the two red spheres) and a purple line joining them. We can also see that the scene contains many polygons.

To find the polygons our ray intersects, we need to feed the ray through the tree and find which leaf nodes it eventually pops out in. We would start by feeding in the ray to the root node and testing it against the bounding volumes of each child of the root. As shown in Step 2, in this first stage, two of the root's children would be rejected because the ray does not intersect them. The rejected quadrants are highlighted in red.

Since we have found children of the root whose bounding volumes are intersected by the ray (the bottom two quadrants of the scene) we must send our ray into each child node. We will follow the path of the bottom left child node first. In Step 3 we can see that once in the bottom left quadrant of the root, we would then test the ray against the four child quadrants of this node. The ray is only found to be intersecting one of its children, so three are rejected from further consideration. These are highlighted in blue in the image.

From the blue children in the bottom left quadrant, only its bottom right quadrant node was intersecting the ray so we send it down to that node (Step 3). In Step 4 we show our ray visiting this node and being tested against that node's four children. Of its children, only one of them intersects the ray and three are rejected. The three rejected children are highlighted black in Step 4. At this point we send the ray into that child and find it is a leaf node which contains polygon data. We add the polygon data to a container so that we will have access to it when traversal is complete.

We have now traversed to the bottom of the tree entered via the bottom left child node of the root, so now it is time to send the ray down the root node's bottom right child. In Step 5 we see that as we visit the bottom right child of the root and test against its four children, two of them are not intersecting the ray (the blue ones). Two of the children are however, so we must traverse with our ray into each. First we start with the top left child where the ray is tested against its four child nodes and found to be contained in only one (Step 6). This one is also a leaf node, so the polygons are added to the polygon container. The rejected children are highlighted black. We have now finished with that branch of the tree so we step up a level and visit the other node our ray intersected -- the bottom left child of the bottom right child of the root (Step 7). Once again, we pass our ray into this node and test against its four children and find our ray is only in one of them. The ones that are rejected are highlighted in black. At this point we have reached the bottom of the tree, so we return. The recursive process unwinds right up to the root node and we have a container with polygons that were contained in the three intersected leaf nodes. These polygons can then be tested one at a time to see if an intersection really does occur.

In this simple example we have used a scene divided up into 16 leaf nodes so only $13/16^{th}$ of our polygon data would have to be tested at the per-polygon level. However, in a real situation we would have the scene divided up into many more leaves and the polygon data collected would be a mere fraction of the overall polygon count of the scene. To prove its efficiency, we can see that by performing four ray/box intersections tests at the root node we immediately reject half the total number of polygons in the scene regardless of the size of that scene.

Remember that although the spatial partitioning examples given here are partitioning polygon soups and storing individual polygons at the leaf nodes, this need not be the case. If your scene is represented as series of meshes for example, you could modify the node structure to contain a linked list of meshes instead of an array of polygons. Assigning a mesh to the tree would involve nothing more than sending its bounding volume down the tree and storing its pointer in the leaf nodes its bounding volume ends up

intersecting. You will often have a single mesh assigned to multiple leaf nodes, so you will have to make sure you do not render it twice during your render pass. In Lab Project 14.1 we will actually implement a spatial tree that manages both static polygon soups and dynamic meshes/actors. The static world space geometry loaded from the IWF file will be (optionally clipped and) assigned to the leaf node's polygon array. Each dynamic object (actor) will contain a list of leaves in which it is contained. When a dynamic object's position is updated, we will send its bounding volume through the tree and get back the list of leaves it intersected. We will store these leaf indices in the object structure. Before rendering any object, we will instruct the spatial tree to build a list of visible leaves. The object will ask the tree whether any of the leaves it is contained in are visible and if so, we can render the object. To be sure, there are other ways to manage this relationship, and we will talk more about it in the next lesson. For now, this gives you a fairly high level view of what is to come.

Now that we basically understand what spatial partitioning is, we will now look at some of the more common choices of spatial partitioning data structures (trees) that are used in commercial game development. There are many different types of trees used to spatially partition scenes into a hierarchy and the tree type you use for your application will very much depend on the scene itself and the type of partitioning it requires. In this lesson and the next we will discuss and implement quad-trees, oct-trees, and kD-trees. In Chapters 16 and 17 we will examine BSP trees. Keep in mind that there are a variety of different ways that each of these trees can be implemented. In this chapter we will discuss the vanilla approaches that tend to be the most common for each tree type. We will begin our exploration with quad-trees since we have already laid some foundation in the prior section.

14.3 Quad-Tree Theory

A quad-tree is essentially a two dimensional spatial partitioning data structure. This does not mean that it cannot be used to spatially partition three dimensional worlds, only that it spatially subdivides the world into bounding volumes along the (typically) XZ axis of the world. In a vanilla implementation where polygon data is only assigned to the leaf nodes, each one of these leaves contains all the geometry that falls within the X and Z extents of its bounding volume. No spatial subdivision is done along the third axis (traditionally, the Y axis). That is, the Y extents of every leaf node will be the same; the maximum and minimum extents of the entire scene, which creates bounding volumes with identical heights. As discussed in the last section, each node in the tree has four children that uniformly divide its space into quadrants.

Because of the two dimensional subdivision scheme used by the quad-tree, it is ideally suited for partitioning scenes that do not contain many polygons spread over a wide range of altitudes. For terrain partitioning, a quad-tree is a logical choice since a terrain's polygon data is usually aligned with the XZ plane. During a frustum culling pass, there will not be many times when parts of the terrain that are not visible will be situated above or below the frustum. Because every leaf node shares the same height, we will never be frustum culling geometry that is above or below the camera in a given location on the terrain. We might say that the quad-tree allows us to frustum cull data that is either in front or behind us and to the left or right of us. It is very unlikely that you will be standing on a terrain square and have parts of the terrain located nearby but very far above you or below you. Of course, there may be times

when you might be standing at the foot of a hill and perhaps the top of that hill could be culled because it is situated above the top frustum plane, but in general quad-trees work fairly well for terrains.

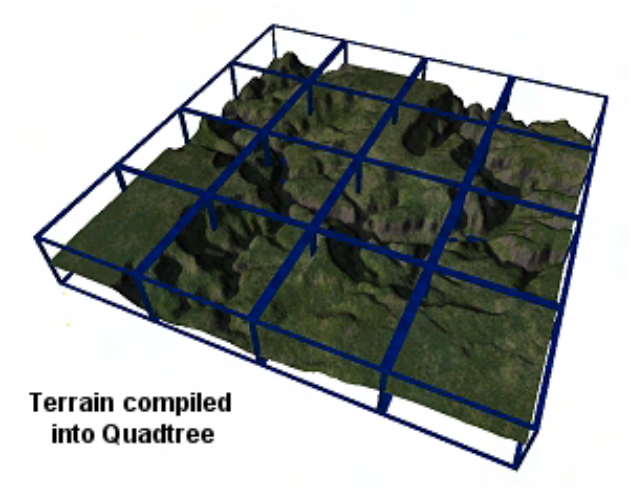

Figure 14.22

As you can see in Figure 14.22, a terrain like this has much larger dimensions along the X and Z axes of the world, so little would be gained from subdividing space vertically as well. This would introduce many more nodes into the tree and make traversals slower for very little (if any) benefit.

Figure 14.22 shows a terrain compiled into a quad-tree and although in reality this terrain would be compiled into many more leaf nodes than illustrated here, it should be obvious why this would be an efficient partitioning scheme for a terrain.

The height of each of the leaf node's bounding volumes can either be the max Y extents of the polygons that exist in that leaf node or it can be taken from the Y extents of the bounding box compiled for the entire scene at the root node. In the previous examples and in Figure 14.22, we have used the Y extents of the bounding box compiled for the entire scene for each leaf node's Y extents. We can see in Figure 14.22 that this generates nodes of identical height throughout the entire tree. In certain cases, leaf nodes may be more efficiently frustum culled or rejected from polygon queries earlier if the Y extents of each node's bounding box is not inherited from the bounding volume for entire scene but is instead calculated at node creation time from the polygon data in that node. Calculating the Y extents for a node would be easy -- we could just loop through each polygon that made it into that node during the compile and record the maximum and minimum Y coordinates of the polygon set. This will yield the minimum and maximum Y coordinates of any polygons stored at that node (or below it) which can then be used as the Y extents of its bounding box. This type of quad-tree (which we will refer to as a *Y-variant quad-tree*) generates children at each node which may not fill the space of the entire parent node, but will still always be totally contained inside it.

Figure 14.23 shows a how a quad-tree node normally has its space uniformly subdivided for each of its children. The height of all child nodes is equal to the height of the parent, even if there is no polygon data stored at that height. The circular inset shows how the children of the quad-tree node might look if, when each child node is created, the Y extents of its bounding volume are calculated from the polygon data that made it into that node. The Y-variant quad-tree is a favourite of ours here at the Game Institute as it performs consistently well in all of our benchmarks.

Before we discuss how to create a quad-tree, we should look at situations where it might not be the best choice of spatial manager due to its two dimensional spatial partitioning. A space-combat scene is one such scenario where the quad-tree might not be the best choice.

Figure 14.23

In such a scene, you could (for example) have a hundred complex spaceship meshes all situated at exactly the same X and Z coordinates in space but at different positions along the Y axis of the coordinate system. We can think of these spaceship models as being positioned in the world such that they would look like they were on top of each other when the scene was viewed from above. If we were using a quad-tree to spatially manage this scene of dynamic objects, all one hundred space ship models would exist in a single leaf node. When the camera entered this leaf node, all of the spaceships in this node would be rendered. This would be true even if all the ships were positioned far above and below the frustum. Essentially, we would be sending one hundred space ship models through the transformation pipeline even if none of them can be seen. Therefore in this example, where the scene has large Y extents, we would rather use a spatial partitioning technique that allows for the scene to be subdivided vertically as well. Although the examples given are associated with efficient frustum culling, the same is true for collision queries. If our swept sphere's bounding volume intersected that same leaf node, the polygons of all one hundred space ships would be collected by the broad phase and sent to the narrow phase as potential colliders (assuming we did no further bounding volume tests). However, the space ships could be positioned nowhere near the swept sphere.

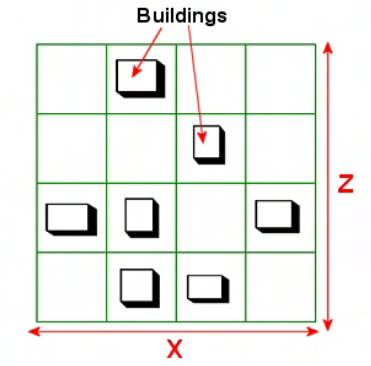

Figure 14.24

Another example where a quad-tree might not be the best choice is when representing a scene that models a cityscape with towering skyscrapers. We will use a very simple example to demonstrate why this is the case.

In the Figure 14.24 we see a scene consisting of seven tall buildings compiled into a quad-tree. In this first image we are looking at the scene from the top down perspective and at first glance this scene appears to fit nicely into a quad-tree.

In this example the scene has been divided into 16 leaf nodes along the X and Z axes of the world. What cannot be seen from this two dimensional representation is how high each building is, and thus how tall the bounding boxes are. In Figure 14.25 we see another view of the scene rendered three dimensionally to better demonstrate this point.

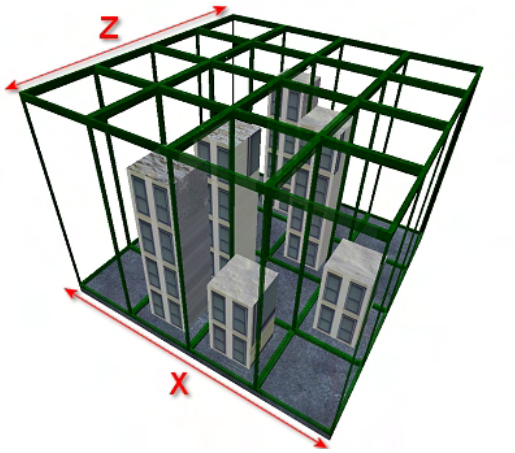

Figure 14.25

In this example, the Y extents of each quad-tree node are the same as the Y extents of the entire scene's bounding box, generating leaf nodes of identical size along the Y axis. Now let us imagine that the camera is located in front of the first two buildings at ground level with a rather narrow frustum.

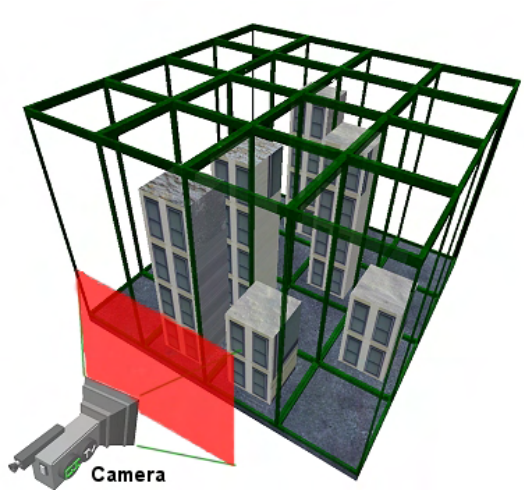

Figure 14.26

The red highlighted area in Figure 14.26 illustrates the section of the two front buildings that are actually inside the frustum and would need to be rendered. The camera can only see the bottom section of the two front buildings and therefore it is only the polygons comprising the bottom sections of each building that need to be rendered. However, because the polygons in each building are assigned to a single leaf node, when the leaf node is partially visible all of the polygons in that leaf are rendered. In this image we can see that the front three leaf nodes (with respect to the camera) can be partially seen from the camera position and as two of those leaf nodes contain buildings, these building will be rendered in their entirety. This is a shame as there are many polygons in each building which are situated well above the range of the frustum and they would be needlessly transformed and rendered (or collected as potential colliders). If you imagine a large cityscape scene consisting of hundreds of tall skyscrapers and imagine that the camera is usually situated at the ground level, using a quad-tree to partition the scene would result in many polygons in the upper regions of these buildings being rendered when they cannot even be seen. An oct-tree (discussed later) might prove to be a better choice of partitioning scheme in this instance.

You may be thinking that the simple answer is to always use an oct-tree instead of a quad-tree when working in three dimensions, but that is not a wise rule to live by. In our terrain example, nothing would be gained (or very little) by spatially subdividing the scene vertically. All we would achieve is a larger tree that is slower to traverse. More AABB/Frustum tests would need to be performed to reject a section of terrain that, in a quad-tree, would fit in a single leaf node and be rejected with a single AABB/Frustum test.

Note: Do not assume that an oct-tree is the best solution even if your scene does contain a large distribution of objects along the Y axis. Oct-trees create many more nodes which makes them slower to traverse and causes the polygons to be rendered in smaller batches. On modern hardware this might cause it to underperform with respect to the quad-tree. In most of our tests performed with the partitioning and rendering of static polygon data, the Y variant quad-tree outperformed the oct-tree in almost every case. However, this might not be true for a mesh based tree and would certainly not be true for our collision system's broad phase. We would not want to send polygon data to the expensive narrow phase which is above or below our swept sphere's volume. However, for rendering purposes, the quad-tree has been consistently hardware friendly. The lesson is to always to test the tree types on a variety of different scenes and machine configurations before deciding which one to use. Of course, you do not have to use the same tree for your collision geometry as you do for your render geometry. For example, you could compile your collision data using an oct-tree but render the scene data using a quad-tree.

14.3.1 Partitioning a Quad-Tree Node

When building a quad-tree node, we will essentially have a list of polygons that are contained in the parent node volume that need to be assigned to its four child nodes. The parent volume will be subdivided into four equally sized volumes along the X and Z axes. The centerpoint of the parent node's bounding box describes the position where the edges of each of the four child node's bounding boxes will meet. Each child node is created and is assigned a bounding volume representing a quadrant of the parent node (top left, top right, bottom left or bottom right). Once we have the child nodes and their bounding volumes calculated, we can start to test which child node(s) a given polygon in the parent node's polygon list is in. It is possible that a polygon in the list passed down from the parent might span the bounding volumes of multiple child nodes. In such a case we can either choose to add the polygon to the polygon list of each child it intersects, or we can clip the polygon to the bounding volumes and store each polygon fragment in the child for whose bounding volume it will now be totally contained.

Placing the polygon in multiple leaf nodes does come with its fair share of problems. We will need to make sure that we do not render or query the polygon multiple times if more than one of the leaves in which it exists is being rendered or queried. This can add some traversal overhead, although not much. Another problem with not clipping the polygons is that when a leaf node is rendered or queried, the node no longer describes the polygons exactly stored in that volume. For example, we might assign a polygon to a leaf node that is much larger than the node. When that node is visible, we have a looser fit for the exact data that can be seen and should be processed. Of course, the problem with clipping is that we essentially perform a process that creates two polygons from one. If this happens hundreds of times during the building procedure it is not uncommon for the polygon count to grow between 50 to 90 percent depending on the type of tree you are using and the size of the leaf nodes. The larger the leaf nodes, the less clipping will occur but more polygons will be contained in a single leaf.

In our implementation, we will provide options for clipping the static polygon data to the bounding volumes of the tree and will also implement a system that elegantly handles the sharing of polygons between multiple nodes when clipping is not being used.

We will store in our node its bounding volume and two clip planes that are used for the classification and clipping of polygon data during the tree building process. We will discuss how to clip polygons to planes later in this lesson. The benefit of clipping is that any node in the tree will contain an exact fit of

the data contained inside it and more importantly, no polygon will ever belong to multiple leaf nodes. Of course, it does mean that whenever a split happens we introduce more polygons into the scene.

> **Note:** Until otherwise stated, we will assume for the sake of the next discussion that we are clipping our polygon data to the nodes in which they belong. Later we will discuss the non-clip option.

Please note that in this section we are currently talking about the assigning of static world space polygon data to the tree, such as the internal geometry loaded from a GILES™ created IWF file. As this data never changes throughout the life of the application, we will clip it exactly to the tree at compile time and store the polygon data in the leaves. Later we will discuss how we can also link dynamic objects to leaf nodes in the tree. These objects are not clipped and are linked to the leaf nodes implicitly by storing a list of leaves they are contained within. Meshes and actors do not have their polygon data stored in the tree. Instead we will maintain an internal array of leaf indices in which the object currently resides. The spatial tree will expose a method that will allow dynamic objects to pass their bounding volume down the tree and get back a list of leaf indices in which they are currently contained. The dynamic object can optionally store these indices and only render itself if any of these leaves are visible (although the system will maintain this information internally for later querying if desired).

Because a given node is really just an axis aligned bounding box, generating the clip planes for a quad-tree node is delightfully easy. Two planes will be needed: one that will split the node's volume halfway along its depth (Z) axis and another that will split the volume half way along its width (X) axis. We know that the normal to a plane that will divide its depth in two will be <0, 0, 1> (or <0, 0, -1> as it represents the same clip plane) and that the centerpoint of the node's bounding volume will be a point on that plane as shown in Figure 14.27.

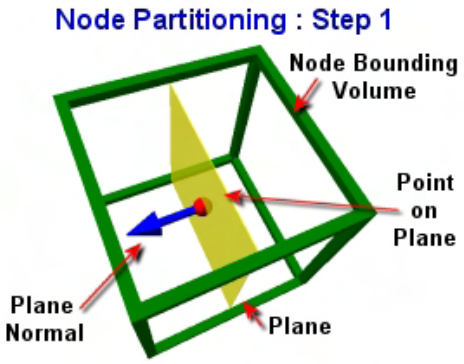

Figure 14.27

In this image we are assuming that the blue arrow is the plane normal pointing along the world Z axis and that the red sphere is the centerpoint of the node's bounding volume. Thus, these two pieces of information are all we need to describe the clip plane shown as the yellow slab in Figure 14.27.

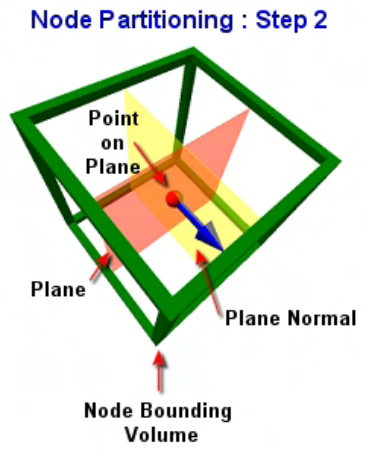

Figure 14.28

The creation of the second clip plane is equally as easy. Once again, the centerpoint of the bounding volume describes the point on the plane and this time we use a normal of <1, 0, 0> so that we have a plane that divides the volume's width in two.

Once we have generated the two planes, we take each polygon in the node's list and clip it to each plane. This is done in two passes. For each polygon in the list we classify it against the first node plane. If it is either in front or behind the node we leave it in the list and continue on to the next polygon. If we find that a polygon is spanning the plane we split it at the plane. The original polygon in the list is deleted and the two new split polygons are added to the list. After every polygon in the list for this node has been tested against the first plane, any polygon that was spanning the plane will have been removed from the list and replaced with two polygons that fit entirely in the front and back half space of the node's volume.

We then clip this list against the second plane using the same scheme. That is, each polygon is classified against the plane and if not spanning, the second plane is left in the list unaltered. If it does span the second plane, we split the polygon in two, deleting the original from the list and adding the two split fragments in its place. At the end of this process, we will have not yet determined which child nodes each polygon should be assigned to, but we know the polygons have been clipped such that every polygon will neatly fit into exactly one child node (one quadrant).

The following code shows this step. Do not worry too much about how the actual functions that are called work at the moment; we will get to all that later when we implement everything. For now just know that this code would be executed during the building of a node. The node is passed an STL vector of all the polygons that have made it into that node during the compilation process so far. For the root node, this vector will contain all the polygons in the scene. Each polygon is assumed to be represented by a CPolygon class that has a method called 'Classify' which returns a flag describing whether it is in front, behind, or spanning a plane. It also has a method called 'Split' which splits the polygon to a plane and returns two new CPolygon structures containing the split polygon fragments. Remember, this code is not yet trying to determine which polygon in the list should be passed to which child node, it is just clipping any polygons that straddle the quadrant borders.

The first thing we do is generate the two clip planes using the D3DXPlaneFromPointNormal method. This method accepts as its parameters a point on the plane and a normal and returns (via the first parameter) the plane represented as a D3DXPlane structure (in a,b,c,d format). For both planes, the point on plane is simply the centerpoint of the node's bounding box (2nd parameter). For the plane normal of the first plane we pass in the vector (0,0,1) which is the world Z axis; for the second plane we pass the vector (1,0,0) which is the world X axis.

```
D3DXPlane ClipPlanes[2];

D3DXPlaneFromPointNormal( &ClipPlanes[0], &((BoundsMin + BoundsMax) / 2.0f),
                          &D3DXVECTOR3( 0.0f, 0.0f, 1.0f ) );

D3DXPlaneFromPointNormal(  &ClipPlanes[1], &((BoundsMin + BoundsMax) / 2.0f),
                           &D3DXVECTOR3( 1.0f, 0.0f, 0.0f ) );
```

Notice in the above code how we have allocated an array of two D3DXPlane structures on the stack which will receive the clip planes that we calculate. In the first element we store the XY plane and in the second element we store the YZ plane.

Now that we have both planes temporarily calculated for the current node, we will classify the polygons in the list against each one. Therefore, we set up an outer loop for each plane and an inner loop that tests each polygon against the current plane being processed.

```
    // Split all polygons against both planes
    for ( i = 0; i < 2; ++i )
    {
        for(PolyIterator= PolyList.begin();PolyIterator != PolyList.end(); ++PolyIterator)
        {
            // Store current poly
            CurrentPoly = *PolyIterator;
            if ( !CurrentPoly ) continue;
```

The first thing we do is test the current polygon being processed to see if its pointer is NULL, and if so, we skip it. You will see in a moment why we perform this test.

Now that we have a pointer to the current polygon we want to test we will call its Classify method and pass in the current plane. The Classify method of CPolygon simply returns a value that describes the position of the polygon with respect to the plane. The four values it can return are CLASSIFY_INFRONT, CLASSIFY_BEHIND, CLASSIFY_ONPLANE and CLASSIFY_SPANNING. As you can see, these tell us whether the polygon we are testing is in front or behind the plane or whether it is spanning the plane. In this loop, we are looking for polygons that are spanning the current plane being tested because if we find a polygon spanning a plane, we must spilt it into two new polygons at that plane. Here is the remainder of the code.

```
            // Classify the poly against the first plane
            ULONG Location = CurrentPoly->Classify( ClipPlanes[i] );

            if ( Location == CPolygon::CLASSIFY_SPANNING )
            {
              // Split the current poly against the plane,
              // delete it and set it to NULL in the list
                CurrentPoly->Split( ClipPlanes[i], &FrontSplit, &BackSplit );

                delete CurrentPoly;
                *PolyIterator = NULL;

                // Add these to the end of the current poly list
                PolyList.push_back( FrontSplit );
                PolyList.push_back( BackSplit );

            } // End if Spanning

        } // Next Polygon

    } // Next Plane
```

As you can see, if the classification of the current polygon does not return CLASSIFY_SPANNING then we leave it in the list and skip on to the next one. That does not mean of course that this same polygon will not be clipped when the second plane is tested in the second iteration of the outer loop. If

the polygon is spanning the current plane then we call its Split routine. This function takes three parameters. The first is the plane we would like to clip the polygon against and the second and third parameters are where we pass in the address of CPolygon pointers which on function return will point to the new split fragments.

After this function returns, FrontSplit and BackSplit will contain the two polygon fragments that lay in front of the plane and behind it, respectively. At this point we no longer want the original polygon in the list as it will now be replaced by these two fragments. Therefore, we delete the original CPolygon structure and set that element in the STL vector to NULL. We then add the front and back splits to the polygon list. Of course, these split fragments may each get clipped again when they are tested against the second plane in the second iteration of the outer loop.

Notice in the above code that whenever we split a polygon, that original polygon is deleted and its pointer in the STL vector is replaced with a NULL. The two split polygons are added to the end of the vector. Now you can see why we did the polygon pointer test for NULL at the top of the list. When processing the second clip plane, many of the pointers in the list may be NULL. There will be a NULL in the list for every original polygon that was split by the first plane.

Now that we have the polygons such that every polygon is contained in exactly one quadrant of the node, it is now time to build four children polygon lists. That is, we need to calculate which polygons will need to be passed into each child node. We will build a list for each quadrant which will result in four polygon lists which we can then pass into the child nodes during the recursive build process. The next section of code shows these four polygon lists (STL vectors) being compiled.

```
PolygonList            ChildList[4];

// Classify the polygons and sort them into the four child lists.
for(PolyIterator = PolyList.begin(); PolyIterator!=PolyList.end(); ++PolyIterator )
{
 // Store current poly
 CurrentPoly = *PolyIterator;
 if ( !CurrentPoly ) continue;

 // Classify the poly against the planes
 Location0 = CurrentPoly->Classify( ClipPlanes[0] );
 Location1 = CurrentPoly->Classify( ClipPlanes[1] );

 // Position relative to XY plane
 if ( Location0 == CPolygon::CLASSIFY_BEHIND )
 {
    // Position relative to ZY Plane
    if ( Location1 == CPolygon::CLASSIFY_BEHIND )
         ChildList[0].push_back( CurrentPoly );
    else
         ChildList[1].push_back( CurrentPoly );

  } // End if behind

 else
  {
    // Position relative to ZY Plane
```

```
    if ( Location1 == CPolygon::CLASSIFY_BEHIND )
         ChildList[2].push_back( CurrentPoly );
    else
         ChildList[3].push_back( CurrentPoly );

  } // End if in-front or on-plane

} // Next Polygon
```

The code first allocates four empty CPolygon vectors that will contain the polygon lists for each child node that we generate. We then loop through each polygon in the clipped list that we just modified. Remembering to skip past any polygon pointer that is set to NULL in the array, we then classify the polygon against both of the node's clip planes and store the results in the Location0 and Location1 local variables. Finding out which list the polygon should be assigned to is now a simple case of testing these results.

We can see in the above code that if the polygon is found to be behind the first clip plane (the Z axis split) then the polygon is obviously contained in the back half space. We then test to see what its classification against the second clip plane was. Remember the second clip plane is the plane that splits the width of the volume and has a normal (1,0,0). If it is behind then we know that not only is the polygon in the back halfspace of the node, but it is also in the left halfspace behind the first clip plane. Thus, this polygon must be contained in the top left quadrant. The else case says that if we are not behind the second clip plane but we are behind the first clip plane, then this polygon must be contained in the top right quadrant of the node. We perform the same tests when the polygon is found to be in front of the first clip plane to determine whether it belongs to the bottom left or bottom right quadrant.

As the above code shows, once we find the quadrant a polygon is in, we add it to the relevant polygon list. After this code has executed, ChildList[0] will contain the polygons for the top left quadrant and ChildList[1] will contain the polygons for the top right. ChildList[2] and ChildList[3] will contain the polygons for the bottom left and bottom right quadrants, respectively.

At this point, all that would be left to do is allocate the four child nodes, construct their bounding boxes as quadrants of the parent node's volume and recur into each child sending the list that was compiled for it by the parent node and the whole process repeats. Only when the list of polygons is small or the bounding box of the child node is small do we decide to stop subdividing and just assign the polygon list to the node, making it a leaf.

> **Note**: Do not worry if the above code did not provide enough insight into how to fully create a quad-tree. It was intended only to show the clipping that happens at each node during the build process. Later in this lesson we will walk through the code to a quad-tree compiler line by line.

Notice that the clip planes will be generated only during the construction of the node's child lists and they will not be stored. The only thing we store in the node (apart from any polygons) is its axis aligned bounding box and the child node pointers. Of course, you could decide the store the clip planes in the node as well if you think you will need them at a later stage. It is possible that you may wish to perform some query routines on the tree using the clip planes instead of the axis aligned bounding boxes, but we do not in our lab project. However, we will store the clip planes in the nodes of the kD-tree that we implement (and in the BSP tree, as we will see later in the course).

We now have a good idea of exactly what a quad-tree is, and this will go along way towards our understanding of the other spatial tree types. Later in this chapter we will cover the source code to a quad-tree compiler which we can then use in our applications. Each tree type we develop will all be derived from an abstract base interface, so we will be able to plug any of them in as the broad phase of our collision system.

That concludes our coverage of the quad-tree from a theoretical perspective, so we will now go on to discuss the other tree types. After we have discussed the various tree types, we will examine the separate processes involved in building them, such as the clipping of polygons and the mending of T-junctions introduced in the clipping phase.

14.4 Oct-Tree Theory

The great thing about the topic of hierarchical spatial partitioning is that whether we are implementing a quad-tree, an oct-tree or a kD-tree, the building and traversal of those trees are almost identical in every case. They are all trees consisting of nodes which themselves have child nodes which can be queried for intersection and traversed recursively. This is especially true in the case of an oct-tree where the only real difference between the quad-tree and the oct-tree is in the number of children spawned from each node.

In a quad-tree, each node's bounding volume is divided into quadrants along the X and Z axes and assigned to each of its four children. In an oct-tree, a node's bounding volume is divided along the X and Z axes and also along the Y axis. Therefore, each non-leaf node has its bounding volume divided into octants ($1/8^{th}$) and each non-leaf node of an oct-tree has eight children instead of four. The bounding volume of each child node represents $1/8^{th}$ of the parent node's bounding volume. Figure 14.30 shows how a single node's bounding box is divided into octants within an oct-tree, compared to being divided into quadrants for a quad-tree.

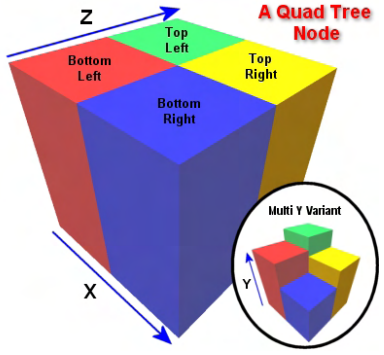

Figure 14.29

Figure 14.29 shows how the bounding volume of a non-terminal quad-tree node is subdivided into four smaller bounding volumes along its X and Z axes. In this image the child nodes each have the same height taken from the Y extents of the entire scene (the root node's bounding box). The circular inset in the image shows a variation of the quad-tree where the Y extents of each child node are calculated using the actual polygon data that was passed into that node during the building process.

In Figure 14.30 we see how the bounding volume of a non-terminal oct-tree node is divided into octants. Not only do we divide the parent node's bounding volume in two along the X and Z axes as we do with the quad-tree, but we also divide the parent volume into two along the Y axis. This creates eight child bounding volumes instead of four. The subdivision of the node's bounding volume resembles a double decked version of the quad-tree subdivision. Instead of just having Top Left, Top Right, Bottom Left and Bottom Right child nodes, the child nodes can now be described by prefixing the label with the deck to which they belong: Upper Top Left, Upper Top Right, Upper Bottom Left, Upper Bottom Right, Lower Top Left, Lower Top Right, Lower Bottom Left, and Lower Bottom Right as labeled in the diagram

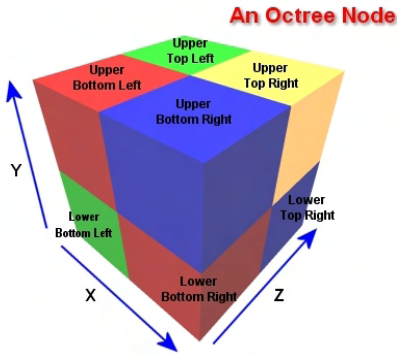

Figure 14.30

As you might imagine, building an oct-tree is a nearly identical process to building a quad-tree. The exception being of course that each non-leaf node has eight children instead of four so we have to divide our polygons into eight bounding boxes instead of four when building each node. Everything else is as before. The leaf nodes are the nodes at the end of a branch of the tree and in our implementation, are the only nodes that can contain geometry data.

The process of building an oct-tree requires only small changes to the code we saw earlier. The node structure used for an oct-tree will have pointers to eight child nodes instead of four and when building the node itself (in our implementation) we will now use three clip planes instead of two to build the clipped polygon lists for each child (see Figure 14.31).

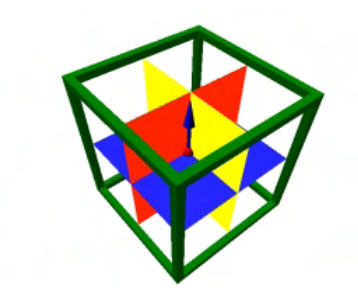

Figure 14.31

Trying to draw an image of what an oct-tree looks like in memory on a piece of paper is virtually impossible if the oct-tree is more than a few levels deep. Each node has eight children, each of which have eight children of their own, and so on right down the tree. In fact, if we think about how many leaves a 10 level oct-tree would partition our scene into, we would get a staggering result of 8^10 = 1,073,741,824 nodes at the lowest level of the tree. Not surprisingly, it is pretty much never the case that we will compile an oct-tree that has anywhere near this many levels. The good thing about oct-trees then is that they are typically going to be fairly shallow tree structures. Of course, when traversing the tree, we have eight child tests to perform at each node (instead of just four in the quad-tree case) to find the child nodes we wish to step into.

Figure 14.32 depicts a partial oct-tree that is three levels deep. The gray node represents the root node of the tree, the red nodes represented the eight immediate child nodes of the root, and if the width of a printed page was not an issue, each one of these nodes would have their own eight blue child nodes which in this example are leaf nodes. So that we can fit the image on a piece of paper we have only shown the child nodes of two of the red nodes. Remember, each one of these red nodes would have their own eight blue leaf nodes. Hopefully, this diagram will illustrate just how much the quad-tree and the

oct-tree are alike at their core. The oct-tree has double the number of branches leaving each node obviously, but it has the same arrangement with leaf nodes at the branch tips.

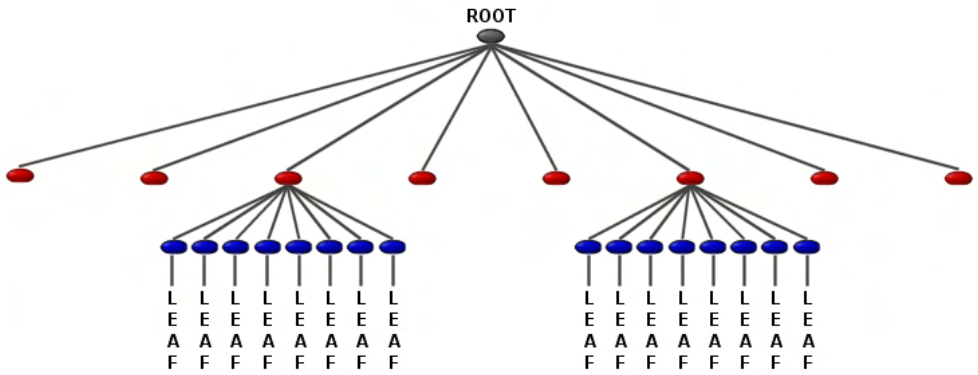

Figure 14.32

Rendering the oct-tree would also not be that different from the quad-tree case. The only real difference would be that when traversing the nodes of an oct-tree, we now have to perform Frustum/AABB tests against eight bounding volumes at each node instead of four, before we traverse down into the visible children.

As you can see from examining Figure 14.33, with an oct-tree, the scene is also divided vertically as well. Looking at the same position and orientation of the camera in this image, we can see that only the bottom two leaf nodes fall within the camera's frustum so only the polygons assigned to those leaf nodes would need to be rendered, which in this case would be the polygons in the bottom sections of each building only. The only time the top sections of the buildings would be rendered is when the camera is rotated upwards (like a person looking up at the sky) because only then would the upper leaf nodes intersect the frustum. At this point however, there is a good chance that the bottom leaf nodes of the building would no longer be inside the frustum and therefore when rendering the upper portions of the building in this example, the lower portions of each building will be frustum rejected and not rendered. Clearly this shows the advantages of an oct-tree and the limitations of the quad-tree in certain scenarios. We have seen that even if the camera is not rotated upwards, using a quad-tree, the entire building would be rendered even if the upper portions of the building cannot be seen.

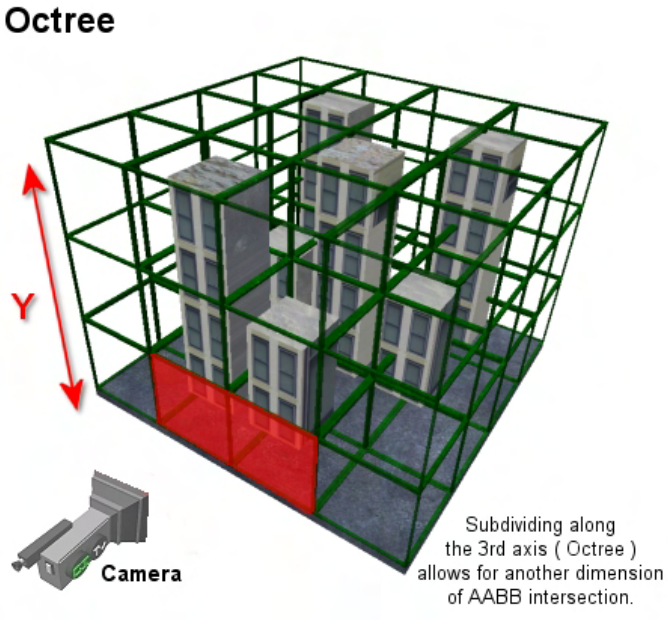

Figure 14.33

Of course, the same would also be true of intersection queries, if an object is contained in the lower leaves, only the polygons comprising the base of the buildings would need to be tested in the narrow phase. So we have discovered that the oct-tree allows us to more finely collect or cull the number of

polygons that need to be considered. If the scene geometry is distributed over a large vertical range, the oct-tree is often a better choice for multi-level indoor environments, cityscapes and areas that have immense freedom of movement along all three axes (such as a space scene). That being said, you should always benchmark your trees and find out for sure which is the best performer for a given scene. As mentioned previously, the oct-tree does suffer from creating more nodes to traverse and clips the polygon data much more aggressively. If care is not taken, you could find your polygon count doubling during oct-tree compilation.

14.5 kD-Tree Theory

A kD-tree is a partitioning technique that partitions space into two child volumes at each node. Each node contains a single split plane and pointers to two child nodes. The split planes chosen at each node are always axis aligned to the world and alternate with tree depth to carve the world into rectangular regions, much like an oct-tree. That is, at the first level of the tree, a split plane that partitions the space along the X axis might be chosen to create two child volumes. When each child is partitioned, the split plane used would divide their space along the Y axis to create two child volumes for each. For each of their children, the split plane used would be one that divides their volume along the Z axis. For their children, the process wraps around to the beginning and we start using the plane that divides space along the X axis again. This process of alternating between three axis aligned clip planes at each node repeats as we step down the tree until we wish to stop our subdivision. That node is then considered a leaf node.

Because the kD-tree partitions space in two at each node, it is a binary tree. Further, because this particular binary tree is used to partition **space** at each node, we might also refer to it as a binary space partitioning tree (BSP tree). While this is certainly true, the kD-tree is not normally what people are referring to when a BSP tree is referenced. A BSP tree is almost identical to a kD-tree except for the fact that at every node an arbitrarily oriented plane can be chosen (instead if using an axis-aligned one). This allows the BSP tree to expose very useful properties that allow for the determination of what is solid and empty space within the game world, which can then be used to optimize rendering by an order of magnitude. Because the kD-tree uses axis aligned planes, a kD-tree is often referred to as an *axis aligned BSP tree*.

The kD-tree allows space to be partitioned arbitrarily at each node as long as the clip plane is still being aligned to a world axis. That is, clip planes can exist at variable positions within the node's volume. The clip plane does not always have to divide the node's volume into two uniformly sized child volumes. This allows for the space to be subdivided such that only areas of interest (where geometry exists) get divided (more on this in a moment).

To summarize, a kD-tree is a spatial partitioning tree with the following properties.

- Each node represents a rectangular bounding volume. Just like an oct-tree or a quad-tree, the faces of each node's bounding box are aligned with the axes of the coordinate system.
- Each node stores a single split plane which is aligned to one of the coordinate system axes. This split plane does not have to cut the region into two equally child volumes (although we may wish it too).

- Each node has two child nodes representing the volumes each side of its split plane.
- The world axis used for the alignment of a node's split plane alternates with tree depth.

Building the kD-tree is much the same process as for an oct-tree or a quad-tree although there may be some differences in how the split plane at the node is chosen. To get across the basic idea of a kD-tree we will show images to illustrate the subdivision of a scene during the construction of such a tree. In this example we will simply calculate each node's split plane to cut through the center of the node's bounding volume. This will divide each node's volume into two equally sized child volumes. As you will see in the following examples, because the split plane being chosen partitions each node's volume into two along its center, we partition the scene in the same way as an oct-tree.

In this first image we show the construction of the root node. After creating the node we would loop through each of the scene's polygons and compile a bounding box that encompasses them all. This will be assigned to the root node as its bounding volume. At this point we have the root node's volume and a list of polygons that need to be passed into two child nodes. Our next task it to choose a split plane for the root. In this image we create a split plane whose normal is aligned with the world X axis (1,0,0). In this example we are using the center of the bounding volume as the point which describes the plane during plane creation and as such the plane cuts through the center of the box dividing its width in two.

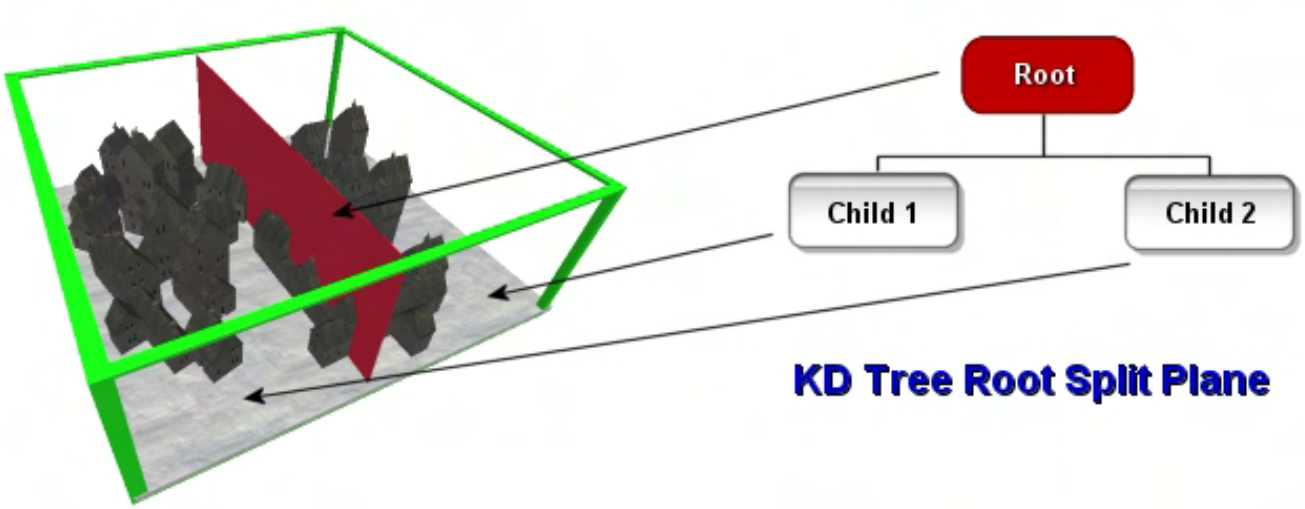

Figure 14.34

At this point we store the split plane in the node and loop through each polygon in the list and classify them against this plane. This allows us to build two polygon lists (one for each child node) describing the polygons that belong in each list. We will assume for this demonstration that we are once again clipping our geometry to the partitions, so any polygon in the root list that straddles the plane will be clipped in two by that plane and the each child fragment added to the respective child list.

At this point we have to recur into each of the children and perform exactly the same task (just as in the oct-tree/quad-tree case). The difference being now that as we step down to each level of the tree, we alternate the normal that we are going to use for the node's split plane. In Figure 14.34 we can see that at the first level in the tree we used a plane normal which is equal to the X axis of the coordinate system. This cuts the box's width in two.

In the next level of the tree we have to switch the clip plane to use one that is aligned to the Z axis of the system (0,0,1). That is, every node at the second level of the tree will use this same normal for its clip planes, as shown in Figure 14.35.

> **Note:** It does not really matter the order in which you alternate the clip planes used at each level of the tree, as long as you alternate between the three as you step through the levels of the tree. That is, you could use a plane normal equal to the world Y axis at the root, one that is equal to the world Z axis at the second level and one that is equal to the world X axis at the third level. As long as you repeat the pattern, everything will be fine and you will have a valid kD-tree.

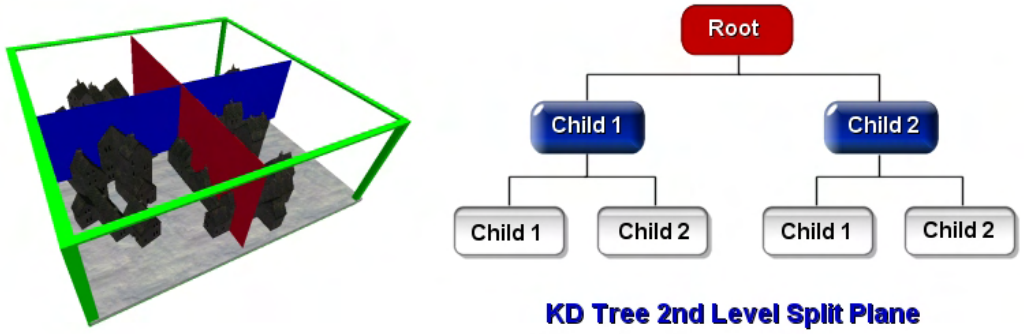

Figure 14.35

Figure 14.35 illustrates what happens when we step into each blue child of the root. For each child we are passed a list of polygons that are known to fit inside this child. We then compile a bounding box for that child based on its list of polygons and store it in the node. A split plane is then chosen which divides the child volume in two. Because we have stepped down a level, we alternate the world axis we use as our plane normal. In this example, the center point of the box is still used to construct the plane, which equates to a plane that splits each child into two equally sized children. In Figure 14.35 a plane aligned with the XY plane (the blue plane) of the coordinate system is being used for each child node, which carves each of their volumes along the depth coordinate. The polygons passed into each child node are then classified against (and clipped to) the split plane to build two child lists for each of its children (the white nodes in the hierarchy diagram).

In Figure 14.36 we see the construction of the next level of the tree, where the children of each child of the root are constructed.

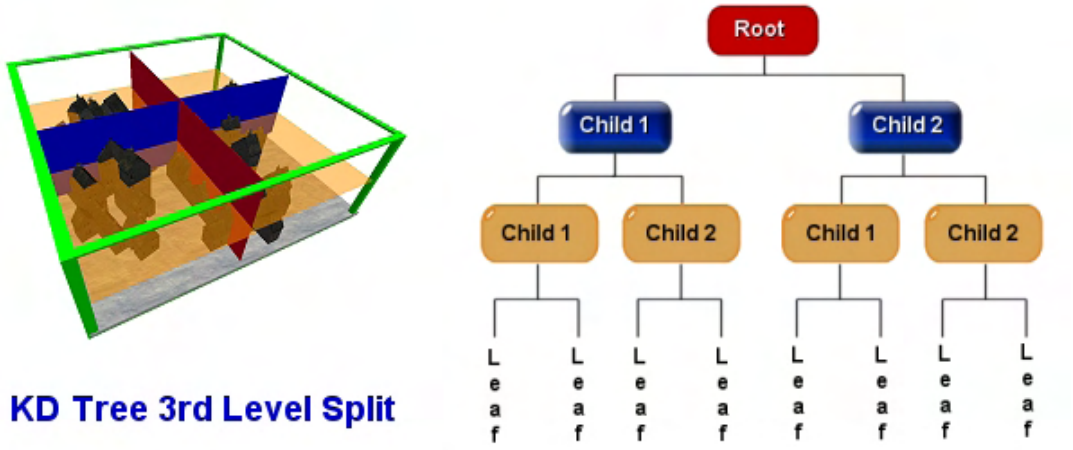

Figure 14.36

In Figure 14.36, when we step into the third level of the tree, the split plane alternates again. This time a plane normal aligned with the Y axis of the coordinate system is chosen. This creates a plane that carves each orange node in two vertically. Once again, the polygons that made it into each orange node would be classified against its plane to create two polygon lists for each of its children. In this diagram, we are assuming that when we stepped down to the fourth level of the tree, the child node's polygon list was considered to be so small that it was not worth subdividing further. At this point, we create leaf nodes which contain the actual polygon data. A leaf node is just a node like any other, with respect to representing an area of space. It has a bounding volume, no children, and it has polygon or mesh data associated with it.

We will see later that building and querying a kD-tree is even easier than both the oct-tree and the quad-tree since we have only one plane and two children to worry about at each node and we are simply trying to determine in which of the two children our query volume belongs. Performing a ray intersection test on a kD-tree is extremely simple since we can essentially just perform a ray/plane intersection test at each node.

Although the splitting strategy used above carves the space up in a uniform way like an oct-tree, this need not be the case for the kD-tree. At any given node we must always choose the correct axis aligned plane to split with, but that plane need not cut the volume into two equally sized child volumes. This is where a kD-tree generalizes the oct-tree, by allowing the world to be carved up into arbitrarily sized AABBs.

Figure 14.37 shows the same tree but with varying split plane positions being used for each child of a node. We can see that the root node (the red plane) splits its volume into two equal volumes as before. Both of its children split their volumes (the blue planes) at arbitrary positions along the depth of their volumes. We can also see that all the children at the 3rd level of the tree (the orange planes) have split planes at different heights from one another.

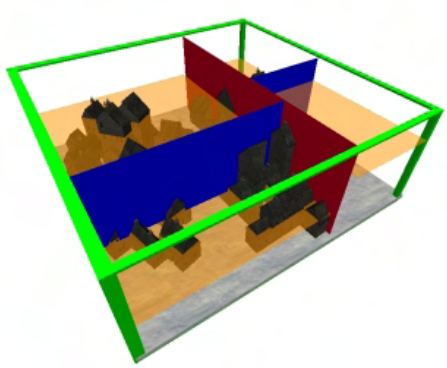

Figure 14.37

A useful characteristic of the kD-tree is that it allows us to favor subdivision in areas of the level that are more densely populated with geometry while still maintaining a balanced tree.

We now have a basic understanding of what a quad-tree, oct-tree, and kD-tree is, even if we are not yet intimate with the concepts behind coding each of these tree types. We are almost ready to start studying the implementation of our tree system, but before we do we will discuss the importance of tree balance, how to clip and split polygons to nodes, and explore exactly what T-junctions are and how we can repair them. Once done, we will be ready to start examining the code to all our tree types.

14.6 Mesh Trees and Polygon Trees

Whether you decide to store raw polygon data at the leaves of a spatial tree or just store whole meshes (or even clusters of meshes) is a decision you will have to make based on what the needs of your application are. Let us first have a quick discussion of the options.

14.6.1 Polygon Trees (Clipped/Unclipped)

If the geometry you intend to store in your tree is a totally static scene (e.g., a large static indoor level), then subdividing the scene at the polygon level might prove advantageous. This is especially true when using the tree in the broad phase of a collision system. A single leaf node will more accurately describe only the polygons that are contained within it, providing the ability to reject trivial data during polygon queries. A leaf node will contain only the polygons that are stored within the bounds of that leaf and the only polygons you are interested in intersection testing if the swept sphere is contained inside that leaf during a collision test. For rendering purposes, when a leaf is inside the frustum, the data we render associated with that leaf contains very few potentially non-visible polygons, even if the polygon data has not been clipped to the leaf nodes.

Obviously, if the polygon data has been clipped to the planes of the leaf node, then a leaf node will always contain an exact set of polygon data that fits inside that leaf node. Building the tree at the polygon level is obviously much slower than at the mesh level because every individual polygon has to be sent down the tree until it pops out in a leaf node and is added to its polygon buffer. If clipping is

being used then this process is slower again, and more polygons will be produced as a result. Certainly, the per-polygon approach is not ideal if the scene is largely dynamic because whenever geometry is moved, the tree will need to be rebuilt from scratch. This could potentially take an unacceptably long time and will not be practical to do in real-time between frame updates. If the scene is static however, then this is not a concern and we can benefit from the more exact fitting of the polygon dataset.

14.6.2 Mesh Trees

When building trees at the mesh level, tree construction is much quicker. We are no longer concerned with the individual polygons that a mesh is constructed from, but instead, we just use its world space bounding volume to determine which leaf nodes the mesh belongs in. This is extremely quick to do because even if a mesh contained 10,000 polygons, when traversing the tree to determine which leaf nodes the mesh belongs in, we are simply doing an AABB/AABB test at each node until we locate all the leaves the AABB intersects. The bounding volume test we perform when classifying the mesh against the child nodes depends on the bounding volume we are using to represent our meshes. If we are representing the bounds of our meshes with a bounding sphere for example, then determining whether a mesh intersects the bounding volume of a child node becomes a simple Sphere/AABB test. If the mesh's bounding volume is represented as an AABB (as ours will be), then the mesh/node test is an AABB/AABB test. As you might image, this is quite a bit faster than performing a Polygon/AABB test for each node and for every polygon in the mesh.

As an example, we might have a level constructed from 100 meshes, each containing 1000 polygons. If we were to compile our oct-tree or quad-tree at the polygon level, compiling the tree would mean traversing the tree with 100,000 polygons until they all eventually ended up being stored in their respective leaf nodes (perhaps with lots of clipping being performed). This is the approach we used in the quad-tree example earlier and as you can imagine, an awful lot of Polygon/AABB tests have to be performed at each node before the tree is fully compiled. If we decided instead to simply build the tree as a mesh tree, then all we would need to do to build the tree is send in the 100 bounding volumes of our meshes. It is the bounding volumes that would be classified against the nodes of the tree and would eventually end up in leaf nodes. In a tree used purely for the partitioning of mesh data, the leaf structure could contain a linked list or array of all the meshes stored in it.

> **Note:** It is common for a mesh that is large or just situated very close to the split planes to be assigned to multiple leaf nodes. There are strategies that exist to minimize this problem and guarantee that a mesh fits completely in a single node. Thatcher Ulrich's discussion of 'loose' oct-trees in *Game Programming Gems 1* (2001) would be a worthwhile read if you are interested in exploring this further.

A mesh tree is ideal for entities that are constantly having their position updated in the scene. If a mesh moves in our scene, we can simply unhook it from the leaf nodes to which it is currently assigned and feed it in at the top of the tree, and traverse the tree again with its bounding volume until we find the new leaf nodes that its bounding volume intersects. A mesh oct-tree for example might be ideal for a space combat game for example, where space could be uniformly subdivided into cubes (leaf nodes) and as a space ship mesh moves around the game world, the tree is traversed again to find the new leaf nodes it is contained within. A mesh is only rendered if one of the leaves it is contained in exists inside the frustum; otherwise it (along with all its polygons) is rejected from the rendering pipe.

When performing intersection queries on the tree (e.g., testing our swept sphere against the tree) the polygons of a mesh only have to be individually tested for intersection if the intersection volume intersects the bounding volume one of the leaf nodes in which the mesh is assigned. Since an entire mesh might exist in many leaf nodes simultaneously, it is important that the system establish some logic to avoid rendering the mesh more than once or checking its polygons for intersection more than once during a single query. As mentioned, this can also be a problem with a polygon tree when the polygons have not been clipped to the nodes. However, this is a relatively smaller problem with the polygon based tree since it would typically be only a handful of polygons here and there that would be rendered or queried multiple times. This might be something we are prepared to accept since it would probably not impact performance by a significant amount in the typical case. For a mesh tree however, it is crucial that this problem be resolved. The bounding volume for an entire mesh may well span dozens of leaf nodes, and if all those leaf nodes were visible, we certainly would not want to render the entire mesh with its thousands of polygons multiple times. The same is true for polygon queries. If our swept sphere intersected dozens of leaf nodes which all contained the same 20,000 polygon mesh, we certainly would not want to perform the swept sphere/polygon intersection tests for 20,000 polygons more than once, let alone dozens of times. Suffice to say our game would become less than interactive at that point.

14.6.3 Mesh Trees vs. Polygon Trees

It is easy to be seduced by the ease with which a mesh tree can be constructed and the speed at which the tree can be dynamically updated when objects in the scene move. To be sure, in many cases it will absolutely be the right choice for the job, whether you are creating a quad-tree, oct-tree or kD-tree (or any other type of tree – like a sphere tree, which is also very popular for dynamic objects). Of course, this decision will also be based on the format of your input data. If the scene is built from a set of mesh objects then the mesh tree would be much easier to implement. If the scene is represented as a static world space polygon soup (a little like the static geometry imported from an IWF file) a polygon tree is probably the best bet.

We do have to be aware of the disadvantages of a mesh tree however, since it may not always be a better choice than a polygon tree if the scene is comprised of multiple static meshes. Ease of construction and update speed does not always come without a cost. Whether that cost is significant depends of the specifics of your application. When you have dynamic objects in your scene, they absolutely have to be connected to the tree at the mesh level, so that they can have their positions within the tree updated in an efficient manner. When you have a scene represented as a static polygon soup, that will most likely fit in well with the polygon level subdivision techniques we have discussed. However, when the scene is comprised of multiple *static* meshes which do not need to have their positions updated, should a mesh tree or a polygon tree strategy be used?

To understand the disadvantages of a mesh tree, let us imagine a situation where a single large mesh consisting of 20,000 polygons spans dozens of leaf nodes (perhaps a terrain mesh). To be sure, this is a worst case example, but it will help to highlight the potential disadvantages of the mesh tree at performing frustum culling and polygon queries. Now, let us also imagine that we have a ray that spans only two leaf nodes which we wish to use to query the tree. In other words, when the ray is sent down the tree to retrieve the closest intersecting polygon, ideally only the polygons that exist in those two leaf

nodes would need to be tested. With the mesh tree, the leaf nodes might contain indices or pointers to the mesh objects that are attached to that leaf. When a leaf is found to be relevant to a query, every polygon in every mesh attached to that leaf will need to be queried at the polygon level. In the case of our large example mesh, only a very small subset of polygons (say 100) actually reside within those two leaf nodes, but we have no way of knowing that with a mesh tree. We simply know that some of the mesh's polygons may intersect the ray. Therefore, we would have to perform per-polygon intersection tests on the entire mesh (all 20,000 polygons) even though only a handful are within the space represented by the leaf nodes in which our ray currently resides. That certainly is not good for performance, and if this mesh was not dynamic, it would probably be wise for a broad phase collision implementation to partition this mesh at the per-polygon level.

> **Note:** The mesh itself could also be internally managed using some form of partitioning structure, even though it exists in a higher level scene mesh tree as single object.

In the case of a polygon tree where we have not performed clipping of the polygons, things are certainly a whole lot better as only a very small subset of polygons of the original mesh will be assigned to those two leaf nodes. This might not be an exact set of polygon data that fits inside the leaf nodes because some polygons may only be partially inside, but as long as we test those polygons and make sure that we do not test a single polygon multiple times if it exists in multiple leaf nodes, we only have to query the polygons that are (to some extent) inside the bounding volumes represented by the leaf nodes.

In the case of a polygon tree where clipping has been performed, we only ever query or render polygons that are completely contained within the leaf nodes that are intersected by the ray. The following diagram illustrates the disadvantages of using a mesh tree in such a situation where a ray/polygon query is being performed on the tree and the mesh is large enough to span multiple leaf nodes.

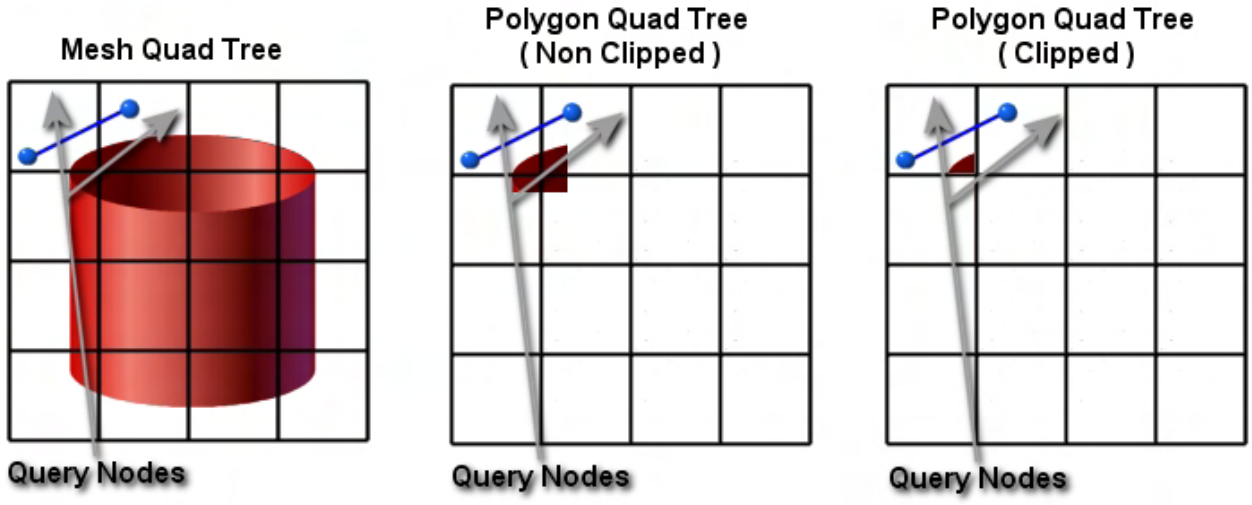

Figure 14.38

In this example we show a quad-tree as it is easier to represent on a 2D sheet of paper, but the same logic holds true for all trees. On the left we can see a single mesh of a cylinder consisting of our 20,000 polygons. As you can see, it spans a large region of the overall scene and therefore, is assigned to multiple leaf nodes. In this particular example the mesh is partially inside every single leaf node so would be assigned to each. The two blue connected spheres represent the ray being used to query the

scene and we can see in all three examples that it only ever intersects two leaf nodes in the top left corner of the scene. Ideally, only the polygons of the mesh that exist in those two leaf nodes should be queried. In the case of the mesh tree, we would have to test all the polygons of the cylinder for intersection, even though we can see that only a very small number of the mesh's polygons exist inside the two queried leaf nodes. If we were to render this mesh tree, the entire mesh would be transformed and rendered by the pipeline every single frame because the cylinder exists in every leaf node. This obviously means that this mesh would never be frustum culled and would always be rendered in full.

The middle image shows a non-clipped polygon quad-tree. Because the leaf nodes contain only the polygon data that are either inside or partially inside those nodes, only a very small portion of the mesh would need to be queried for collision detection with our ray. As you can see in this example, although the polygon data does not always exactly fit the leaf nodes (notice the overspill in the diagram) this does not affect the efficiency of our collision detection routines because only polygons that have some of their area inside the leaf nodes are tested. This would obviously be a lot quicker than querying every polygon in the entire mesh as was the case with the mesh tree. We can also see that during the frustum culling pass through the tree, most of the mesh's polygons will be rejected and only a very small subset would be rendered if the camera was positioned such that only a handful of leaf nodes existed inside the frustum. Some of those polygons may lie partially outside the frustum and would need to be clipped by the pipeline, but this would be negligible to performance in the typical case.

In the rightmost image we see the clipped version of the quad-tree where the leaf nodes contain only polygons that fit exactly inside them. If any polygon was found to be spanning multiple leaf nodes during tree compilation, the polygon would be clipped to those nodes and the fragments assigned to their relevant leaf nodes. This provides very little benefit during the polygon query phase as the same number of polygons would still need to be queried. The fact that those polygons have been clipped and are smaller has no affect on the speed of the ray/poly intersection routines. That is assuming of course that in the case of the non-clipped tree, provisions are made so that a polygon that spans multiple leaf nodes is not queried multiple times. We will use an application timer to assure that this is the case, which we will explain later in this lesson.

It is true when looking at the clipped polygon tree that less of the scene would need to be rendered because only polygon data that exactly fits inside the leaf nodes would be rendered if that leaf node is visible. The same number of polygons would still need to be rendered in the typical case and more polygons in the worst case where everything is visible (because of the splitting of polygons). We can imagine that if a triangle spanned a leaf node during the tree building process, that polygon could be clipped into two fragments, a triangle and a quad. We have now created three triangles where one previously existed. Frankly, on today's hardware, we would probably see little to no benefit from this type of tree versus the non-clipped case. In some cases, we may even see a *decrease* in performance due to the larger polygon count and increased number of DrawPrimitive calls. A clipped tree still provides benefits in other areas where we absolutely must know which section of a polygon lay inside a bounding volume, and you will see later that this is definitely the case when we create a node based polygon aligned BSP tree. For example, a non-clipped tree means that a single polygon may be assigned to multiple leaves. Thus, during a rendering pass we may render it multiple times. Sure, we can embed some logic that prevents a polygon that has already been rendered from being rendered again during a single traversal, but then this would introduce a per-polygon test. We want to render polygons in huge batches as quickly as possible and certainly do not want to be doing a per-polygon test to determine if

we should render each one. On modern hardware, it would generally be quicker just to render those polygons again. However, what about collision queries?

If we are using a non-clipped polygon tree for our broad phase collision system then we still have this problem to overcome. We certainly do not want to test the same polygon in the expensive swept sphere/polygon test more than once. This involves the costly transformation of the polygon into eSpace and the various intersection routines to determine if an intersection occurs. As discussed, we will implement a system so that the collision system can query non-clipped polygon trees without querying a single polygon multiple times.

So we have seen that while the mesh tree has some advantages, it certainly has disadvantages over its polygon based counterpart in other areas. The examples given above are somewhat extreme because if your meshes are of a size such that they fit inside a leaf node in their entirety, this situation will not arise. This situation only becomes problematic on a dramatic scale when the meshes in your scene can span many leaf nodes and have high polygon counts.

Object/Object Collision Testing

Spatial hierarchies can also speed up the collision detection between multiple dynamic objects in our scene. Let us imagine that we have created a space combat game and the region of space that our meshes will occupy has been spatially divided into uniform sized leaf nodes using an oct-tree. Our scene might very well have many spaceships all flying around in space, and while the polygon queries we have examined in this chapter show how a spatial hierarchy can be used to determine which polygons are intersected by rays or bounding volumes or swept spheres, what about the fact that every dynamic object in our scene might collide with every other dynamic object in our scene? In other words, collision detection does not have be performed only between our player and the static scene and any dynamic objects it may contain, but collisions can also be performed to make sure that the dynamic objects in our scene to not collide with one another.

It is quite common for dynamic objects to use simplified bounding volume collision detection in a game. In the interests of speed, when two objects collide in our world, we are very rarely interested in which polygons from each mesh intersected one another. Usually we will perform collision tests between meshes using bounding volumes such as spheres, OBBs or AABBs. Testing collision detection between two bounding volumes is generally much cheaper than testing two objects at the polygon level, which makes it ideal for a broad phase collision step for dynamic objects. If the bounding volumes of two objects do intersect, then you have two choices: you can either treat this as a collision and allow the meshes to respond to the collision accordingly, or you can use the intersection result as a test to see whether the meshes should be queried at the polygon level to make sure that an actual polygon/polygon intersection occurred between the two objects. You will usually find that using the bounding volume intersection result as a test for inter-object collision will suffice. Even if the objects did not physically collide (i.e., their polygons did not physically touch), everything is usually happening so quickly in a 3D game that the player will rarely notice the difference. Of course, the success of this approach depends on the bounding volume being used and how tightly it fits the actual object.

The quickest bounding volumes to test for intersection are spheres, but these are usually the bounding volumes that least accurately fit the shape of the object. When using a bounding sphere around a non-spherical object or an object that is much longer along one of its dimensions, the player may see two meshes respond to a collision of their spheres, even though it was quite visible to the player that the objects did not actually collide. If you are simply using the result of the bounding volume test to progress to the more accurate per-polygon testing process, then this is not so much of an issue. In this case, the sphere tests act more like a broad phase for objects that cannot possibly collide and therefore do not need to be tested at the polygon level.

A generally better fitting volume with fast intersection testing is the AABB. Therefore, one approach is to use an AABB for each of your objects and calculate it each time the player's position/orientation changes. While this might sound extremely slow this does not involve having to compile the AABB from scratch by testing each of the mesh's vertices whenever it rotates. This step only has to be performed when the AABB is first constructed and from that point on we can use some very quick and efficient math to recalculate a new AABB for the object in its new orientation. We will discuss such a technique later in the lesson but for now, let us assume that we are using AABBs for our dynamic objects for the remainder of this discussion.

One of the best fit bounding volumes is the Oriented Bounding Box (OBB). It is similar to an AABB in that it is also a box, but it differs in that it is calculated to try to fit the general shape of the object. Rather than be restricted to using the primary world axes, OBBs use a system closer to object local space to calculate the size and orientation of the box based on the general spatial distribution of vertices in the model. OBBs are a very popular choice for collision systems, especially ones that only wish to respond to collisions between bounding volumes and not perform actual polygon collision detection (although it can obviously be done if desired). Testing collisions between two OBBs is a fair bit slower than intersection testing two spheres or AABBs, but the results are going to be more accurate since the bounding volume is a better fit. They can certainly be worth it when the situation calls for it. Indeed an OBB (or multiple OBBs arranged hierarchically) can be constructed to bound a mesh so tightly that it allows us to do away with Polygon/Polygon' testing altogether in many cases and therefore greatly speeds up our ability to do more realistic collisions. Of course, there will still be times when the objects will react to a collision that did not actually happen between their physical geometry, even though their bounding boxes collided. However, this will likely go unnoticed by the player if the OBBs fit nicely. OBB construction and OBB intersection testing is fairly complicated from a mathematical perspective and takes more cycles to perform than simple AABB/AABB intersections. For the moment, we will hold off on discussing OBBs and revisit them a little later in the training series.

Now, let us imagine that we have decided that our space game is going to use a mesh tree and will use AABB/AABB intersection testing for the collision detection of its dynamic objects. Let us also imagine that in our space combat game a mighty battle is taking place between 500 ships. One approach to dealing with their collision status might say that for every frame, we loop through all 500 meshes and perform an AABB/AABB intersection test with the other 499 meshes in the scene. This seems to be a rather non-optimal approach since typically only a handful at most will actually be colliding. In fact, it is likely that most of these meshes will not even be in the same leaf nodes as any other ships and could not possibly collide at all.

This is where the hierarchy system can begin to show its true colors. The leaf structures in a mesh tree could contain a list of meshes that are inside it (or partially inside it) and depending on how much we subdivide our scene and the size of our final leaf nodes, there is a good chance that at most, a single leaf will contain only a few meshes. There is also a good chance that many leaves may contain only one mesh. Therefore, instead of naively testing every dynamic object against every other dynamic object, we could instead just test it against the mesh lists for the leaves the source mesh is contained within. For example, if the dynamic object structure could retrieve a list of leaves it is currently contained within, then we know the object could not possibly collide with anything that is not in one of those leaves. Therefore, we just have to access each of those leaves and test against the meshes stored in the mesh lists of those leaves.

Although we will be implementing our mesh tree strategy in a different way, the following code snippet demonstrates this concept. pDynamicObject is assumed to be an object that we wish to test for collision against other dynamic objects that exist in the same leaves. It is assumed to contain an array (LeafArray) of all leaf indices it is currently assigned to. Obviously, if any of these leaves contain only one mesh then this must be the only mesh in that leaf so no collision can occur there and we move on to process the next leaf it is contained within. Otherwise, we loop through and test the mesh's volume against every other mesh in the leaf using the ProcessCollision function. We might imagine how such a function would compare the AABBs of both meshes and perform some response if both objects collide. This is a very simple example using pseudo structures and functions and exists to give you a basic understanding of the way the information stored in a spatial hierarchy (especially a spatial tree that has the ability to also link dynamic objects to leaves) can be used to accelerate a multitude of processes.

```
for ( int i = 0 ; i < pDynamicObject->LeafCount; i++ )
{
  if ( pDynamicObject->LeafArray[i].DynamicObjectCount > 1 )
  {
        pLeaf = &DynamicOject->LeafArray[i];

        for ( int i = 0; i < pLeaf->DynamicObjectCount; i++ )
        {
            CDynamicObject *pTestObject = pLeaf->DynamicObjects[i];

            if (pTestObject!=pDynamicObject) ProcessCollision( pDynamicObject,
                                                               pTestObject );

        } // End for each object in current leaf

   } // If more than one object in leaf

} End for each leaf the dynamic object is currently in
```

Using the system described above, even if you had 10,000 meshes in your scene, if none of the meshes shared a single leaf node, no bounding volume collision tests need to be done. That is obviously much quicker than just blindly testing every object with every other object for collision. How much quicker? Well in the 10,000 mesh case you would have to do 49,995,000 tests! This is because you are calculating an addition series that amounts to the following formula:

$$\#tests = \frac{n(n-1)}{2}$$

If there are *n* objects, you do not test an object against itself and you only test between objects once (i.e., after testing A against B, there is no need to test B against A since the result is the same), thus cutting the number of tests in half. Even still, with a modest 50 objects in your scene, that is 1,225 tests that will need to be run. Granted, you will also have to weigh the cost of object insertion into the hierarchy versus the linear approach to determine which is more efficient for your system. However, if you are running the objects through the tree anyway (e.g., for their static collision testing) then you would not have to worry about adding overhead for traversals since that cost has already been incurred. In that case, the hierarchy will win out since you will only test objects that share leaves.

14.6.4 Combining Polygon Trees and Mesh Trees

So with the differences between the various tree types distinguished, which are we going to use in our lab project? Are we going to use a mesh tree, a clipped polygon tree, or a non-clipped polygon tree? Actually, we are going to allow our application to support all three tree types. We will have a single tree (such as a quad-tree for example) that compiles any static polygon/mesh data such that it is stored in the leaf nodes at the polygon level (polygon tree), but will also keep track of which leaves contain our dynamic objects (mesh tree). The basic building strategy will be as follows…

First we will load the data in from an IWF file. Any static data that is loaded from the IWF file (GILES™ internal mesh geometry stored in world space) will be added polygon by polygon to the spatial tree we are currently using. Once we have added all the polygons to the tree, the tree object will have a big list of all the static polygons we wish to have compiled into a spatial tree. The application will then call the tree's Build function which will instruct the tree to partition the space described by its polygon list. At the end of the build process, the space containing the polygon data will have been subdivided into a number of leaf nodes and each leaf will contain an array of the polygon pointers contained inside it. Further, we will allow the application to set a flag that instructs whether this polygon tree should be compiled using clipping. If not, then during the build process, a polygon will always be assigned to any leaf nodes it spans. If clipping is enabled, a polygon will be split if it spans leaf boundaries so that each leaf will only contain pointers to polygons that exactly fit within their volume.

It sounds like we have basically just decided to build a polygon tree, but that is not the full story. The leaf nodes of the tree itself will also be allowed to store pointers to dynamic objects (in actuality, a more generic structure will be used so that literally anything can be stored, but the end result will be the same). We can simply send the bounding volume of the dynamic object down the tree and store its pointer in any leaf nodes it is found to be contained within. We can also add some functionality to retrieve a list of these objects from the leaves as needed for various purposes (collision detection, rendering, etc.).

So we can see that our tree is basically both a mesh tree and a polygon tree although the tree will only directly store the static polygon data (meshes and other objects will simply be stored as pointers). In our

next chapter we will learn that the tree will even know how to render the polygon data. That is, in our main scene render function we can just call the ISpatialTree::DrawSubset function and it will only render the polygons contained in the leaves which are visible and have polygon data belonging to that subset. Since the objects can easily find out which leaves they are contained within, determining their visibility prior to rendering will also be quite straightforward.

Although this might all sound a little complicated you will see when we examine the code that it really is not that bad. In prior applications we had a single rendering pool, an array of CObjects which had to be rendered. Now, we essentially have two pools. We have a tree to render (which will contain all the static polygon data) and the array of CObjects (although they are ultimately linked into the tree as well, in a manner of speaking). However, only dynamic objects will be stored in the scene's CObject array from now on. All static geometry will be contained inside the tree and rendered/queried using the tree's rendering/querying methods. The tree will know how to render its polygon data efficiently and in a hardware friendly manner.

The tree will also expose methods such as ISpatialTree::CollectLeavesAABB. This method when passed an axis aligned bounding box will return a list of leaves intersected by that AABB. Functions like this can be called to run queries on any number of external objects to query their position within the tree even if the tree is not aware of their existence. Dynamic objects and terrain blocks will all use this function to determine whether or not the regions of space they are contained within are currently visible without their geometry ever having to be compiled into the tree. We could build a pure mesh tree (a space scene for example) by compiling an empty tree (subdividing empty space into a fixed number leaves) and then associate dynamic objects and terrain blocks with their leaves using this function.

> **Note:** The lab project that ships with this chapter imports its data from an IWF. The internal mesh data is treated as static polygon data and is compiled directly into the tree. Any external X file references will (as always) be treated as dynamic objects, loaded into CActors and stored in the scene's CObject array as usual. However, they will still be tracked by the tree itself. If you have a static X file that you would like to have compiled into a tree at the polygon level, then simply import it into GILES™ and export it as an IWF file. The X file data will become static geometry in the IWF file. If you have dynamic X file objects that you would like to place in the scene then place them in GILES™ as reference entities. Our application loading code will then know not to compile them into the tree at the polygon level and they will be treated as dynamic objects.

14.7 Areas of Interest

Before we start to examine the code there is one more matter that we must discuss and make provisions for if we are to make our tree classes as useful as possible. We must allow for the spatial tree to be instructed to partition space where perhaps no geometry exists during the compilation process.

Up until now we have discussed that during the recursive building process we will decide to stop subdividing nodes down a given branch of the tree if that node's bounding volume is very small or if only a small number of polygons exist there. These settings are all going to be configurable, so you may decide that you wish to have leaves with the capacity to store 1000s of polygons or perhaps only a few dozen. The same is true with the minimum node size setting. You may decide that you would only like

to only modestly subdivide your scene and set the minimum leaf size (the size at which a node is no longer further partitioned) to be a rather large volume of space. Alternatively you may instead decide to make the tree partition space is to lots of very small leaves. The choice is yours and trial and error will often be as good as any deductive reasoning when deciding for a given level what you strategy should be. However, there is still a problem with this procedure which, if nothing was done to remedy it, would make our tree classes useless as mesh only trees.

The problem is that the bounding boxes of the nodes (including the root node) are computed during the build process by finding the tightest bounding box that fits around the polygon data living in that node. In the case of the root node, this means that the bounding box will be calculated using the static polygon data that will be stored in the tree itself. We do not bother factoring the positions of any dynamic objects at this point for a few reasons. First, building the tree based on the positions of objects that will change in the very next frame makes little sense. Second, it is quite common in a game level for dynamic objects to be spawned on the fly in response to some game event, which means the dynamic objects would not even be available during the building of the tree. Finally, we have also stated that with our design, the tree will have no knowledge of what polygons a dynamic object contains. We will provide a means for determining which leaves an object is in, but those objects will manage their own polygon information.

Of course, we do not always want our spatial tree to be as small as the static polygon data that will be fed in. This is definitely the case if we wanted to build an empty tree (i.e., partition empty space) and then use it to manage the collision querying and rendering of dynamic objects. The root node would have been passed no static polygon data, its bounding box would have zero volume, and it would be the only node in the tree because it has no polygon data and is infinitesimally small.

Consider once again the creation of a space combat simulation where ships will be flying around and attacking each other. Imagine that there are no planetary bodies, so all we have is an area of space that will, at some point, contain many dynamic objects. The obvious thing to do here would be to first partition the empty region of space into an oct-tree, for example. Essentially, we wish to create a tree that will subdivide the space that the ships will be permitted to fly around in, but at build time we wish this tree to be empty. That is, none of the leaf nodes will contain any static polygon data. Why? Because in this example there is no static polygon data; we simply want to partition space for the benefit of our dynamic objects. Once the tree was built, each time a dynamic objects position is updated, we can feed its AABB into the tree (using the ISpatialTree::CollectLeavesAABB method). This method determines which leaf nodes contain the dynamic object and store this information internally (as well as export it to the caller).

Figure 14.39 shows how three dynamic objects might look when placed within the region of space subdivided by the oct-tree. Remember, the oct-tree itself would still think it was an empty tree as it has no polygon data stored at its leaf nodes, but it does update itself each frame and determines which leaves are currently inside the frustum and are therefore visible. Once the dynamic objects are introduced, it can keep track of this information internally using some generic data structures and return the list of visible leaves as needed, or even return the list of visible dynamic objects if desired. Incidentally, as Figure 14.39 also shows, there would be no need to test the dynamic objects against each other for collision as none of them exist in the same leaves.

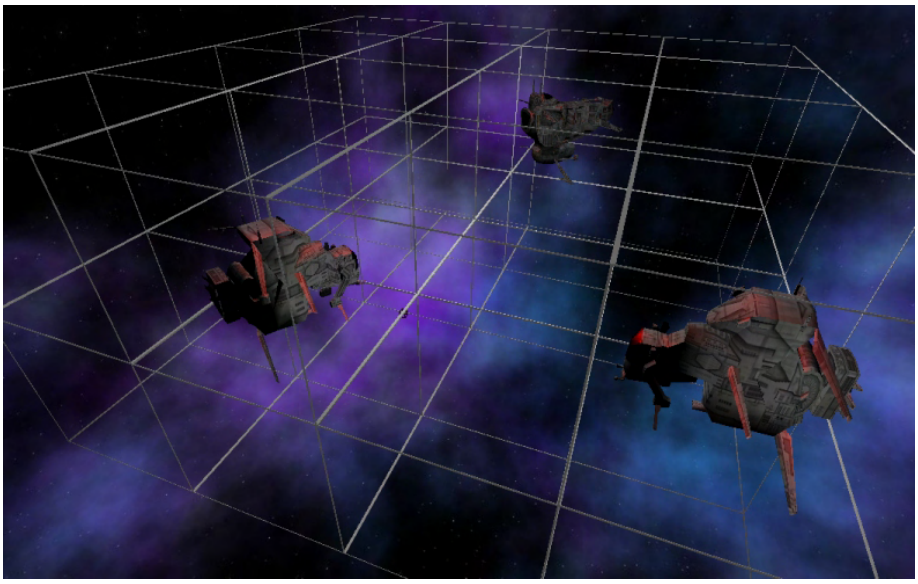

Figure 14.39

So we can see that we need the ability to create empty trees of a specific spatial size specifically so that we can control the region of space that will become part of the tree, even if that region is not described (or fully described) by the static polygon data from which the tree is generally built. Even if there is static data with which to build the tree, we might not want to simply compile only this exact region into the tree. We still may want the sky above a cityscape model to be partitioned and stored in the tree so that flying objects can enter the cityscape's airspace and benefit from the tree as well.

In the example shown in Figure 14.39 we might pass a large AABB into the tree building function which specifies a region of space that must become part of the tree and be spatially subdivided. We refer to these in our system as *detail areas* (or *areas of interest*). The tree can then continue to carve this space just as if there was polygon data contained in it. Only in this instance, the leaf nodes would contain no polygon data.

Another example where this is useful is when using a scene that contains a CTerrain object. As we know, a CTerrain object is constructed from a series of CTerrainBlocks where each block is a separate mesh. As terrain blocks could be quite efficiently frustum culled by testing their bounding boxes against the frustum it would be wasteful to store copies of the every triangle in the terrain in a tree. We saw in the previous lesson how our collision system essentially avoided doing the same thing by converting the swept sphere's AABB into terrain space and building only the relevant triangle data on the fly that needed to be tested. The same should also be true for our rendering; it would be overkill to store the triangle data for each terrain block in the tree when we could instead treat each terrain block as a dynamic/detail object. That is, we could pass the AABB of the of the terrain blocks down the tree and have pointers to them stored in the leaf nodes in which they belong. Only when those leaf nodes are visible does the terrain block render itself.

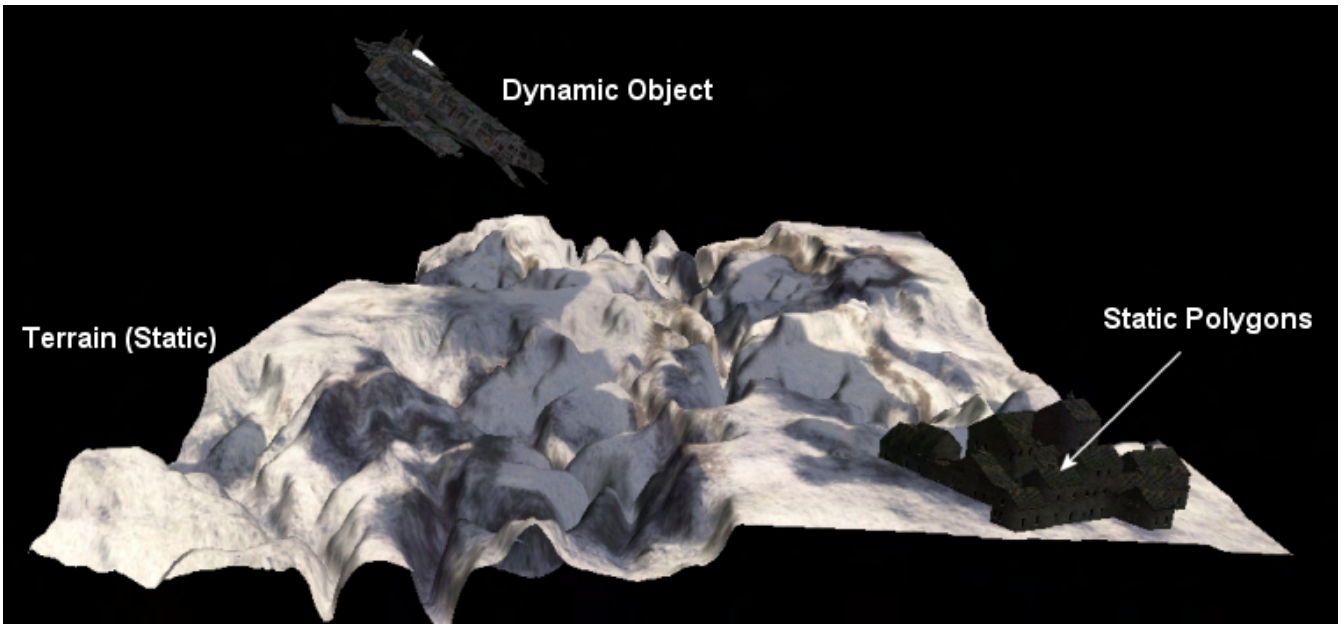

Figure 14.40

This is a good example of why we need the ability to add areas of interest (detail areas) to the tree. In Figure 14.40 we see a scene that contains a terrain (composed of multiple terrain blocks), a dynamic object in the sky above the terrain, and a small settlement made using static geometry. Because we do not wish to assign the terrain triangle data to the tree and we do not wish to factor in any temporary position of the detail object during the tree building process, the only polygons initially input to the tree building phase would be the static polygons labelled on the image. However, using the building strategy we have discussed thus far, the root node of the tree would have its bounding volume calculated only to be large enough to contain those static polygons. In Figure 14.41 we show that this would create an oct-tree that actually subdivides only a small section of the overall space in the scene we wish to use.

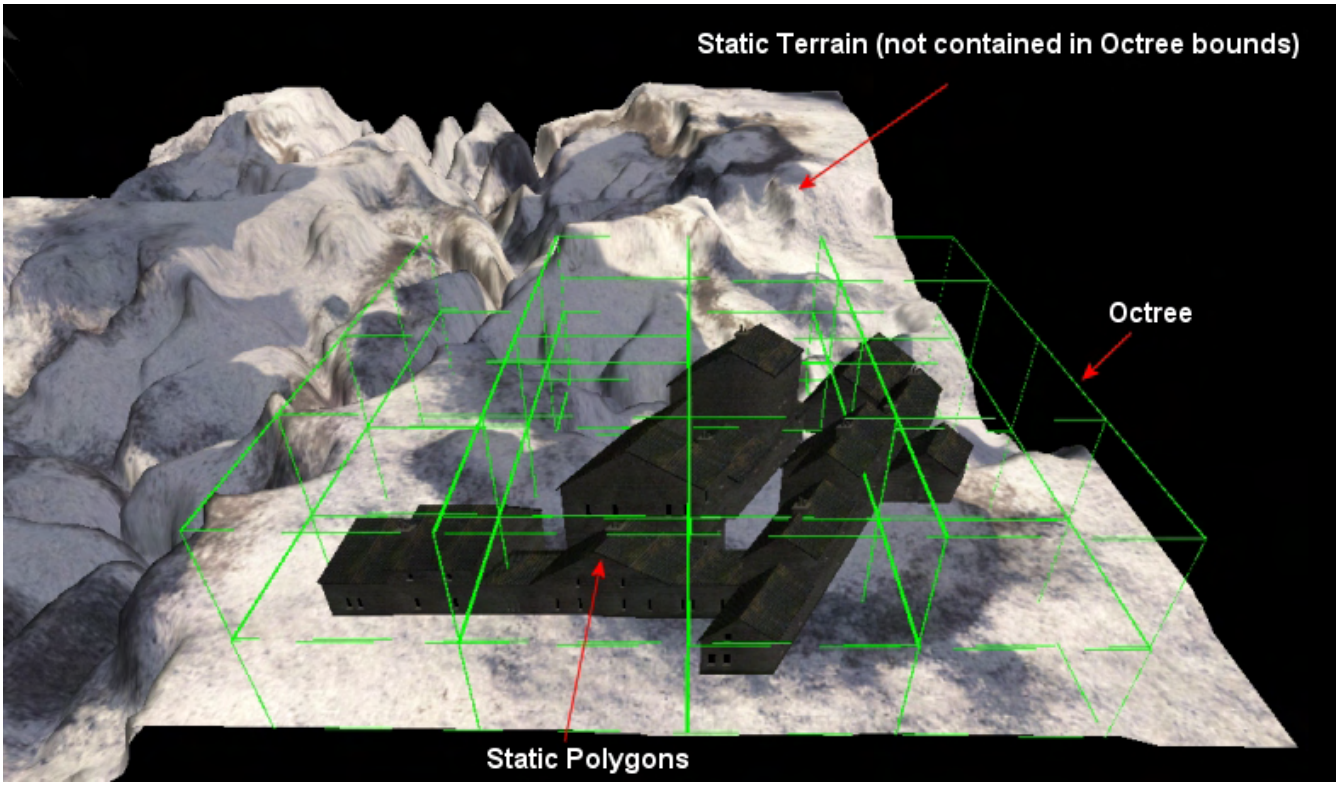

Figure 14.41

Now imagine that after the tree has been built, we decide to send the bounding volumes of each terrain block down the tree to find out in which leaf nodes they belong. We have a problem -- most of the terrain blocks are not even within the bounds of the root node's volume, so they would be found to be outside the tree and would not be able to benefit from the tree's various properties. The same is true once we place our spaceship (dynamic object) in the skies above the terrain. The detail object would have its AABB passed down the tree each time it is updated and we would find that it is contained in no leaf nodes since it is not within the area of space occupied by our partitioning scheme. This might mean the object does not get rendered at all (because it is technically not inside a visible leaf) or that such objects must be individually tested and rendered (depending on the rendering strategy you are using).

Alternatively, using the same detail area example seen above, we could pass into our tree building function a large bounding box that encompasses not only the stone settlement but also the terrain and all the sky above the terrain we intend to use for our dynamic objects. This would force the root node of the tree to be of a size that is large enough to contain the entire scene and each level in the tree would further subdivide this space.

If we imagine that we have done just that and that our tree building strategy is updated to calculate the correct size of a node's bounding box (not only on the static polygon data in its list, but also any detail area AABBs that have be registered with the tree object prior to the commencement of the build process), we can see the results would be exactly as needed as shown in Figure 14.42.

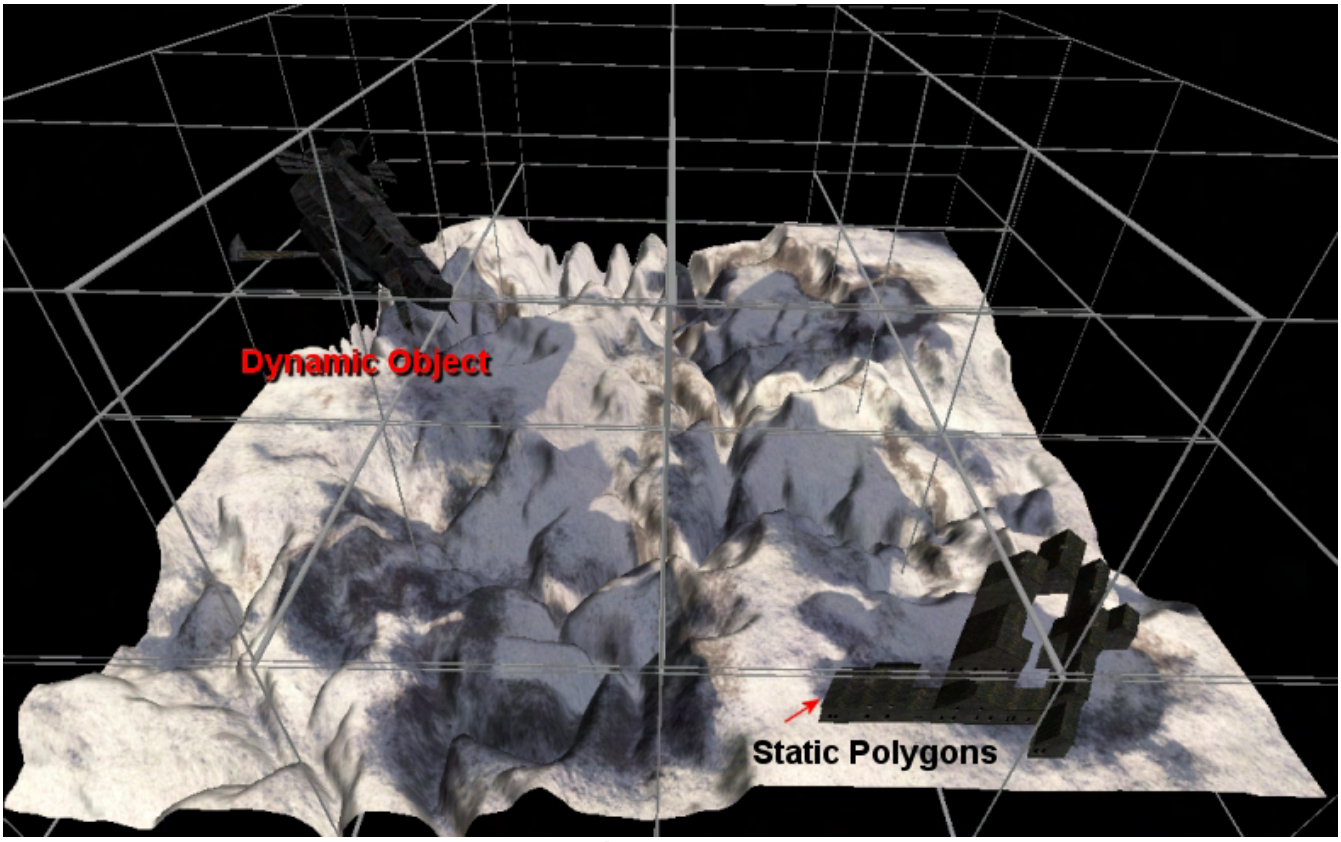

Figure 14.42

This really does solve all of our problems and allows us to build trees that either completely partition empty space or that partition space that is not necessarily fully occupied with static input polygon data.

Of course, this does not mean that we are restricted to passing only a single AABB as an area of interest. We might pass in multiple areas of interest at different positions in the level identifying areas where nodes should be partitioned even if no polygon data currently exists there. During the building process the condition used to determine whether a given node should be made a leaf node is now either of the following:

1. The bounding volume of the node is sufficiently small.
2. The bounding volume contains a small amount of polygon data *and no area of detail*.

The second condition (polygon count) has subtly changed, but it is an important one. Before we said that we would make a node a leaf if the number of polygons in that node's list is below a certain threshold amount. But now, even if there are no polygons in the node, but there is a detail area intersecting that node and the node has not been subdivided down to our minimum leaf size, we will continue to subdivide. This means that not only do these detail areas allow us to include space in the tree that is outside the region described by the static polygon set, but they also allow us to specify areas at any point in the level where we would want the space to be more finely partitioned down to the minimum leaf size.

It will be easy to add these areas of interest to our tree system. Our tree classes will expose a function called AddDetailArea which allows the application to register any bounding volumes with the tree as areas of interest. These areas must be registered prior to the Build function being called so that the construction of the tree can them in to its computations when determining the bounding boxes of each node and figuring out whether or not a node should be further subdivided. Further, we will also provide the ability to register a context pointer with the detail area which can point to application specific data. This could, for example, point to a terrain block that needs to be rendered or a sound that should be played whenever the player is in that leaf (or if that leaf is visible). Although we will actually have no need to use this context pointer in our first implementation, it is handy to have around and is something we will undoubtedly find useful moving forward.

14.8 Tree Balance

Before we begin to code, we must be aware of the implications of creating a wildly unbalanced tree. A perfectly balanced tree is a tree where all leaf nodes exist at exactly the same level in the hierarchy. Although it is rarely possible to achieve a perfectly balanced tree (while not subdividing empty space and introducing unnecessary nodes) it is something we wish to strive for as much as possible in many cases because it allows us to keep tree traversal times consistent during queries. The last thing we want is one part of our tree to be many levels deep and another section of the tree to be only a few levels deep. This will cause inconsistent frame rates when querying the deepest parts of the tree. Figure 14.43 shows an unbalanced quad-tree.

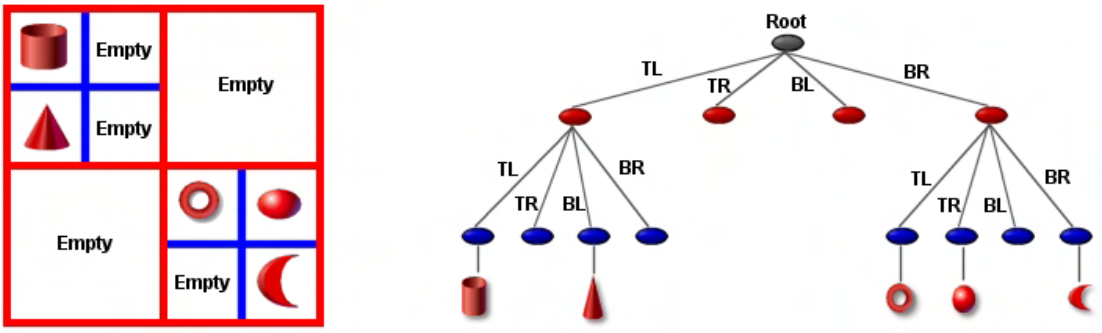

Figure 14.43 : Unbalanced Quad-tree

In this example we can see that only two of the four children of the root node have geometry to subdivide and as such, nodes TR and BL (which have no geometry passed to them) become empty leaf nodes (terminal nodes). However, the polygon data passed into the TL and BR children of the root do have geometry that falls within their bounds, so their volumes are further divided. Although this is a simple and small example, we can see that queries would take longer to perform in the top left and bottom right quadrants of the scene than in the top right and bottom left quadrants. That is, we would reach the terminal nodes quicker for the top right and bottom left quadrants. The difference in query times in the real world is much greater when we deal with trees that are many levels deep. It is better to have a scene that can be rendered/queried at a consistent 60 frames per second than it is to have a scene where the frame rate runs at 150 frames per second in some areas and at 10 frames per second in others.

This is a somewhat drastic example but the point is that the application will benefit from smoother physics, collision response, and general movement if the frame rate can stay relatively consistent throughout.

If we imagine that we had the ability in the quad-tree to slide the clip planes to arbitrary positions at each level, we might imagine that we could end up reducing this to a two level tree where all four children of the root (2^{nd} level) has mesh/polygon data of its own. This is essentially what can be achieved using a kD-tree -- choosing a split plane at any given node that is positioned such that it splits any remaining geometry into exactly two pieces, even if all that geometry is located on one side of the parent nodes volume.

> **Note:** One possible method for choosing a split plane is to divide the polygon data into two equal sets at a given node. If splitting along the X axis at a given node for example, we could sort all the vertex data by their X component and then build a plane that passes through the median vertex.

kD-trees are generally much deeper trees than oct-trees if you intend to get the same level of spatial partitioning because they only divide space into two spaces at each node, so we will usually have to traverse deeper into a kD-tree. However, each level in the tree has fewer child nodes assigned to it than its equivalent level in an oct-tree, so traversal is cheaper at each level. In the above example, we see a quad-tree that has four nodes on its second level and eight nodes on its third level. The kD-tree on the other hand would have only two nodes on its second level and four nodes on its third level. Therefore, the deeper tree traversal required in the kD-tree case is offset by the speed at which the kD-tree can traverse its tree (to some extent). For example, we may find when testing a bounding volume against the split plane stored in the root that the query volume is contained in the front halfspace of the clip plane. With one plane/volume test we have just rejected half of the entire scene. In an oct-tree, each AABB/AABB test we perform will reject only $1/8^{th}$ of the parent node's volume.

Choosing a split plane at a kD-tree node is not simply about finding the plane that best balances the tree since we sometimes have other considerations (perhaps more important ones) that we wish to factor in. For example, a common goal when choosing a split plane is to find one that produces the least number of polygons that will have to be split (if we are building a clipped tree) in order to fit into the child nodes. Every time we split a polygon into two pieces we increase the polygon count of our scene and this could grow significantly if split planes are being chosen arbitrarily. Furthermore, clipping polygons arbitrarily also often introduces a nasty visual artifact called a T-junction in the polygon data. We will discuss T-junctions later, but for now just know that due to the rounding errors accumulated in the rendering pipeline, two polygons that are neighbors (i.e., they look like one polygon), but that do not have their vertices in identical places along the shared edge, can produce a sparkling effect. Essentially, because their vertices are not in identical places, there are sub-pixel gaps produced during rendering. This results in odd pixels between the two polygons (along the seam) that do not get rendered and anything rendered behind it can show through. You have probably seen this artifact in some video games -- it is commonly referred to as *sparkling*. T-junctions also wreak havoc with vertex lighting schemes as we will find out later.

T-junctions often occur whenever a great deal of polygon clipping is employed on a scene, so these artifacts can manifest themselves with all the tree types we have discussed thus far (or indeed with any clipping process). However, when we are using uniform partitioning (such as with the quad-tree or oct-tree) we generally create many fewer T-junctions in our geometry (this will make sense later when we

cover T-junction repair). When using a kD-tree that is allowed to arbitrarily position its split plane, T-junctions artefacts are common. Although T-junctions can be repaired after the tree has been compiled (we will cover how to do this later in the lesson) the repair of a single T-junction introduces an additional triangle into the scene. Therefore, in the case of a kD-tree that is using non-uniform split planes, hundreds or maybe thousands of T-junctions could be produced by the tree building process. The repair of these T-junctions would introduce hundreds or thousands of additional triangles in our scene, which is far from ideal. The existence of T-junctions are only a concern if the polygon data contained in the tree is intended to be collected and rendered. If the tree polygon data is only being used for collision queries, we can typically leave the T-junctions alone since they will not affect our collision queries.

Because our tree class will also be used as a render tree in addition to a collision query tree, we will force our kD-tree to always split into two equally sized child volumes at any given node. This will hopefully reduce the number of T-junctions produced during the building of the tree and keep our polygon count from growing too large during the T-junction repair.

> **Note**: Do not worry too much about what T-junctions are for now as they will be discussed over the next few sections. They are only mentioned now as a justification for why our kD-tree implementation will always use a split plane at each node which partitions the node's volume into two uniformly sized children.

So the balance of a tree is important but as noted, it is not our only goal when compiling our trees. Often trial and error will produce the best results and this is where benchmarking your code is ***very important***. You may find for example that using an arbitrary split plane at a kD-tree node creates a more balanced tree at the cost of many triangles being inserted into the scene to repair the T-junctions produced. This increase in polygons could create a consistently deeper tree and undo much of what you were trying to achieve by balancing the tree in the first place.

We have now discussed the theory behind the oct-tree, the quad-tree, and the kD-tree and we are ready to start looking at the code to both the tree building processes as well as the support structures, routines, and intersection queries that will need to be implemented. We will delay our discussion of the BSP tree until Chapter 16, after we have stepped through the source code needed to build the three tree types we have already discussed. We will also discuss some of the core mathematical routines we will need to run queries on our tree. The BSP tree, although constructed in a similar way, ultimately exhibits very different characteristics due to the fact that it divides space arbitrarily. The application of a BSP tree is often done to achieve a different goal than just spatial subdivision as we will see later in the course.

In the remainder of this textbook, we will cover all the code that builds the quad-tree, oct-tree, and kD-tree. Ultimately we will integrate them into our collision system as a broad phase suite. Building a tree rendering system that is hardware friendly is rather complex and will be discussed in its own chapter. Lab Project 14.1 uses the rendering system that will be discussed in the following lesson, so you should probably ignore most of the tree rendering code for now.

14.9 Polygon Clipping

Several times throughout this chapter we have mentioned that our system will have the optional ability to create clipped trees. That is, trees that are constructed such that the polygon data stored in each leaf fits completely in its volume. This means that the tree building process will involve a good amount of clipping of the original polygon data to the split planes that subdivide the node into its children. This section will discuss the process of clipping polygons.

If you have never implemented code that clips a polygon to a plane, you will probably be pleased to learn how simple it actually is. The basic process is one of stepping around each edge of the polygon and classifying its vertices against the plane in order to build two vertex lists that will describe the front and back split polygons (i.e., the polygon fragments that lay on each side of the plane). If the current vertex being processed is in front of the plane and the following vertex is also in front of (or on) the plane, then the current vertex belongs in the front split polygon and is added to its vertex list. Likewise, if the current vertex being processed is behind the plane and the next vertex in the list is also either behind or on the plane, then the current vertex being processed is added to the vertex list of the back split polygon.

If however, the current vertex being processed and the next vertex in the list are on opposing sides of the plane, then we have found an edge in the original polygon where an intersection occurs with the plane. In this instance we use the two vertices in the edge to create a ray and perform a Ray/Plane intersection test with the split plane. The result of this intersection test will be the position on the plane at which the ray intersects it. The vertex in the edge that was in front of the plane is added to the front split polygon and the other vertex in the edge located on the back side of the plane is added to the back split polygon. The intersection point where the ray intersected the plane is made into a new vertex and is added to *both* the front split and the back split polygons.

After having done this for every vertex/edge in the original polygon, will have two new polygons and the original polygon can be discarded. Obviously, if you do not intend to the split the polygon into two fragments, but are instead interested only in clipping polygons to a plane, you can simply discard the vertices on the half space of the plane that you are clipping away and return only a single polygon. Thus, a polygon splitting function could easily double as a polygon clipping function by simply being instructed to discard any vertices located in a certain plane halfspace. We do a similar thing in our polygon clipping function. The function will accept as parameters the original polygon that is to be split/clipped and will also be passed pointers to two polygons that, on function return, will be filled with the front split and back split polygons. Passing NULL as one of these parameters will turn the splitter function into a clipper function. If you pass NULL as the parameter where you would normally pass a pointer to a polygon that will receive the back split data, the function will recognize that you have no interest in the vertex data that is behind the plane and simply clip the polygon to the plane and return only the section of the polygon that is in the plane’s front halfspace.

Figure 14.44 shows how a pentagonal polygon would be split into two by an arbitrary split plane.

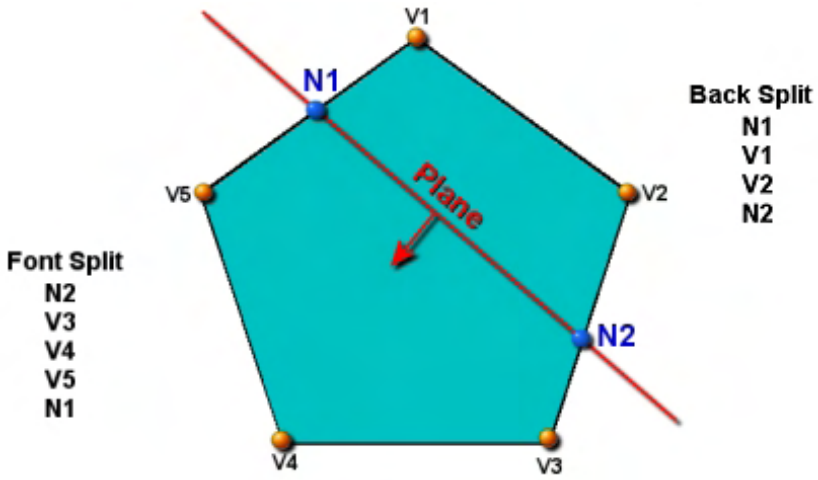

Figure 14.44

Let us step through this example using the technique described above. The original polygon has five vertices labelled v1 – v5 as shown. The plane can be seen as the red line in the diagram clearly carving the polygon into two parts. We would set up a loop starting at the first vertex v1. We would classify this point against the plane and discover it is in the back space of the plane. If v2 is also in the plane's back space, then a new polygon structure is allocated for the back split and v1 is added to its vertex list.

In the next loop iteration we check vertex v2 which is also in the plane's back space. If v3 is also in the plane's back space, then v2 would be added to the back split polygon also. However in this case we can see that v3 is actually in the plane's front space so we know for sure that the polygon edge (v2,v3) intersects the plane. Therefore, we create a ray from v2 to v3 and perform a ray/plane intersection test. This will return the position at which the ray intersects the plane, shown as N2 in the diagram. We add v2 and N2 to the vertex list of the back split polygon and add the vertex N2 to the vertex list of the front split polygon as well. The back split polygon now has vertices v1,v2, and N2 in its vertex list and the front split polygon so far has a single vertex, N2.

Next we test vertex v3 and find it is in the plane's front space. Because v4 is also in the front space, v3 is added to the vertex list of the front split polygon so that now it contains two vertices, N2 and v3. Next we test vertex v4 which is in the plane's front space also. v4 is added to the front split polygon's vertex list because the next vertex v5 is also in front of the plane. The front split polygon now has vertices n2, v3, and v4 in its vertex list.

Finally, in the last iteration of the loop we classify vertex v5 against the plane and discover it is in the plane's front space. However, vertex v5 is the last vertex in the original polygon and it forms an edge with the first vertex v1, so we must test that this edge does not span the plane. We discover that v1 is in the back space of the plane and therefore the edge (v5 ,v0) does indeed span the plane. Thus, we create a ray from v5 to v1 and perform a ray/plane intersection calculation to return to us the intersection point N1 where the ray intersects the plane. v5 and N1 are added to the front split polygon and N1 is also added to the back split polygon and we are done. In this example, the front split polygon would have vertices N2, v3, v4, v5, and N1. The back split polygon would have vertices v1, v2, N1, and N2. We now have two polygons with a clockwise winding order which can be returned from our polygon splitting function. At this point, the original polygon can be discarded.

14.10 Implementing Hierarchical Spatial Partitioning

In order to split and clip polygons, certain utility functions will be added to our CCollision class as static methods. We will add methods to help our clipping routines as well as new bounding volume intersection methods that will be used by the tree during traversals. The CCollision class has very much become our core library of intersection and plane classification routines.
